CONTENTS

GENERAL, PHYSICAL AND INORGANIC

William H. Bromley, Jr., and W. F. Luder: The Conductance of Some Salts in Ethylenediamine 107
Leonard H. Cohan: Hysteresis and the Capillary Theory of Adsorption of Vapors 98
J. Hopfield, S. A. Hall and L. A. Goldblatt: Raman Spectra of Two Forms of *allo*-Ocimene 115
H. James: Ascorbic and Iso-ascorbic Acids as Photographic Developing Agents 91
Joseph J. Jasper and J. Russell Bright: Molecular Surface Energy of Sulfur Dioxide Addition Compounds. III 105
R. L. Livingston and L. O. Brockway: The Molecular Structures of Dimethyl Silicon Dichloride, Methyl Silicon Trichloride and Trifluoro Silicon Chloride 94
J. W. McBain and K. E. Johnson: Solubilization and the Colloidal Micelles in Soap Solution 9
O. Redlich, E. K. Holt and J. Bigeleisen: The Ionization of Strong Electrolytes. II. Ionization, Raman Spectrum and Vibrations of Perchloric Acid 13
Horace Russell, Jr., D. R. V. Golding and Don M. Yost: The Heat Capacity, Heats of Transition, Fusion and Vaporization, Vapor Pressure and Entropy of 1,1,1-Trifluoroethane 16

ORGANIC AND BIOLOGICAL

Roger Adams, J. H. Clark, Nathan Kornblum and Hans Wolff: Substituted Aminobenzofuroquinolines 22
F. H. Allen and J. VanAllan: On the 1,3-Rearrangement of a Phenyl Group 7
G. Assaf, R. H. Haas and C. B. Purves: A Study of the Amorphous Portion of Dry, Swollen Cellulose by an Improved Thallous Ethylate Method 59
G. Assaf, R. H. Haas and C. B. Purves: A New Interpretation of the Cellulose–Water Adsorption Isotherm and Data Concerning the Effect of Swelling and Drying on the Colloidal Surface of Cellulose 66
R. Baldwin, R. S. Bear and R. E. Rundle: The Relation of Starch–Iodine Absorption Spectra to the Structure of Starch and Starch Components 111
Melvin S. Bloom and Charles R. Hauser: The Use of Certain Phenyl Esters in the Reformatsky Reaction 152
Charles K. Bradsher: The Anomalous Oxidation of an Ethylene Derivative by Perbenzoic Acid 45
Herman Alexander Bruson and Thomas W. Riener: The Chemistry of Acrylonitrile. V. Cyanoethylation of Aldehydes 277
Kenneth N. Campbell, Armiger H. Sommers and Barbara K. Campbell: The Preparation of Unsymmetrical Secondary Aliphatic Amines 82
James Cason and Franklin S. Prout: Branched-Chain Fatty Acids. II. Syntheses in the C_{18} and C_{28} Series. Preparation of Keto Esters 46

(*Continued on second page of cover*)

PUBLISHED MONTHLY BY THE AMERICAN CHEMICAL SOCIETY

Copyright, 1944, by the American Chemical Society

Entered at the Post Office at Easton, Pa., as second-class Matter. Acceptance for mailing at special rate of postage provided for in Section 1105, Act of October 3, 1917, authorized July 13, 1918

Manuscripts submitted for publication and books sent for review in the Journal of the American Chemical Society, and all inquiries regarding them, should be sent to the Editor, Arthur B. Lamb, Chemical Laboratory of Harvard University, 12 Oxford Street, Cambridge 38, Massachusetts

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

(Concluded from first page of cover)

J. C. Colbert, W. W. Hauser, H. R. Schmidt and J. L. Abernethy: The Iodination of 4-Hydroxybiphenyl..... 122
John C. Cowan and Donald H. Wheeler: Linear Superpolyesters from Dilinoleic Acid..... 84
R. H. J. Creighton, R. Damley Gibbs and Harold Hibbert: Studies on Lignin and Related Compounds. LXXV. Alkaline Nitrobenzene Oxidation of Plant Materials and Application to Taxonomic Classification..... 32
R. H. J. Creighton and Harold Hibbert: Studies on Lignin and Related Compounds. LXXVI. Alkaline Nitrobenzene Oxidation of Corn Stalks. Isolation of *p*-Hydroxybenzaldehyde..... 37
Norman H. Cromwell, Charles E. Harris and Donald J. Cram: α,β-Diamino Ketones. I. Reactions of Heterocyclic Secondary Amines with α-Bromo-β-aminoketones..... 134
B. F. Daubert and H. E. Longenecker: Unsaturated Synthetic Glycerides. III. Unsaturated Symmetrical Mixed Diglycerides..... 53
Arthur M. Eastham, H. E. Fisher, Marshall Kulka and Harold Hibbert: Studies on Lignin and Related Compounds. LXXIV. Relation of Wood Ethanolysis Products to the Hibbert Series of Plant Respiratory Catalysts. Allylic and Dismutation Rearrangemen tsof 3-Chloro-1-(3,4-dimethoxyphenyl)-2-propanone and 1-Bromo-1-(3,4-dimethoxyphenyl)-2-propanone..... 26
Jared H. Ford: Concerning Racemic α-Hydroxy-β,β-dimethyl-γ-butyrolactone (Pantolactone)..... 20
Robert L. Frank, Henning Eklund, John W. Richter, Clinton R. Vanneman and Arnold N. Wennerberg: Some 2,3-Disubstituted Indones..... 1
Robert L. Frank, Peter G. Arvan, John W. Richter and Clinton R. Vanneman: The Preparation of Cyclopentenones from Lactones..... 4
Marshall Gates: The Condensation of Naphthoquinones with Polar Ethylenes..... 124
E. K. Gladding and C. B. Purves: 2,3,4-Triacetyl-α-methylglucopyranoside-6-nitrate and 3,4,6-Triacetyl-β-methylglucopyranoside-2-nitrate..... 153
Dorothy Nightingale and J. R. Janes: The Alkylation of *o*- and *p*-Xylene..... 154
E. K. Gladding and C. B. Purves: The Formation of Anhydro Derivatives by the Action of Alkali upon Some Mononitrate-acetates of Cellobiose and Methylglucoside..... 76
Raymond M. Hann, A. T. Ness and C. S. Hudson: Diacetone Xylitol (2,3,4,5-Di-isopropylidene-D,L-xylitol)..... 8
Klaus Hofmann: The Synthesis of 3,4-Dicarboxy-2-furanvaleric Acid and Some of Its Derivatives..... 51
Max N. Huffman and Hugh H. Darby: 16-Substituted Steroids. I. Isoestriol-A..... 150
Treat B. Johnson: Reactions Characterizing the Oxide of 6-Methyl-6-oxy-5-chloro-1,5-bicyclouracil..... 146
Treat B. Johnson: The Acid Hydrolysis of a 6-Aryl-5,5-dichloroxyhydrouracil..... 148
Irving M. Klotz: Spectroscopic Evidence for Conjugation in Cyclopropane Systems..... 88
Gennady M. Kosolapoff: Isomerization of Tri-alkyl Phosphites 109
Marshall Kulka, Herbert E. Fisher, Samuel B. Baker and Harold Hibbert: Studies on Lignin and Related Compounds. LXXVII. Re-investigation of the Ethanolysis Products of Maple Wood..... 39
W. S. MacGregor, T. H. Evans and Harold Hibbert: Studies on Lignin and Related Compounds. LXXVIII. Chromic Acid Oxidation of Lignin-type Substances, Wood Ethanolysis Products and Wood..... 41
W. B. Renfrow, Jr.: The Use of Potassium *t*-Amyloxide for the Alkylation of Acetoacetic Ester and its Alkyl Substitution Products..... 144
R. E. Rundle, Lester Daasch and Dexter French: The Structure of the "B" Modification of Starch from Film and Fiber Diffraction Diagrams..... 130
Herbert E. Ungnade and A. Douglas McLaren: The Preparation of Cyclohexanols by Catalytic Reduction of Phenols.. 118
L. Zechmeister and A. Polgár: *cis–trans* Isomerization and *cis*-Peak Effect in the α-Carotene Set and in Some Other Stereoisomeric Sets..... 137

NOTES

Harry F. Pfann: Pyrazine–Water Azeotrope..... 155
H. R. Snyder and George W. Cannon: Carbon–Carbon Cleavage in the Hydrogenolysis by Raney Nickel Catalyst of Ethylenedithiol and its Ethers..... 155
R. B. Thompson: Reaction of Diazomethane with α-Tetralone. 156

COMMUNICATION TO THE EDITOR

Klaus Hofmann: The Synthesis of Two Stereoisomeric 3,4-Diamino-2-tetrahydrofuran-valeric Acids..... 157

NEW BOOKS

The Chemical Background for Engine Research. Edited by R. E. Burk and Oliver Grummitt. (Frontiers in Chemistry, Volume II.) Review by Harold A. Beatty..... 157
The Adsorption of Gases and Vapors. Volume I. Physical Adsorption. By Stephen Brunauer. Review by A. S. Coolidge..... 158
Books Received..... 158

NOTICE

Because the Government requires the Society to cut its use of paper to an absolute minimum, it will no longer be possible to print the customary number of excess copies to supply demands for volumes and sets in subsequent years. Therefore it is suggested that any subscribers who do not bind their Journals, save current issues for later sale.

CONTENTS

GENERAL, PHYSICAL AND INORGANIC

Marion H. Armbruster and J. B. Austin: The Adsorption of Gases on Smooth Surfaces of Steel 159
Robert J. Berndt and Cecil C. Lynch: The Ternary System: Dioxane–Benzene–Water 282
Jerry Donohue and Lindsay Helmholz: The Crystal Structure of Potassium Silver Carbonate, $KAgCO_3$ 295
K. K. Kelley and G. E. Moore: Specific Heats at Low Temperatures of Calcium Sulfite, Sodium Sulfite, and a Manganese Dithionate Dihydrate 293
John J. Lander and W. J. Svirbely: The Dipole Moments of Friedelin, Cerin, Isomers of Friedelinol and Isomers of 3-α-Naphthyl-1-chloro-1-propene 235
Choh Hao Li: Kinetics of Reactions between Iodine and Histidine 225
Choh Hao Li: Catalytic Effect of Acetate and Phosphate Buffers on the Iodination of Tyrosine 228
M. V. Noble and A. B. Garrett: A Thermodynamic Study of Lead Chloride in Mixed Solvents by Means of Electromotive Force and Solubility Data at 25° 231
Richard Pomeroy and H. Darwin Kirschman: The Solubility of Sodium Iodide in Sodium Hydroxide Solutions at 20° 178
Thor R. Rubin, Blaine H. Levedahl and Don M. Yost: The Heat Capacity, Heat of Transition, Vaporization, Vapor Pressure and Entropy of 1,1,1-Trichloroethane 279
Wm. F. Seyer, Ralph F. Patterson and John L. Keays: The Density and Transition Points of the n-Paraffin Hydrocarbons 179
R. Nelson Smith and Philip A. Leighton: The Photolysis of Hydroxylamine 172

ORGANIC AND BIOLOGICAL

Roger Adams and N. J. Leonard: Structure of Monocrotaline. XI. Proof of the Structure of Retronecine 257
Richard T. Arnold, Robert Buckles and Janet Stoltenberg: A Study of the Haloform Reaction 208
Richard Baltzly, Johannes S. Buck, Emil Lorz and William Schön: The Preparation of N-Monosubstituted and Unsymmetrically Disubstituted Piperazines 263
Felix Bergmann and H. Emile Eschinazi: 1,2,3,4-Dibenzanthrene and its Derivatives. II. Some New Synthetic Attempts 183
Vincent P. Calkins and H. A. Mattill: The Kinetics of the Antioxygenic Synergism of Quinones with Ascorbic Acid in Fat Systems 239
B. F. Daubert: Unsaturated Synthetic Glycerides. V. Unsymmetrical Monoelaidyl-Disaturated and Monosaturated-Dielaidyl Triglycerides 290
G. O. Doak, H. G. Steinman and Harry Eagle: Arsenoso Compounds Containing Amide Groups 194
G. O. Doak, H. G. Steinman and Harry Eagle: Arsonic Acids and Arsenoso Compounds Containing the Azo Linkage 197

(Concluded from first page of cover)

H. E. French and J. E. Kircher: Normal and Pseudo Structures of 8-Benzoyl-1-naphthoic Acid and Derivatives... 298
Edward H. Frieden, Herschel K. Mitchell and Roger J. Williams: Folic Acid. II. Studies on Adsorption... 269
Lewis F. Hatch and Allen C. Moore: Dehydrochlorination of 3-Chloro-2-propen-1-ol: Preparation of Propargyl Alcohol 285
Max H. Huebner: The Phthaleins from Phenol and 1,2-Naphthalenedicarboxylic Acid... 255
F. L. Jackson, B. F. Daubert, C. G. King and H. E. Longenecker: Unsaturated Synthetic Glycerides. IV. Symmetrical Monooleo-disaturated Triglycerides... 289
William S. Johnson and Frederick J. Mathews: Cyclization Studies in the Benzoquinoline Series... 210
William S. Johnson: Introduction of the Angular Methyl Group. II. *cis*- and *trans*-8-Methylhydrindanone-1... 215
William S. Johnson, John M. Anderson and Wesley E. Shelberg: Derivatives of 5-Methoxyhydrindene and 6-Methoxytetralin. Synthesis of β-(2-Carboxy-5-methoxyphenyl)-propionic Acid... 218
R. Norman Jones: The Spectrographic Characterization of a Hydrocarbon Synthesized by Bergmann and Eschinazi... 185
Fred Linsker and Marston Taylor Bogert: Amidino Arsenicals. II. Some Trivalent Arsenicals... 191
Paul J. McLaughlin and E. C. Wagner: Hydrogenation–Dehydrogenation Reactions Involving Some Compounds of Ammono-aldehyde, Ammono-acetal and Aquo-ammono-aldehyde Types... 251
Herschel K. Mitchell, Esmond E. Snell and Roger J. Williams: Folic Acid. I. Concentration from Spinach... 267
Herschel K. Mitchell and Roger J. Williams: Folic Acid. III. Chemical and Physiological Properties... 271
Herschel K. Mitchell: Folic Acid. IV. Absorption Spectra 274
A. Polgár and L. Zechmeister: A Spectroscopic Study in the Stereoisomeric Capsanthin Set. *cis*-Peak Effect and Configuration... 186
Peter P. Regna and B. P. Caldwell: The Preparation of 2-Ketopolyhydroxy Acids... 243
Peter P. Regna and B. P. Caldwell: A Method for the Preparation of Calcium-D-Altronate... 244
Peter P. Regna and B. P. Caldwell: Kinetics of Transformation of 2-Ketopolyhydroxy Acids... 246
Robert H. Saunders and M. J. Murray: The Aldol Condensation. III. Aldol-aldehyde Addition Products and their Derivatives... 206
R. L. Shriner and Robert Bruce Moffett: Benzopyrylium Salts. IV. Nitration of 2,3-Diphenyl-benzopyrylium Perchlorate 301
H. R. Snyder, Curtis W. Smith and John M. Stewart: Carbon-Alkylation with Quaternary Ammonium Salts. A New Approach to the Synthesis of Compounds Containing the β-Indolemethylene Group... 200
H. G. Steinman, G. O. Doak and Harry Eagle: *p*-Arsenosobenzoylurea and Related Compounds... 192
Welcome I. Weaver, J. K. Simons and Wilmer E. Baldwin: Morpholinomethyl Derivatives of Urea and Substituted Ureas... 222
M. L. Wolfrom, S. M. Olin and Evan F. Evans: The Action of Diazomethane upon Acyclic Sugar Derivatives. VI. D-Sorbose... 204
Thomas R. Wood, F. L. Jackson, A. R. Baldwin, and H. E. Longenecker: The Preparation of Some Unsaturated Fatty Acid Chlorides... 287

NOTES

Erich Baer: Dioxane Diphosphate... 303
Erwin Baumgarten, Howard G. Walker and Charles R. Hauser: The Preparation of Certain Phenolic Esters... 303
F. F. Blicke and J. L. Powers: The Preparation of 1- and 2-Phenylpyrrole... 304
Fred Frostick, Erwin Baumgarten and Charles R. Hauser: Reactions of *t*-Butyl Cinnamate and *t*-Butyl Benzoate with Phenylmagnesium Bromide... 305
A. R. Kemmerer and G. S. Fraps: Nature of Carotenes in Alfalfa... 305
C. F. Koelsch: The Action of Sodium Cyanide on Methyl γ-Bromo-α,α-dimethylacetoacetate... 306
Therald Moeller and H. E. Kremers: Observations on the Rare Earths. I. The Separation of Erbium from Yttrium by Fractional Precipitation of the Ferrocyanides... 307
Walter Nudenberg and Lewis W. Butz: 3,6-Epoxycyclohexene from Furan and Ethylene... 307
Mary Louise Quaife: Coupling of Gamma Tocopherol and Failure of Beta Tocopherol to Couple with Diazonium Salts... 308
J. C. Shivers, B. E. Hudson, Jr., and Charles R. Hauser: The Alkylation of Isopropylmalonic Ester Using Sodium Triphenylmethide... 309
Henry Tauber: Color Reactions for Certain Amino Acids... 310
A. Weizmann: Substituted α-Amyl-cinnamylaldehydes... 310

NEW COMPOUNDS

Johannes S. Buck, Richard Baltzly and Alan E. Ardis: Some Aryl and Aralkyl Ureas... 311
W. G. Christiansen and M. A. Dolliver: *o*-Phenylene Dioxyacetic Acid and its Ethyl Ester... 312
Winslow H. Hartford: A New Ammine of Basic Copper Chromate... 312
Theodore D. Perrine: Di-*n*-butyl-*n*-propylamine... 312

COMMUNICATIONS TO THE EDITOR

J. E. Haggenmacher: An Equation of State for Saturated Fluids... 313
M. A. Jakus, C. E. Hall and F. O. Schmitt: Electron Microscope Observations of Clam Muscle Fibrils... 313
M. J. Murray and Eugene H. Stevenson: Spiropentane... 314

NEW BOOKS

How to Solve Problems in Qualitative Analysis. By Joseph A. Babor and J. Kenneth W. Macalpine. Review by Allen D. Bliss... 315
Proteins, Amino Acids and Peptides as Ions and Dipolar Ions. By Edwin J. Cohn and John T. Edsall. Review by Hans T. Clarke... 315
Treatment of Experimental Data. By Archie G. Worthing and Joseph Geffner. Review by F. G. Keyes... 316
Books Received... 316

NOTICE

Because the Government requires the Society to cut its use of paper to an absolute minimum, it will no longer be possible to print the customary number of excess copies to supply demands for volumes and sets in subsequent years. Therefore it is suggested that any subscribers who do not bind their Journals, save current issues for later sale.

CONTENTS

GENERAL, PHYSICAL AND INORGANIC

Raymond W. Bremner: Temperature Coefficients of Electrical Conductance of Solutions Containing Sodium Chloride, Potassium Chloride or Magnesium Sulfate or Mixtures Thereof 444

Herbert C. Brown, Moddie D. Taylor and Melvin Gerstein: Acid–Base Studies in Gaseous Systems. I. Precise Dissociation Measurements 431

Herbert C. Brown, Herman Bartholomay, Jr., and Moddie D. Taylor: Acid–Base Studies in Gaseous Systems. II. The Anomalous Base Strength of the Methylamines 435

Theodore H. Clarke and G. Stegeman: The Heat of Acetylation of α- and β-D-Glucose from the Heats of Combustion of the Pentaacetates 457

A. Dorinson and A. W. Ralston: Refractive Indices of the Normal Saturated Aliphatic Nitriles 361

Guy Ervin, Jr., A. L. Giorgi and C. E. McCarthy: The System Potassium Carbonate–Sodium Carbonate–Water at 100 and 150° 384

Douglas V. Frost and Floyd C. McIntire: The Hydrolysis of Pantothenate: A First Order Reaction. Relation to Thiamin Stability 425

Julius D. Heldman and Carl D. Thurmond: The Solubility of Aluminum Bromide in *n*-Butane 427

Edward O. Holmes, Jr., and David Revinson: The System Ammonium Nitrate–Sodium Nitrate 453

Charles B. Hurd, Renato C. Pomatti, John H. Spittle and Frank J. Aloisi: Studies on Silicic Acid Gels. XV 388

Charles B. Hurd and Winterton U. Day: Studies on Silicic Acid Gels. XVI. The Effect of Radiant Energy upon the Time of Set 391

Irving M. Klotz: The Mode of Action of Sulfonamides 459

L. G. Longsworth: The Concentration Distribution in Two-Salt Moving Boundaries 449

Jack G. Roof: Reaction of Acetaldehyde with Ethyl Bromide at 400° 358

Robert Schuman and A. B. Garrett: The Vapor Pressure of Beryllium at 1170–1340°K 442

S. E. Sheppard and H. R. Brigham: Some Effects of Solvents upon the Absorption Spectra of Dyes. III 380

Frederick T. Wall: Osmotic Pressures for Mixed Solvents 446

W. E. Wallace, L. S. Mason and A. L. Robinson: Heats of Dilution of Sodium Chloride in Ethylene Glycol at 25° 362

P. M. Williamson, R. C. Anderson and G. W. Watt: Electrolyte Catalysis in the Ammonolysis of 9-Phenyl-9-chlorofluorene by Liquid Ammonia 376

W. G. Young and L. J. Andrews: Allylic Rearrangements. XIV. The Hydrolysis of Butenyl Chlorides 421

ORGANIC AND BIOLOGICAL

Robert H. Baker and Patty Campbell Weiss: The Reduction of Ester Vinylogs 343

Karl J. Brunings and Alsoph H. Corwin: Effect of Substituents on the Structure of the Dipyrrylmethenes 337

C. A. Buehler, Troy A. Powers and Julian G. Michels: The Action of Formaldehyde on *m*-Hydroxybenzoic Acid. I 417

Norman H. Cromwell, John A. Caughlan and Gordon F. Gilbert: α,β-Diamino Ketones. II. Reactions of Thalline 401

David Davidson and Julian Feldman: The Action of Sulfuric Acid on 1-Phenyl-2-alkylcyclopropanes 488

E. M. Filachione, J. H. Lengel and C. H. Fisher: Pyrolysis of Lactic Acid Derivatives. Production of Phenyl and *o*-Tolyl Acrylate 494

Jacob Finkelstein: N-Substituted Sulfonamides 407

T. A. Geissman and Charles D. Heaton: Anthochlor Pigments. V. The Pigments of *Coreopsis grandiflora*, Nutt. 486

(*Continued on second page of cover*)

Manuscripts submitted for publication and books sent for review in the Journal of the American Chemical Society, and all inquiries regarding them, should be sent to the Editor, Arthur B. Lamb, Chemical Laboratory of Harvard University, 12 Oxford Street, Cambridge 38, Massachusetts

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

(concluded from first page of cover)

Francis H. Gerhardt and Cliff S. Hamilton: Derivatives of 10-Chlorobenzo(g)quinoline..... 345
Charles R. Hauser and Joe T. Adams: The Acetylation of Certain Unsymmetrical Aliphatic Ketones with Acetic Anhydride..... 392
Albert L. Henne and Henry H. Chanan: Diolefins from Allylic Chlorides. II..... 395
Albert L. Henne and Henry H. Chanan: Conjugated Diolefins by Double Bond Displacement. II..... 464
Robert C. Hockett and Maryalice Conley: The Structure of Styracitol..... 467
Robert C. Hockett, Margaret T. Dienes, Hewitt G. Fletcher, Jr., and Hugh E. Ramsden: Lead Tetraacetate Oxidations in the Sugar Group. V. The Rates of Oxidation.. 469
Robert C. Hockett and Hewitt G. Fletcher, Jr.: Lead Tetraacetate Oxidations in the Sugar Group. VI. The Structures of Certain Di- and Tribenzoates of D-Sorbitol and D-Mannitol..... 472
Robert C. Hockett, Mortimer H. Nickerson and William H. Reeder, III: Lead Tetraacetate Oxidations in the Sugar Group. VII. Some Oxidation Rates..... 365
M. S. Kharasch, Frances Engelmann and W. H. Urry: Factors Determining the Course and Mechanisms of Grignard Reactions. XII..... 368
M. S. Kharasch, R. Morrison and W. H. Urry: Factors Determining the Course and Mechanism of Grignard Reactions. XIII..... 481
M. S. Kharasch, D. C. Sayles and E. K. Fields: Factors Determining the Course and Mechanism of Grignard Reactions. XIV. Reagents and Cobaltous Chloride..... 412
C. F. Koelsch and Virgil Boekelheide: The Coupling of α,β-Unsaturated Compounds with Diazonium Salts..... 415
C. S. Marvel, John Whitson and H. W. Johnston: The Dissociation of Hexaarylethanes. XV. Methoxyl Substituents..... 475
C. S. Marvel and C. G. Overberger: An Optically Active Styrene Derivative and its Polymer..... 349
Chester M. McCloskey, Ronald E. Pyle and George H. Coleman: The Preparation of β,β-Trehalose Octaacetate..... 409
C. R. McLellan and W. R. Edwards, Jr.: 1,n-Alkylcyclopentanols and their Derivatives..... 483
Eleanor Mitts and R. M. Hixon: The Reaction of Glucose with Some Amines..... 404
Marcus S. Morgan, R. Stuart Tipson, Alexander Lowy and W. E. Baldwin: Some Derivatives of *cis*-3,6-Endomethylene-Δ⁴-tetrahydrophthalic Acid..... 371
David T. Mowry: Unsaturated Esters of Glycolonitrile..... 352
Dorothy Nightingale and J. R. Janes: The Preparation of Ketones from Nitroölefins..... 489
Arnold C. Ott and Charles D. Ball: The Isolation of Stigmasterol and β-Sitosterol from the Common Bean, *Phaseolus vulgaris*..... 330
Linus Pauling, David Pressman, and Dan H. Campbell: The Serological Properties of Simple Substances. VI. The Precipitation of a Mixture of Two Specific Antisera by a Dihaptenic Substance Containing the Two Corresponding Haptenic Groups..... 372
S. G. Powell and French Hagemann: The Condensation of Isobutyraldehyde with Aliphatic Ketones..... 477
Charles C. Price and William Kaplan: The Reaction of γ-Anisyl-γ-butyrolactone with Potassium Cyanide..... 396
Frederic Richter and G. Frederick Smith: Derivatives of 1,10-Phenanthroline..... 398
Edwin A. Risley, Ann C. Buffington and L. Earle Arnow: Tryptic Digestion of Bovine Serum and Other Proteins in the Presence of Ethyl Alcohol..... 491
Harold R. Schmidt, Cora May Savoy and John Leo Abernethy: Studies in the Biphenyl Series. IV..... 350
H. R. Snyder and Curtis W. Smith: A Convenient Synthesis of *dl*-Tryptophan..... 419
E. D. Walter: Isolation of Partheniol, Parthenyl Cinnamate, and Other Constituents from Guayule Resin..... 354
William G. Young and Samuel Siegel: The Reaction of Citronellal with Benzylmagnesium Chloride..... 317
L. Zechmeister and R. M. Lemmon: Contribution to the Stereochemistry of Cryptoxanthin and Zeaxanthin..... 322
L. Zechmeister and R. B. Escue: A Stereochemical Study of Methylbixin..... 322

NOTES

David Lester and Leon A. Greenberg: Polarographic Behavior of Aniline Oxidation Products..... 496
Glenn S. Skinner, J. H. Taylor and J. L. Ernst: Alkylcyanopyruvic Esters from Aliphatic Nitriles..... 496
M. F. Stubbs: Reaction of Potassium Chromate with an Indium Salt..... 498
Elijah Swift, Jr., and Dexter Leigh Wolfe: The Viscosities of Dimethyl and Trimethylamine at 15, 25 and 35°..... 498
A. D. F. Toy: The Use of Trimethyl Phosphate as a Methylating Agent..... 499

COMMUNICATIONS TO THE EDITOR

N. F. Albertson, S. Archer and C. M. Suter: A New Synthesis of Tryptophan..... 500
I. Fankuchen and M. Schneider: Low Angle X-Ray Scattering from Chrysotiles..... 500
John R. Johnson, Walter C. McCrone, Jr., and William F. Bruce: Gliotoxin, the Antibiotic Principle of *Gliocladium fimbriatum*..... 501

NEW BOOKS

Dictionary of Science and Technology in English–French–German–Spanish. By Maxim Newmark. Review by A. S. Coolidge..... 502
Physical Biochemistry. By Henry B. Bull. Review by John T. Edsall..... 502
The Chemistry of Large Molecules. (Frontiers in Chemistry, Volume 1.) By R. E. Burk and Oliver Grummitt. Review by P. J. Flory..... 502
Industrial Chemistry. By William Thornton Read. Review by Grinnell Jones..... 503
A Text-Book of Inorganic Chemistry. By Fritz Ephraim. English Edition by P. C. L. Thorne and E. R. Roberts. Fourth Edition—Revised and Enlarged. Review by Arthur B. Lamb..... 503
Inorganic Qualitative Analysis. Semi-micro Technique. By Harold A. Fales and Frederic Kenny. Review by James J. Lingane..... 504
Organic Chemistry. By C. W. Porter and T. D. Stewart. Review by Avery A. Morton..... 505
Manometric Methods as Applied to the Measurement of Cell Respiration and Other Processes. By Malcolm Dixon. Second Edition. Review by F. J. W. Roughton..... 505
Plants and Vitamins. By W. H. Schopfer. Translation by Norbert L. Noecker. Review by Roger J. Williams..... 505
Books Received..... 505

CONTENTS

GENERAL, PHYSICAL AND INORGANIC

Leigh C. Anderson and W. A. Fisher: Quinoidation of Triaryl Compounds—Hydroxyphenylbiphenylcarbinols..... 589
Leigh C. Anderson and W. A. Fisher: Quinoidation of Triaryl Compounds—Hydroxybiphenyldiarylmethyl Cations.... 594
Ralph W. Brauer and Luville T. Steadman: The Autoxidation of β-Eleostearic Acid. The Application of the Spectrophotometer to the Study of the Course and the Kinetics of the Reaction..... 563
Joseph F. Foster and R. M. Hixon: Relationship between Solution Viscosity and Molecular Weight in the Amylose Series..... 557
J. Karle and L. O. Brockway: An Electron Diffraction Investigation of the Monomers and Dimers of Formic, Acetic and Trifluoroacetic Acids and the Dimer of Deuterium Acetate .574
H. K. Livingston: Cross-Sectional Areas of Molecules Adsorbed on Solid Surfaces..... 569
W. F. Luder and Saverio Zuffanti: Generalized Acid-Base Catalysis. I. Condensation of o-Benzoylbenzoic Acid in Sulfuric Acid..... 524
R. M. McCready and W. Z. Hassid: The Preparation and Purification of Glucose 1-Phosphate by the Aid of Ion Exchange Adsorbents..... 560
Wilbur H. Miller, M. Frank Mallette, Lloyd J. Roth and Charles R. Dawson: A New Method for the Measurement of Tyrosinase Catecholase Activity. II. Catecholase Activity Based on the Initial Reaction Velocity..... 514
J. Carrell Morris: The Thermal Decomposition of Acetaldehyde..... 584
Carl L. Rollinson and John C. Bailar, Jr.: Studies in the Chromammines. III. Preparation of Di-acido Diethylenediamine Salts by Thermal Decomposition of Triethylenediamine Luteo Salts..... 641
W. Shand, Jr., Verner Schomaker and J. Rodney Fischer: The Structures of Methylenecyclobutane and of 1-Methylcyclobutene..... 636

ORGANIC AND BIOLOGICAL

W. E. Bachmann and R. D. Morin: The Synthesis of Compounds Related to the Sex Hormones..... 553
Hugo Bauer and Sanford M. Rosenthal: 4-Hydroxylaminobenzenesulfonamide, its Acetyl Derivatives and Diazotization Reaction..... 611
Ernst Berliner: The Influence of n-Alkyl Groups on the Rate of a Cyclization Reaction..... 533
John H. Billman and Earl E. Parker: Amino Acids. III. α-Amino-n-butyric Acid and α-Amino-isobutyric Acid.... 538
John H. Billman and John L. Rendall: Amides of Nicotinic Acid and Related Acids. II..... 540
William F. Bruce, James D. Dutcher, John R. Johnson and Leon L. Miller: Gliotoxin, the Antibiotic Principle of *Gliocladium fimbriatum*. II. General Chemical Behavior and Crystalline Derivatives..... 614
H. B. Charmbury and C. C. Wright: The Hydrogenolysis of Abietic Acid..... 526
James D. Dutcher, John R. Johnson and William F. Bruce: Gliotoxin, the Antibiotic Principle of *Gliocladium fimbriatum*. III. The Structure of Gliotoxin: Degradation by Hydriodic Acid..... 617
James D. Dutcher, John R. Johnson and William F. Bruce: Gliotoxin, the Antibiotic Principle of *Gliocladium fimbriatum*. IV. The Structure of Gliotoxin: the Action of Selenium..... 619

Herbert E. Fisher, Marshall Kulka and Harold Hibbert: Studies on Lignin and Related Compounds. LXXIX. Synthesis and Properties of 3-Hydroxy-1-(3,4-dimethoxyphenyl)-2-propanone 598

J. A. F. Gardner and Harold Hibbert: Studies on Lignin and Related Compounds. LXXXII. Synthesis and Properties of 1,3-Diacetoxy-1-(4-acetoxy-3-methoxyphenyl)-2-propanone and 1-Acetoxy-3-chloro-1-(4-acetoxy-3-methoxyphenyl)-2-propanone and their Relation to Lignin Structure 607

Henry Gilman and Sydney M. Spatz: Some Quinolines Patterned as "Open Models" of Atabrine 621

Henry Gilman, David A. Shirley and Paul R. Van Ess: The Metalation of Phenothiazine 625

Robert C. Hockett and Leonard B. Chandler: A Large-Scale Preparation of D-Altrose. D-Altrose Oxime and its Rate of Mutarotation 627

Joseph V. Karabinos and J. Lester Szabo: Hydantoins of Some Sulfur Containing Amino Acids 649

John F. Lane, John D. Roberts and William G. Young: Allylic Rearrangements. XV. The Carbonation of Butenylmagnesium Bromide 543

John F. Lane, James Fentress and L. T. Sherwood, Jr.: Allylic Rearrangement in the Reaction of Cuprous Cyanide with Butenyl Halides 545

H. L. Lochte, E. D. Thomas and Price Truitt: The Nitrogen Compounds in Petroleum Distillates. XXV. Isolation and Identification of 3- and 4-Cyclopentylpyridines from California Petroleum 550

Leonard Mitchell and Harold Hibbert: Studies on Lignin and Related Compounds. LXXX. The Ethanolysis of 1-Acetoxy-1-(4-acetoxy-3-methoxyphenyl)-2-propanone and its Relation to Lignin Structure 602

Leonard Mitchell, T. H. Evans and Harold Hibbert: Studies on Lignin and Related Compounds. LXXXI. Properties of 1-Bromo-1-(4-acetoxy-3-methoxyphenyl)-2-propanone and Relation to Lignin Structure 604

Milton Orchin: Hydrogenation of Anthracene by Tetralin 535

Charles C. Price and George P. Mueller: Condensation of Cyclohexene Oxide, 1,2-Dichlorocyclohexane, and 3,4-Dichlorohexane with Anisole 628

Charles C. Price and George P. Mueller: The Synthesis of Two Dihydroxyterphenyls 632

Charles C. Price and George P. Mueller: The Pinacols and Pinacolone from *p*-Methoxyacetophenone 634

Richard F. Riley: Metabolism of Phosphoryl Choline. I. Synthesis of Calcium Phosphoryl Choline Chloride Containing the Radioactive Isotope, P^{32} 512

Alfred Russell and E. A. Kaczka: Fish Poisons from *Ichthyomethia Piscipula*. I 548

Robert R. Sealock and Ruth L. Goodland: Thiamine Inactivation by the Chastek-Paralysis Factor. Inhibition 507

H. R. Snyder and George W. Cannon: A New Synthesis of Homocystine and a Further Improvement in the Synthesis of Methionine 511

J. Lester Szabo and Joseph V. Karabinos: The Dehydration of Hydantoin-5-propionic Acid 650

George E. Ward, O. Glenn Pettijohn, Lewis B. Lockwood and Robert D. Coghill: Optical Isomers of 2,3-Butanediol Produced by Fermentation 541

R. B. Woodward and Harold Baer: Studies on Diene-addition Reactions. II. The Reaction of 6,6-Pentamethylenefulvene with Maleic Anhydride 645

William G. Young, Lawrence J. Andrews and Stanley J. Cristol: Polyenes. I. The Synthesis and Absorption Spectra of the Ionylideneacetones and Related Compounds 520

NOTES

Paul Z. Bedoukian: Synthesis of Bromoacetals 651

John H. Billman, Bernard Wolnak and David K. Barnes: An Improved Method for the Synthesis of Quinone 652

Edith Ju-Hwa Chu, Zoe-Ing Shen, Tsui-Lin Chien and T. S. Tuan: Syntheses of Compounds Related to Vitamin K. II. *p*-(3-Alkyl-4-hydroxynaphthylazo)-benzenesulfonamides 653

Hans T. Clarke: Preparation of *o*-Aminobenzyl and *β*-Aminoethyl Thiazolium Salts 652

James Curry and Z. Zimmerman Hugus, Jr.: The Second Ionization Constant of Deuterocarbonic Acid 653

L. A. Goldblatt and S. Palkin: The Production of *α*- and *β*-Pyronene from *allo*-Ocimene 655

Charles F. Huebner and Karl Paul Link: Brominated 4-Hydroxycoumarins 656

Thomas L. Jacobs, John D. Roberts and W. G. MacMillan: The Dielectric Constants and Dipole Moments of Acetylenic Ethers 656

D. H. Laughland and Leslie Young: *p*-Bromoaniline Salts of Monoaryl Sulfates 657

Werner L. Lipschitz: The Action of Ammonia on Allophanic Azide 658

John E. Ricci: On the Cryoscopic Constant of Camphor 658

NEW COMPOUNDS

S. I. Gertler and W. F. Barthel: N-Substituted Piperonylamides 659

Chien-Pen Lo and Lucy Ju-Yung Chu: N¹-Acetyl-N⁴-benzoylsulfanilamide 660

COMMUNICATIONS TO THE EDITOR

Frederick G. Bordwell and Irving M. Klotz: Structure and Activity of Sulfanilamides 660

Julius D. Heldman: An Azeotrope in the System *n*-Butane-Methyl Bromide 661

Robert P. Jacobsen: A New Method for the Degradation of Bile Acid Derivatives 662

Walter J. Peterson, F. M. Haig and A. O. Shaw: Destruction of Riboflavin in Milk by Sunlight 662

David F. Waugh: The Linkage of Corpuscular Protein Molecules. I. A Fibrous Modification of Insulin 663

NEW BOOKS

Optical Crystallography. By Ernest E. Wahlstrom. Review by W. M. D. Bryant 664

The Biochemistry of Malignant Tumors. By Kurt Stern and Robert Willheim. Review by R. Norman Jones 664

Books Received 664

Zuffanti, S., 524.

NOTICE

Because the Government requires the Society to cut its use of paper to an absolute minimum, it will no longer be possible to print the customary number of excess copies to supply demands for volumes and sets in subsequent years. Therefore it is suggested that any subscribers who do not bind their Journals, save current issues for later sale.

CONTENTS

GENERAL, PHYSICAL AND INORGANIC

A. W. Davidson, H. H. Sisler and Raymond Stoenner: The System Acetic Acid–Ammonia 779
C. V. King and J. J. Josephs: Dielectric Constant and Temperature on the Catalyzed Decomposition of Azodicarbonate Ion 767
Chia-Si Lu and Jerry Donohue: An Electron Diffraction Investigation of Sulfur Compounds 818
John M. Lupton and Cecil C. Lynch: Polarographic Examination of Carbonyl Compounds 697
J. Mitchell, Jr., Walter Hawkins and Donald Milton Smith: Karl Fischer Reagent. XI. Determination of Amines 782
Linus Pauling, David Pressman, and A. L. Grossberg: The Serological Properties of Simple Substances. VII 784
Frank W. Putnam and Hans Neurath: The Precipitation of Proteins by Synthetic Detergents 692
F. O. Rice and Mary Thomas Murphy: The Thermal Decomposition of Substituted Cyclohexenes 765
C. H. Shomate and F. E. Young: Heats of Formation of Solid and Liquid $Mn(NO_3)_2 \cdot 6H_2O$ 771
Donald Milton Smith, J. Mitchell, Jr., and Walter Hawkins: Karl Fischer Reagent. X. Determination of Aliphatic Hydroxy Amines 715
R. A. Stillings and R. J. Van Nostrand: The Action of Ultraviolet Light upon Cellulose 753
A. Weissberger and J. E. LuValle: Autoxidation of Ascorbic Acid in the Presence of Copper 700
F. E. Young: Heats of Formation of $Mg(NO_3)_2$, $Mg(NO_3)_2 \cdot 6H_2O$, $Ca(NO_3)_2$, $Ca(NO_3)_2 \cdot 4H_2O$ and $Ba(NO_3)_2$ 773
F. E. Young: The Heats of Formation of $Al(NO_3)_3 \cdot 6H_2O$ and $Al(NO_3)_3 \cdot 9H_2O$ 777

ORGANIC AND BIOLOGICAL

Roger Adams and J. W. Mecorney: Condensation of Ethyl Acetoacetate with 4-Chloro-3,5-dimethylphenol 802
C. F. H. Allen, Alan Bell and C. V. Wilson: Sulfonamides in the Benzimidazole, Benzothiazole and Benzotriazole Series. 835
R. C. Behm and J. M. Nelson: The Activity of Tyrosinase toward Phenol 709
R. C. Behm and J. M. Nelson: The Aerobic Oxidation of Phenol by Means of Tyrosinase 711
J. H. Billman and J. L. Rendall: Antispasmodics and Anticonvulsants. III. Miscellaneous Amides and Esters 745
E. Campaigne: The Synthesis of 2,4-Diarylthiophenes 684
B. F. Daubert and T. H. Clarke: Polymorphism of Symmetrical Monoöleyl-disaturated Triglycerides 690
Max Frankel and Ephraim Katchalski: Diazomethane with Ammonium Salts of Organic Acids 763
R. C. Fuson and P. L. Southwick: Reformatsky Condensations. Methyl γ-Bromosenecioate 679
R. C. Fuson, M. D. Armstrong, Wm. E. Wallace and J. W. Kneisley: 1,2-Addition of Methylmagnesium Iodide to Mesityl Ketones 681
T A. Geissman and Lester Morris: Cyclic β-Diketones and Grignard Reagents 716
T. A. Geissman and Vsevolod Tulagin: Cyclic β-Diketones and Grignard Reagents. III. 2-Methyl-2-benzoylhydrindone 719
Henry Gilman, Jack Swiss, H. B. Willis and F. A. Yeoman: Dibenzofuran. XX. 2,3,7,8-Derivatives 798
I. S. Goldstein and H. I. Bernstein: The Rearrangement of the Zeta-Truxinamic Acids 760
R. M. Hann, A. T. Ness and C. S. Hudson: 2,4:3,5-Dimethylene-D,L-xylitol and 2,4-Methylene-xylitol 670
R. M. Hann and C. S. Hudson: The Action of Copper Sulfate on Phenylosazones of the Sugars. Phenyl-D-glucosotriazole 735
Ralph Hill and Garfield Powell: Amines Related to Epinephrine. I. Some Amines of the "Eprocaine" Type 742
V. N. Ipatieff, Herman Pines and R. E. Schaad: Reaction of Benzene with Butadiene 816
Thomas L. Jacobs and Scott Searles, Jr.: Acetylenic Ethers. IV. Hydration 686

(Continued on second page of cover)

PUBLISHED MONTHLY BY THE AMERICAN CHEMICAL SOCIETY

Copyright, 1944, by the American Chemical Society

Entered at the Post Office at Easton, Pa., as second-class Matter. Acceptance for mailing at special rate of postage provided for in Section 1103, Act of October 3, 1917, authorized July 13, 1918.

Manuscripts submitted for publication and books sent for review in the Journal of the American Chemical Society, and all inquiries regarding them should be sent to the Editor, Arthur B. Lamb, Chemical Laboratory of Harvard University, 12 Oxford Street, Cambridge 38, Massachusetts

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

(Concluded from first page of cover)

S. A. Morell and A. H. Auernheimer: Configuration of the 2,3-Butylene Glycols..... 792
M. J. Murray and E. H. Stevenson: Debromination of Pentaerythrityl Bromide by Zinc. Isolation of Spiropentane.. 812
A. T. Ness, Raymond M. Hann and C. S. Hudson: The Acetolysis of Trimethylene-D-sorbitol. 2,4-Methylene-D-sorbitol and 1,3:2,4-Dimethylene-D-sorbitol..... 665
Melvin S. Newman and Bradley T. Lord: Normal and Pseudo Esters of 2-Benzoylbenzoic Acid Types. II..... 731
Melvin S. Newman and Bradley T. Lord: The Behavior of 3,6-Dimethylphthalic Anhydride in Condensations..... 733
W. H. Pearlman: A Study of the Neutral, Non-Saponifiable Fraction of Ox Bile..... 806
A. H. Popkin and G. B. McVea: The Preparation of 2- and 4-Aminobiphenyl-4'-sulfonamides..... 796
A. H. Popkin, G. M. Perretta and R. Selig: Derivatives of 2-Aminobiphenyl..... 833
David Pressman and W. G. Young: Reaction of Dibromides of Mono-substituted Ethylenes with Potassium Iodide.. 705
Byron Riegel and Irving Allan Kaye: The Preparation of 24-Keto and 24-Hydroxycholesterol..... 723
J. R. Spies, E. J. Coulson, D. C. Chambers, H. S. Bernton and Henry Stevens: Isolation and Properties of an Active, Carbohydrate-Free Protein from Castor Beans..... 748
C. M. Suter and H. D. Zook: The Hydrolysis of Trimethylethylene Bromide. Ketone Formation..... 738
C. M. Suter and A. W. Ruddy: The Preparation of 1-(3,4-Dihydroxyphenyl)-2-amino-1-butanol..... 747
S. Wawzonek, H. A. Laitinen and S. J. Kwiatkowski: The Behavior of γ-Keto- and Aldehydo-Acid Derivatives at the Dropping Mercury Electrode. I..... 827
S. Wawzonek, H. A. Laitinen and S. J. Kwiatkowski: The Behavior of γ-Keto- and Aldehydo-Acid Derivatives at the Dropping Mercury Electrode. II..... 830
F. C. Whitmore, H. S. Mosher, R. R. Adams, R. B. Taylor, E. C. Chapin, Charles Weisel and William Yanko: Basically Substituted Aliphatic Nitriles and their Catalytic Reduction to Amines..... 725
M. L. Wolfrom and D. I. Weisblat: An Acyclic Sugar Orthoacetate..... 805
R. B. Woodward and R. H. Eastman: The Dimerization of 6-Methoxy-3,4-dihydronaphthalene..... 674
W. G. Young, L. J. Andrews, S. L. Lindenbaum and S. J. Cristol: Diazomethane with α-Cyanocrotonic Acid..... 810
W. M. Ziegler: Some 4-(ω-Carboxyalkyl)-2-aminothiazoles... 744

NOTES

S. J. Angyal and J. V. Lawler: 1,3:2,4-Dibenzylidene-D-sorbitol 837
Charlotte H. Boatner, Maizie Caravella and Carolyn S. Samuels: An Orange-colored Pigment of Cottonseed..... 838
George Bosworth Brown and C. W. H. Partridge: The Preparation of Ethyl ε-Bromocaproate..... 839
John R. Cann and E. D. Amstutz: Polymerization of Undecylenic Acid in the Presence of Boron Fluoride..... 839
Henry Gilman and Gordon J. O'Donnell: p-(2,5-Dimethylpyrryl-1)-phenyl-magnesium Bromide and -Lithium..... 840
Joseph B. Niederl and Edward J. Kenney: Double Invert Soaps: Symmetrical Di-morpholinium Salts..... 840
Armando Novelli and Jose S. Conticello: The Identification of 2-Methyl-1-4-naphthoquinone..... 842
W. H. Scheub and C. R. McCrosky: The System Sulfur Dioxide–Acetic Acid..... 841
A. G. Taylor and B. V. de G. Walden: Trimethyl Silane and Trimethyl Silicon Chloride..... 842
David E. Worrall and Leo Cohen: Derivatives of Nitrostyrene. 842
David W. Young and Ruth E. Biertuempfel: The Viscosity of the Methyl Ester of Dilinoleic Acid..... 843

NEW COMPOUNDS

Heinz Fraenkel-Conrat and Harold S. Olcott: o-Biphenyl Isocyanate, o-Bicyclohexyl Isocyanate, N,N'-Di-o-biphenyl Urea, N,N'-Di-o-bicyclohexyl Urea..... 845
Joseph B. Niederl and Anthony J. Shukis: New Phenolic Mercurials..... 844
Joseph B. Niederl and Anthony E. Lanzilotti: Double Invert Soaps: Symmetrical Di-piperidinium Salts..... 844
Richard E. Reeves: Methyl 3-Methyl-4,6-ethylidene-α- and β-Glucosides..... 845
Einar Stenhagen and Birgitta Tägtström: n-Nonatriacontane. 845

COMMUNICATIONS TO THE EDITOR

Paul H. Bell, J. Foster Bone and Richard O. Roblin, Jr.: The Relationship of Structure to Activity of Sulfanilamide Type Compounds..... 847
Herbert C. Brown and Moddie D. Taylor: Steric Strain and Anomalous Base Strength of Normal Aliphatic Amines... 846
Edwin K. Buchman and Harry Cohen: Synthetic Thiophane Derivatives..... 847
Frank H. Johnson and Henry Eyring: The Nature of the Luciferin–Luciferase System..... 848
R. B. Woodward and W. E. Doering: The Total Synthesis of Quinine..... 849
R. B. Woodward and R. H. Eastman: Thiophane Derivatives. 849

NEW BOOKS

The Chemistry of Organic Medicinal Products. By Glen L. Jenkins and Walter G. Hartung. Second Edition. Review by C. R. Addinall..... 850
The Extra Pharmacopoeia. By Martindale. 22nd Edition in Two Volumes. Review by F. F. Blicke..... 850
Supplement to The Extra Pharmacopoeia, Vol. I, 22nd Edition, 1941. By Martindale. Review by F. F. Blicke..... 851
Semimicro Qualitative Analysis. By John F. Flagg and Willard R. Line. Review by Allen D. Bliss..... 851
Pyrotechnics, Civil and Military. By G. W. Weingart. Review by Tenney L. Davis..... 851
The Optical Properties of Organic Compounds. By Alexander Winchell. Review by S. B. Hendricks..... 851
Synthetic Resins and Rubbers. By Paul O. Powers. Review by Grinnell Jones..... 852
Principles and Applications of Electrochemistry. Volume II. Applications. By W. A. Koehler. Second Edition. Review by Henry B. Linford..... 852
A Short Course in Quantitative Analysis. By Hobart H. Willard, N. Howell Furman and John F. Flagg. Review by James J. Lingane..... 852
Industrial Chemistry of Colloidal and Amorphous Materials. By Warren K. Lewis, Lombard Squires and Geoffrey Broughton. Review by James W. McBain..... 853
Laboratory Manual of Spot Tests. By Dr. Fritz Feigl. Translated from the German manuscript by Ralph E. Oesper. Review by M. G. Mellon..... 853
The Organic Chemistry of Sulfur. Tetracovalent Sulfur Compounds. By Chester Merle Suter. Review by E. Emmet Reid..... 854
Books Received..... 854

CONTENTS

GENERAL, PHYSICAL AND INORGANIC

Edward S. Amis and Ralph Theodore Overman: A Spectrographic and Kinetic Study of the Alkaline Fading of Tetraiodophenolsulfonphthalein 941
Herbert H. Anderson: Chloro(iso)cyanates of Silicon, Including Rearrangements at High Temperatures 934
H. E. Bent and A. J. Harrison: Single Bond Energies. V. The Association of Ketyls 969
George S. Forbes and Herbert H. Anderson: Redistribution Reactions in the Halides of Carbon, Silicon, Germanium and Tin 931
William D. Harkins and George Jura: Surfaces of Solids. X. Extension of the Attractive Energy of a Solid into an Adjacent Liquid or Film, the Decrease of Energy with Distance, and the Thickness of Films 919
J. J. Howland, Jr., and W. Albert Noyes, Jr.: Photochemical Studies. XXXVII. Some Tests of Mechanism for the Photochemical Decomposition of Acetone 974
Grinnell Jones and Schuyler M. Christian: The Viscosity of Aqueous Solutions of Electrolytes as a Function of the Concentration. VIII. Potassium Ferricyanide 1017
Cecil V. King and Alexander P. Marion: The Ionization Constants of Very Weak Acids. Acetoxime, Methyl Ethyl and Diethyl Ketoximes 977
Otto H. Müller: The Characterization of Capillaries Used for Dropping Mercury Electrodes in Polarographic Studies 1019
Gerald Oster, Donna Price, Leslie G. Joyner and John G. Kirkwood: The Dielectric Constants of Solutions of Glycine and Pyridine Betaine in Water–Dioxane Mixtures 946
Gerald Oster: The Dielectric Properties of Dipolar Ions in Mixed Solvents 948
Harry F. Pfann, D. J. Salley and H. Mark: Mechanism of Peroxide Initiated Styrene Polymerization 983
Osborne R. Quayle and Katherine O. Smart: A Study of Organic Parachors. VI. A Supplementary Series of Tertiary Alcohols 935
Osborne R. Quayle, R. A. Day and George M. Brown: A Study of Organic Parachors. VII. A Series of Saturated Hydrocarbons 938

NOTICE

Because the Government requires the Society to cut its use of paper to an absolute minimum, it will no longer be possible to print the customary number of excess copies to supply demands for volumes and sets in subsequent years. Therefore it is suggested that any subscribers who do not bind their Journals, save current issues for later sale.

JOURNAL OF THE AMERICAN CHEMICAL SOCIETY

Published monthly by the American Chemical Society at Easton, Penna.

Editorial Office: Chemical Laboratory of Harvard University, 12 Oxford St., Cambridge 38, Mass.

Assistant to the Editor (Proof and Make-up): Allen D. Bliss, Department of Chemistry, Simmons College, 300 The Fenway, Boston 15, Mass.

Business Office: American Chemical Society, 1155 16th St., N.W., Washington 6, D. C.

Advertising Office: American Chemical Society, 332 West 42nd St., New York 18, N. Y.

The American Chemical Society and the Editors of the *Journal of the American Chemical Society* assume no responsibility for the statements and opinions advanced by contributors to THIS JOURNAL.

Remittances and orders for subscriptions and for single copies, notices of changes of address and new professional connections, and claims for missing numbers should be sent to the American Chemical Society, 1155 16th Street, N.W., Washington 6, D. C. Changes of address for the *Journal of the American Chemical Society* must be received on or before the 18th of the preceding month.

Claims for missing numbers will not be allowed (1) if received more than sixty days from date of issue (owing to the hazards of war-time delivery, no claims can be honored from subscribers outside of North America), (2) if loss was due to failure of notice of change of address to be received before the date specified in the preceding paragraph, or (3) if the reason for the claim is "missing from files."

Annual subscription—$8.50 to non-members, $3.00 to members. Postage to countries not in the Pan American Union, $1.50; Canadian postage, $0.50. Single copies—current issues $0.75, back numbers $0.80; special rates to members.

The American Chemical Society also publishes *Chemical Abstracts*, *Industrial and Engineering Chemistry* (Industrial and Analytical Editions), and *Chemical and Engineering News*. Rates on request.

NOTICE TO AUTHORS OF PAPERS

Manuscripts for THIS JOURNAL should be submitted to the Editor ready for publication, typewritten (double space), with 2–3 cm. margins, on a good quality, durable paper, preferably of 8.5″ × 11″ size. In addition to the original typewritten copy, one or more carbon copies should be submitted so that the time required for examination by the Editorial Board may thus be considerably shortened. Care should be taken that all pages in a manuscript, including tables (but not the diagrams) be numbered consecutively. In preparing manuscripts authors are requested to observe, for reasons of economy, the utmost conciseness consistent with clarity of presentation. The manuscripts should be addressed to specialists in their particular field rather than to the general reader. Extensive reviews of the literature cannot be accepted. When well-known or previously published procedures have been followed in the experimental work they should only be designated or referred to.

Form of Presentation.—There should be one or more introductory paragraphs setting forth the occasion, significance and main objectives of the investigation and the method of attack. This should be followed by the experimental results and a discussion of them, either *seriatim* or at their conclusion. Finally, there should be a brief summary of the main achievements of the investigation. Sometimes, particularly when the subject matter is involved and there are many details which, though essential for a successful repetition of the experiments, are unnecessary for the main account of the investigation, these details can with advantage be relegated to an appendix or supplement, just preceding the Summary. In intermediate cases it is often advisable to retain a single, straightforward presentation but to intercalate sections in fine print giving the experimental details of procedure. This has the great advantage of keeping the experimental details close to the more general statements based upon them and yet at the same time permitting the reader if he wishes to pass over this section without inconvenience.

It will be of great assistance to the Editor's Office if the style, arrangement and orthography of the manuscripts are made to conform to the usages of the JOURNAL as exemplified in its recent issues and as set forth in the following paragraphs.

Center headings should be employed sparingly; side headings should be indented and run into the text to which they apply, using period and dash. References to the literature and all footnotes regardless of their nature (except those in tables) should be numbered in one consecutive series, repetition of notes being avoided by using simply the superscript number corresponding to the original reference. They should follow immediately in separate lines the line of text containing the text words to which they refer, and may be set off by short rules above and below. The items in the references to the literature should conform to the uniform usages of the Journal as regards order and punctuation, and to the abbreviations as given by *Chemical Abstracts* in its "List of Periodicals Abstracted." The names of all simple compounds rather than their formulas should be used whenever they occur in the text. Periods of time (unless fractional) should be written in words and quantities of material in Arabic numerals, unless occurring at the beginning of a sentence. Letters used to represent quantities in mathematical expressions should be underscored to indicate that they are to be printed in italics, and Greek or other unusual characters should be written plainly or should be explained by annotations. Simple fractional expressions should be written with a slant line rather than in the conventional manner, so that only a single line of type is required. All subscripts and superscripts should be carefully made and placed (the degree sign ° or a small o should not be used to represent zero). For economy, except in unusual circumstances the abbreviations %, °A., cm., cc., ml., g., Å., m. p., f. p., b. p., cal., kcal., expt. and Fig., should be used rather than the words.

Figures and graphs should be carefully prepared line drawings on plain white drawing paper, blue drawing cloth or coördinate paper printed in blue only. The

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

originals are preferable, but clear, well-prepared photographic prints or photostats are acceptable. Illustrations are most conveniently handled when made in the conventional 8.5" × 11" manuscript size; if they are of necessity larger, and therefore liable to damage in mailing, duplicate rough sketches or photographic prints of smaller size should be furnished for dispatch to the Referees. Diagrams should be designed to occupy a single column width and should therefore be tall rather than wide. Particular attention should be given to the correct proportions of the various parts of the figure, especially the experimental points, and if any letters, numbers, or legends must be placed on the diagram to their proportions also. In graphs the frame and actual curves should be ruled and inked more heavily than the coördinate lines, and these latter should not be too close together. Experimental points should always be given and should be indicated not by crosses but by circles or other symbols carefully drawn with drafting instruments. Where feasible it is often helpful to have the diameter of the circles indicate the precision of the measurements. The numbers and legends on coördinate axes are set up in type by the printer; the author, therefore, should place them in pencil outside the axes. The numbers and titles of figures should be placed below the diagrams, or on the back, or collected on a separate sheet. Small photographic prints should be mounted on cardboard and any composite series of photographic prints should be mounted in the order and arrangement desired. Each piece of illustration copy should be marked on the margin or back with the name of the author and brief title of the article (for identification purposes).

Tables.—Tables should not be used indiscriminately as they are much more expensive, line for line, than running text. If reasonably possible, they should be designed to occupy fully a single column (3 inches), which will take 50–75 characters and spaces. Tables occupying the full width can be used, but they are undesirable for the same reasons advanced with regard to page wide figures; their preparation should follow the same principles as for those of single width. Care should be taken to avoid any arrangement which unduly increases the depth of a table, and column heads should be made as small as possible, using abbreviations liberally. Lines of data should not be numbered nor run numbers given unless these numbers are needed for reference in the text. Columns should not be used to contain only one or two entries, nor should the same entry be repeated numerous times consecutively, since these cases may be taken care of more economically in footnotes, or by entries following the title of the table. Data should not be included in one column which are deducible easily by simple arithmetic from data in another column. Tables should be interspersed in the manuscript as near as possible to the places where they are referred to in the text, and need not be placed alone on separate sheets.

Formulas and Equations.—Empirical and structural formulas and mathematical and chemical equations should be arranged to fill adequately the width of a single column. This will often require a continuation of the equation in additional lines, and although this is a disadvantage it is in general preferable to intrusion into the adjoining column. Subscripts and superscripts, especially the latter, should be written with care and the conventional fractional arrangements should not be used in exponents. Organic structural formulas should be arranged to fill the space economically, and arrows should be used horizontally or vertically, not diagonally, wherever possible.

Notes do not differ fundamentally from Articles. They describe fragmentary or less complete studies and hence particular attention must be given to brevity and conciseness of presentation. Summaries are not included. They are collected in a special section near the end of each number of the Journal.

New Compounds.—This department is for brief accounts of new substances which do not appear of sufficient importance to justify separate publication and cannot be described appropriately as part of any other Article or Note. These accounts should report the preparation of the new compound succinctly, yet fully enough so that the operations can be duplicated. Significant properties, formulas and analytical data to establish the identity and purity of the substance should be given. Material appearing in this classification will not be accepted for subsequent publication.

Communications to the Editor are designed to afford prompt, brief, preliminary publication in our Journal of new and significant observations or discoveries. Their total length may in no case exceed 500 words or the equivalent. They will be given as rapid editorial consideration as possible, but at best it will usually be out of the question to include them in a given issue of the Journal if they arrive at the Editor's office later than the 20th of the preceding month. Communications like other contributions should be self-sustaining; that is, they should present experimental or other evidence adequate to establish the *prima facie* credibility of the results or conclusions stated or to permit their appraisal by an expert in the field although because of the 500-word limit a complete presentation cannot usually be expected. These requirements make Communications on many subjects impracticable, particularly those of an involved or theoretical nature.

Communications differ from ordinary Articles or Notes in that their publication does not prevent the re-publication of their subject matter in a later, more complete article in the Journal. In view of this special provision and their expedited publication, it is clear that the contribution made by the Communication should be of special interest or timeliness; mere abstracts of forthcoming articles cannot be accepted. Proof and reprint order will be sent to authors whenever possible, but as this cannot always be done, a memorandum as to the reprints desired should accompany the manuscript.

Microfilm Supplements.—By arrangement with Science Service material supplementary to articles in THIS JOURNAL, such for instance as extensive tables, graphs or calculations, can be distributed at small cost as American Documentation Institute Documents in the form of microfilms with images 25 mm. high on standard 35-mm. film or photoprints 6 × 8 inches legible to the unaided eye. Such material must, however, have been submitted to the Editor of the Journal and must have been approved by him for publication. Attention will then be called to these documents by means of footnotes at appropriate points in the text of the article concerned.

JOURNAL OF THE
AMERICAN CHEMICAL SOCIETY

VOLUME 66 JANUARY 11, 1944 NUMBER 1

[CONTRIBUTION FROM THE NOYES CHEMICAL LABORATORY, UNIVERSITY OF ILLINOIS]

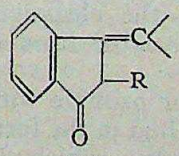
Some 2,3-Disubstituted Indones

BY ROBERT L. FRANK, HENNING EKLUND, JOHN W. RICHTER, CLINTON R. VANNEMAN AND ARNOLD N. WENNERBERG

2,3-Disubstituted indones have been reported to be activators for alcoholic fermentation. According to Pirrone,[1] 2-ethyl-3-phenylindone, 2-methyl-3-phenylindone and 2,3-diphenylindone increase the rate of alcoholic fermentation by as much as 18%. The present research was undertaken in the hope of discovering other compounds that would produce this effect. Nine 2,3-disubstituted indones have been synthesized in which the substituents are alkyl, aryl or substituted aryl groups.

The indones in which the substituent on the 2-position is aromatic were prepared by the addition of excess Grignard reagent to 2-substituted indanediones according to the method employed by Jacobi[2] and by Koelsch[3] (I–IV). Those in which the substituent on the 2-position is aliphatic were prepared by the Reformatsky reaction followed by simultaneous dehydration and ring closure by means of concentrated sulfuric acid (V–VI–IV). This method has been carried out successfully by de Fazi.[4]

When the substituent in the 3-position is a primary or secondary aliphatic group, it is possible for the dehydration of the β-hydroxy ketone (III) to take place in such a way as to form the indone (IV) or the isomeric alkylidene indanone (VII).



VII

Weiss and Alberti[5] have shown that both types of dehydration products form when 2-phenylindane-1,3-dione is treated with benzylmagnesium chloride and the resulting product is dehydrated.

To establish definitely the structures of the indones of this type, the position of the double bond in 3-ethyl-2-phenylindone was determined by ozonolysis.

Ozonization in acetic acid yielded two crystalline products. One of these was colorless and gave the correct combustion analysis for the ozonide (VIII). The other was yellow and had the composition of *o*-propionylbenzil (IX). This compound could only arise from the indone (IV) and not from the alkylidene indanone (VII).

The ozonide from 3-ethyl-2-phenylindone was a remarkably stable compound, melting at 93° with no decomposition. It burned evenly and did not explode when heated in a flame. Treatment with hydrogen and platinum oxide for a long period did not alter it. These properties are perhaps due to the hindrance which might be expected from the groups around the double bond in 3-ethyl-2-phenylindone. Boiling with water converted the ozonide to a yellow oil, presumably due to the formation of the triketone (IX).

Alkaline hydrolysis of the ozonide yielded benzoic acid in 95% yield assuming the formation of one mole from each mole of ozonide. No *o*-propionylbenzoic acid (X), a product which might be expected from the cleavage of the ozonide (VIII), could be isolated from the reaction mixture.

Treatment of the ozonide with hydroxylamine hydrochloride resulted in the formation of a colorless crystalline product which showed no depression in melting point when mixed with a sample of the known 4-ethyl-1-keto-2,3,1-benzoxazine (XI).[6] The latter was obtained by the method of Daube[7] from hydroxylamine and *o*-propionylbenzoic acid (X). *o*-Propionylbenzoic acid (X) can be derived from the indone (IV) but not from the alkylidene indanone (VII).

The ozonide was also heated with phenylhydrazine and a crystalline product was isolated. The same product was obtained when *o*-propionylbenzoic acid (X) was heated with phenylhydrazine. The compound is evidently 1-ethyl-3-phenylphthalazone (XII), although it melts at 111–112°, whereas Gottlieb[8] reported a melting point of 102°.

Ultraviolet absorption spectra also indicate the structure IV rather than VII for these compounds. The spectrum of -3-ethyl-2-phenylindone shows a maximum at 255 mμ ($\log \epsilon = 4.765$ in 95% ethanol), very near the maximum of 259 mμ ($\log \epsilon = 4.702$ in 95% ethanol) in the spectrum of 2,3-diphenylindone, in which the double bond is definitely fixed.

Tests on these compounds as activators for alcoholic fermentation are being carried out by Dr. F. M. Clark of the Department of Bacteriology of this University and the results will be reported elsewhere.

Experimental

2-Phenylindane-1,3-dione.—This compound was prepared by the method of Nathanson[9] from 66 g. (0.30 mole) of benzalphthalide and 9 g. (0.39 mole) of sodium dissolved in 600 cc. of absolute methanol. The yield was 63.0 g. (95%), m. p. 144–145°.

2-Anisyl- and 2-Veratrylindane-1,3-diones.—2-Anisylindane-1,3-dione was prepared by the method of Koelsch[3] using 85 g. (0.634 mole) of phthalide, 85 g. (0.625 mole) of anisaldehyde and 20.5 g. (0.891 mole) of sodium dissolved in 400 cc. of absolute ethanol. The yield of product melting at 153–154° was 54.5 g. (34.6%).

2-Veratrylindane-1,3-dione was prepared in a similar manner from 100 g. (0.746 mole) of phthalide, 120 g. (0.723 mole) of veratric aldehyde and 20.5 g. (0.891 mole) of sodium in 400 cc. of absolute ethanol. The yield of light yellow needles, m. p. 188–190°, was 68.0 g. (33.4%).

Anal.[10] Calcd. for $C_{17}H_{14}O_3$: C, 72.33; H, 5.00. Found: C, 72.60; H, 5.21.

Preparation of Indones by Addition of Grignard Reagents to Indanediones.—The indones prepared by this means are the first seven in Table I, in which the substituent on the 2-position (IV) is aromatic.

The Grignard reagents were prepared in amounts of 0.15 to 0.25 mole in three-necked round-bottomed flasks equipped with efficient stirrers. Equimolar amounts of magnesium and the organic halide were used in 200–400 cc. of anhydrous ether. The indanediones, dissolved in 200–400 cc. of anhydrous benzene or toluene, were added in one-fourth to one-third the molar amounts of Grignard reagent and the solutions were refluxed for one to two hours. It was necessary to use large amounts of benzene or toluene to dissolve the indanediones and also to keep the reaction mixture homogeneous during the addition. In the preparation of 3-ethyl-2-veratrylindone, for example, it was necessary to use a liter of dry benzene for 15 g. of 2-veratrylindane-1,3-dione. The color of the solutions became deep red as the indanediones were added, but this color disappeared as the reactions proceeded. The reaction mixtures were usually pink or colorless before they were worked up.

The Grignard complexes were decomposed by cold dilute sulfuric acid and the benzene (or toluene) layers were washed with dilute sodium carbonate solution and with water. The solvent was then removed by distillation and the residues were subjected to steam distillation for several hours. The taffy-like residues after steam distillation were separated by decantation and crystallized from ethanol or glacial acetic acid.

An alternate method of purification was distillation of the indones under reduced pressure rather than by steam distillation of the impurities. The products were then obtained as clear colored resins and could be crystallized.

Considerable variation in the ease of purification was encountered in the products. 3-Cyclohexyl-2-phenylindone, in particular, was obtained pure only after eight crystallizations from ethanol and methanol.

The phenylhydrazone or oxime of each indone was prepared and recrystallized from ethanol. The melting points and analyses are included in Table I.

[a] de Fazi [*Gazz. chim. ital.*, 45, I, 554 (1915)] recorded 151–153°. [b] Orekhoff [*Bull. soc. chim.*, [4] 25, 597 (1919)] recorded 175–176°. [c] de Fazi[4] recorded 92–93°. [d] de Fazi[4] recorded 182–183°.

All of the indones prepared give a deep green color with concentrated sulfuric acid, as described by de Fazi.[4]

2-Ethyl-3-phenylindone.—This compound was prepared by the method of de Fazi[4] from 6.8 g. (0.104 mole) of powdered zinc (purified by washing successively with 10% hydrochloric acid, water, alcohol, acetone, ether and anhydrous ether and dried at 100° *in vacuo*), 20 g. (0.110 mole) of benzophenone and 20 g. (15.1 cc.; 0.103 mole) of ethyl α-bromobutyrate in 60 cc. of dry benzene. The resulting white tufts were dissolved in 40 cc. of cold concentrated sulfuric acid and the green solution was allowed to stand for six hours and carefully diluted with ice water. The yield of yellow-orange crystals, recrystallized from ethanol, was 5.1 g. (22%), m. p. 92–93°.

3-Phenyl-2-*n*-propylindone.—α-Bromovaleric acid was prepared by the method of "Organic Syntheses"[11] for the preparation o α-bromocaproic acid from 50 g. (0.49 mole) of valeric acid and 78 g. (0.49 mole) of bromine, using 3 cc. of phosphorus trichloride as catalyst. The crude product was esterified by refluxing with absolute ethanol for five hours. The alcohol was then removed by evaporation and the residual liquid, after drying over "Drierite," was fractionally distilled, yielding 55.0 g. (54%) of ethyl α-bromovalerate, b. p. 92–94° (25 mm.); $n^{20}D$ 1.4496.

3-Phenyl-2-propylindone was prepared by the method of de Fazi[4] from 20 g. (0.110 mole) of benzophenone, 20.8 g. (0.099 mole) of ethyl α-bromovalerate and 9 g. (0.138 mole) of purified zinc powder in 60 cc. of dry benzene. Recrystallization of the intermediate product from high-boiling petroleum ether yielded 6.0 g. of white tufts, m. p. 112–113°.

Anal. C, 75.15, 75.18; H, 7.20, 7.26.

This analysis corresponds to the empirical formula of neither the β-hydroxy ester nor the α,β-unsaturated ester, but the compound nevertheless undergoes cyclization to the desired indone.

This material was cyclized by means of concentrated sulfuric acid in the same manner as the ethyl homolog. The yield of yellow-orange needles of 3-phenyl-2-propylindone was 5.6 g. (23%, based on ethyl α-bromovalerate), m. p. 72.5–73°. The analysis and phenylhydrazone are included in Table I.

Ozonization of 3-Ethyl-2-phenylindone

In Acetic Acid.—Eight-tenths of a gram (0.0034 mole) of 3-ethyl-2-phenylindone dissolved in 65 cc. of glacial acetic acid was treated with 3% ozone for two hours at room temperature. It was then diluted with 65 cc. of water, causing a cloudy precipitate. After the addition of 0.24 g. of powdered zinc the mixture was allowed to stand in the icebox overnight, whereupon it became yellow. It was then diluted with water to 300 cc. and neutralized with sodium hydroxide, after which the neutral solution was extracted with one 50-cc. portion and three 25-cc. portions of benzene. The benzene solution was evaporated under an air jet to a yellow oil which was dissolved in ethanol. Two compounds crystallized from the ethanol solution on standing overnight. One of these formed large yellow tabular crystals (60 mg.) and the other formed an equal amount of large white rhombohedra. The crystals were separated by hand with the aid of a magnifying glass, and each compound was recrystallized from ethanol. The yellow compound melted at 93° and gave the correct combustion analysis for *o*-propionylbenzil (IX).

Anal. Calcd. for $C_{17}H_{14}O_3$: C, 76.67; H, 5.30. Found: C, 76.82; H, 5.30.

The white compound melted at 92–93° and gave the correct combustion analysis for the ozonide (VIII) of 3-ethyl-2-phenylindone.

Anal. Calcd. for $C_{17}H_{14}O_4$: C, 72.33; H, 5.00. Found: C, 72.39; H, 4.81.

A mixture of the yellow and white crystals melted at 67–72°.

This experiment was repeated several times, but the yellow compound was obtained in crystalline form only in the one case described here.

In Chloroform.—Four grams (0.017 mole) of 3-ethyl-2-phenylindone dissolved in 100 cc. of dry chloroform was ozonized at 0° with 3% ozone. At the end of one and one-half hours the color became pale yellow and the reaction was stopped. Water was then added (100 cc.) and the chloroform was removed by boiling. The ozonide remaining in the water was then removed by ether extraction. The ether extract was evaporated and the resulting oil was crystallized from alcohol, yielding 4.0 g. (83%) of the white ozonide (VIII), m. p. 92–93°.

Attempted Hydrogenation of the Ozonide.—A mixture of 1.75 g. (0.0062 mole) of the ozonide with 125 mg. of platinum oxide catalyst in 200 cc. of ethanol was treated with two atmospheres of hydrogen at room temperature for fifteen hours. The ozonide was recovered and identified by mixed melting point.

Reaction of the Ozonide with Potassium Hydroxide.—One gram (0.0035 mole) of the ozonide was refluxed for two hours in 50 cc. of 10% alcoholic potassium hydroxide. The mixture was poured into water, acidified with hydrochloric acid, and extracted with ether. The ether layer was extracted with sodium hydroxide solution and this was then acidified with hydrochloric acid. "Darco" was added and the water was heated and filtered. Benzoic acid crystallized from the filtrate, yielding 0.40 g., m. p. 121–122°.

Reaction of the Ozonide with Hydroxylamine.—One gram (0.0035 mole) of the ozonide was refluxed for two hours with 1 g. (0.014 mole) of hydroxylamine hydrochloride, 10 cc. of pyridine and 10 cc. of absolute ethanol. The solvents were removed by evaporation under an air jet and the residual crystals were triturated with water. The product (XI) was recrystallized from ethanol, forming 0.36 g. (58%) of fine white needles, m. p. 117–119°.

Anal. Calcd. for $C_{10}H_9N_2O$: N, 8.00. Found: N, 7.82.

Reaction of the Ozonide with Phenylhydrazine.—One gram (0.0035 mole) of the ozonide was heated at 235–240° for two hours with 4 cc. (0.041 mole) of phenylhydrazine. The reaction mixture was poured into dilute acetic acid and the resulting oil was separated and twice crystallized from ethanol. The yield of product, m. p. 110–112°, was 0.03 g. (2.5%).

Anal. Calcd. for $C_{16}H_{14}N_2O$: C, 76.80; H, 5.60; N, 11.20. Found: C, 76.86; H, 5.74; N, 11.36.

***o*-Propionylbenzoic Acid (X).**—The method was that of Gottlieb,[8] in which 66 g. (0.625 mole) of freshly fused sodium propionate, 130 g. (1.0 mole) of propionic anhydride and 100 g. (0.675 mole) of phthalic anhydride were refluxed at 170° for two and one-half hours. The product, ethylidene phthalide, was obtained as an oil (97 g.). Of this 46 g. (0.29 mole) was refluxed with 10% aqueous sodium hydroxide. The yield of *o*-propionylbenzoic acid was 23.4 g. (44%), m. p. 96–97°.

4-Ethyl-1-keto-2,3,1-benzoxazine (XI).[6]—The method of Daube[7] was used, starting with 3 g. (0.017 mole) of *o*-propionylbenzoic acid, 3 g. (0.043 mole) of hydroxylamine hydrochloride and 10 cc. of 10% potassium hydroxide solution. The yield of product, m. p. 115–117°, was 1.9 g. (64%).

The melting point was not lowered when this compound was mixed with the reaction product of the ozonide with hydroxylamine.

1-Ethyl-3-phenylphthalazone (XII).[8]—One gram (0.0056 mole) of *o*-propionylbenzoic acid was refluxed with 4 cc. (4.4 g.; 0.041 mole) of phenylhydrazine at 235–240° for two hours. The reaction mixture was poured into dilute acetic acid, whereupon crystals formed. These were recrystallized from ethanol, forming 0.35 g. (40%) of long white needles, m. p. 111–112°.

The same product was formed when *o*-propionylbenzoic acid was treated with phenylhydrazine according to the directions of Shriner and Fuson[12] for preparing phenylhydrazones.

The melting point was not lowered when this compound was mixed with the reaction product of the ozonide with phenylhydrazine.

Summary

1. Seven new 2,3-disubstituted indones are described.

2. The dehydration products after the addition of the Grignard reagents of primary and secondary alkyl halides to 2-substituted indanediones have been shown to be indones rather than alkylidene indanones.

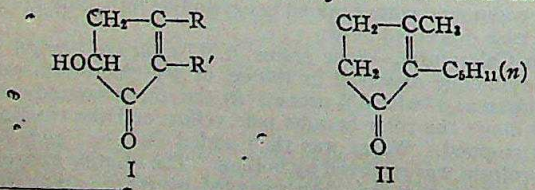
The Preparation of Cyclopentenones from Lactones[1]

BY ROBERT L. FRANK, PETER G. ARVAN, JOHN W. RICHTER AND CLINTON R. VANNEMAN

A method for preparing substituted cyclopentenones has been reported by Plattner and St. Pfau[2] which consists in the removal of the elements of water from γ,δ-unsaturated acids or the corresponding lactones. This reaction has also been reported in the patent literature[3] and has been studied recently by Bryusova and Osipova.[4] It was thought that if the yields for this transformation on a laboratory scale could be improved, it might afford a means of preparing hydroxycyclopentenones similar to pyrethrolone (I, R = CH_3; R′ = C_5H_7), the alcohol portion of the pyrethrins, by the sequence of reactions shown on the following page.



Such compounds could be used in studies relating chemical structure to pyrethrin-like insecticidal activity.

In order to investigate the reaction, γ-methyl-γ-decanolactone (III) was prepared in 28–31% yields by the addition of *n*-hexylmagnesium chloride or bromide to ethyl levulinate. The lactone was formed directly in this reaction due to the splitting out of ethoxymagnesium halide from the Grignard complex.[5] An attempt to prepare the lactone by the use of *n*-hexylzinc chloride was unsuccessful.

The use of phosphorus pentoxide as the dehydrating agent caused the transformation of γ-methyl-γ-decanolactone (III) to dihydrojasmone

(II)[6] to take place smoothly in yields of 50%. The product was identified by boiling point, density, refractive index, formation of its semicarbazone and its ultraviolet absorption spectrum. The spectrum, measured in 95% ethanol at a concentration of 2.5×10^{-5} moles per liter, showed a maximum at 235 mμ (log $\epsilon = 4.33$) (Gillam and West[7] reported 237 mμ). While Plattner and St. Pfau mentioned the formation of dihydrojasmone (II) from γ-methyldecylenic acid, they did not give details of the transformation.

In order to apply this reaction to the preparation of the methoxycyclopentenone (VII) it was first necessary to prepare α-methoxy-γ-methyl-γ-decanolactone (VI). This was successfully accomplished by bromination of γ-methyl-γ-decanolactone (III) and subsequent treatment of the bromolactone (V) with sodium methoxide.

When the bromination product of γ-methyl-γ-decanolactone (III) was distilled, copious amounts of hydrogen bromide were evolved, with much foaming, even if the reaction mixture was first washed with sodium bicarbonate solution. It seems likely that this was due to the formation of α,γ-dibromo-γ-methylcapric acid (IV), which was then dehydrobrominated and cyclized to the desired product (V) during the distillation. This type of reaction is known to occur when γ-valerolactone is treated with hydrogen bromide.[8] The bromolactone (V), once obtained, showed no tendency to undergo dehydrobromination in subsequent distillations.

The reaction of the methoxylactone (VI) with phosphorus pentoxide did not yield the desired methoxycyclopentenone (VII).

(6) Treff and Werner, *Ber.*, **66**, 1521 (1933).
(7) Gillam and West, *J. Chem. Soc.*, 671 (1942).
(8) Emmert, *Ber.*, **40**, 912 (1907); Fittig and Fränkel, *Ann.*, **255**, 31 (1889).

Twenty-three grams (0.112 mole) of the methoxylactone (VI) was poured onto 28.4 g. (0.20 mole) of phosphorus pentoxide in a 250-cc. Claisen flask connected to a receiver cooled by dry-ice. Heat was at once evolved and the contents turned black. The product was then distilled under reduced pressure, yielding 10.2 g. of a dark viscous liquid. This final product from three runs, totaling 19.0 g., was combined and redistilled in a 50-inch Podbielniak column.[9] Eleven fractions were collected varying in weight from 0.8 g. to 2.1 g.

Fraction 2, b. p. 74–82° (3–5 mm.), analyzing C, 87.72; H, 10.51; n^{20}D 1.5190, was evidently an impure hydrocarbon and was found to decolorize both bromine and potassium permanganate.

Fraction 8, b. p. 112–115° (3–5 mm.), which showed the lowest refractive index of all the products, namely, n^{20}D 1.4720, gave saponification equivalents 178 and 180 (seven hours of refluxing with 0.68 *N* sodium hydroxide was necessary).

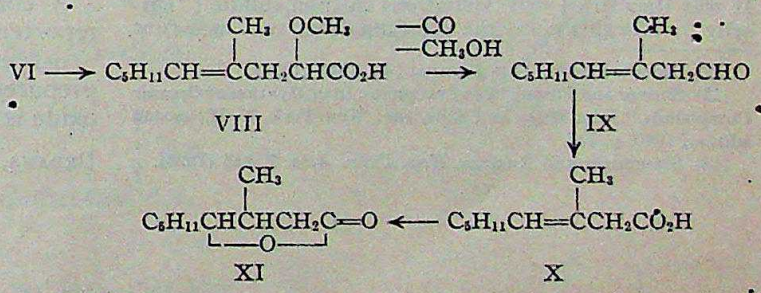
Anal.[10] Calcd. for $C_{10}H_{18}O_2$: C, 70.55; H, 10.66. Found: C, 71.04, 71.05; H, 11.18, 10.02.

It is suggested that Fraction 8 may be β-methyl-γ-pelargonolactone (XI), which could conceivably result from the following transformations (oxidation of the aldehyde (IX) could have taken place during the distillation).

The loss of two carbon atoms to form a lactone in this reaction is evidence that the bromine atom and methoxyl group in the bromolactone (V) and the methoxylactone (VI), respectively, are indeed in the expected *alpha* position.

Experimental Preparations

Ethyl Levulinate.—Five hundred eighty-one grams (5.0 moles) of levulinic acid, 583 cc. (460.7 g., 10.0 moles) of 95% ethanol, 500 cc. of benzene and 5 cc. of concentrated sulfuric acid were refluxed for fifteen hours in a 3-liter, round-bottomed flask equipped with a continuous water



extractor and a reflux condenser. The reaction mixture was then fractionally distilled to yield 583 g. (81%) of product, b. p. 93–94° (18 mm.); n^{20}D 1.4212.

γ-Methyl-γ-decanolactone (III).—A solution of *n*-hexylmagnesium chloride was prepared in the usual manner from 48.6 g. (2.0 moles) of magnesium turnings, 278 cc. (241.2 g.; 2.0 moles) of *n*-hexyl chloride (Sharples) and 500 cc. of anhydrous ether. It was then transferred to a 1-liter dropping funnel and added dropwise to a solution of 288.0 g. (2.0 moles) of ethyl levulinate in 700 cc. of anhydrous benzene and 200 cc. of anhydrous ether contained in a 3-liter, three-necked, round-bottomed flask fitted with the aforementioned dropping funnel, a stirrer and a reflux

(9) Podbielniak, *Ind. Eng. Chem., Anal. Ed.*, **3**, 177 (1931).
(10) The microanalyses reported in this paper were carried out by Miss Theta Spoor, Miss Margaret McCarthy and Miss Dorothy Schneider.

Digitized by Arya Samaj Foundation Chennai and eGangotri

condenser. During the addition of the Grignard reagent a voluminous white precipitate formed in the yellow solution. Stirring and reflux were continued overnight, after which the mixture was cooled in an ice-bath and iced dilute sulfuric acid was added. The ether-benzene layer was then washed with water, dried over anhydrous calcium sulfate ("Drierite") and fractionally distilled in a carborundum-packed column. The first fraction after removal of the solvent consisted of 25.1 g. of ethyl levulinate, b. p. 63–70° (5 mm.); $n^{20}D$ 1.4234. The desired product boiled at 120–125° (4–5 mm.) and the yield was 103.2 g. (28%, based on *n*-hexylchloride), $n^{20}D$ 1.4487; d^{20}_4 0.950; [M]D calcd.,[11] 52.5; found, 52.0. It had a peach-like odor.

Anal. Calcd. for $C_{11}H_{20}O_2$: C, 71.69; H, 10.94. Found: C, 71.59; H, 11.27.

A quantity of residue somewhat greater than the amount of product was left after the fractional distillation.

When *n*-hexyl bromide was used in the same molar amounts instead of the chloride and the reaction was carried out as described above, repeated runs gave yields of 113 g. (31%) of γ-methyl-γ-decanolactone.

Dihydrojasmone (II).—Into a glass-jointed, round-bottomed flask containing 28 g. (0.20 mole) of phosphorus pentoxide was poured 50 g. (0.27 mole) of γ-methyl-γ-decanolactone (III). The contents heated at once and turned black. The flask was quickly attached to a modified Widmer column and evacuated, whereupon 21.0 g. (50%) of product distilled in high purity, b. p. 91° (2 mm.); $n^{20}D$ 1.4785; d^{20}_{20} 0.920.

The semicarbazone, prepared according to the directions of Shriner and Fuson,[12] melted at 173–174° (Staudinger and Ruzicka[13] reported 175–176°).

α-Bromo-γ-methyl-γ-decanolactone (V).—To 60 g. (0.33 mole) of the lactone (III) and 75 cc. of dry carbon tetrachloride in a 500-cc., three-necked, round-bottomed flask equipped with a mechanical stirrer, a 125-cc. dropping funnel and a reflux condenser to which was attached a gas trap was added 55 g. (0.34 mole) of bromine, dried with concentrated sulfuric acid. The mixture was stirred for five hours at room temperature after which it was heated at 70–75° for two hours. A mercury-vapor lamp was placed so that the maximum amount of light fell on the reaction vessel (ordinary white light gave much lower yields). The flask was cooled to room temperature and the contents washed successively with dilute aqueous sodium bisulfite, 5% aqueous sodium bicarbonate and water. It was then dried with anhydrous calcium sulfate ("Drierite"). At this point the solutions from two such runs were combined. The greater portion of the carbon tetrachloride was then distilled on a steam-bath and the residue heated at 150° under reduced pressure, using a water pump, until the pressure fell to 20 mm. The residue was then fractionally distilled in a carborundum-packed column and yielded 26.0 g. of starting material boiling at 128–134° (4–5 mm.), 27.0 g. of a mixture of starting material and product boiling at 134° (4–5 mm.)–160° (7 mm.), and 36.0 g. (27%, taking into account the recovered starting material) of nearly pure α-bromo-γ-methyl-γ-decanolactone, b. p. 160–165° (7 mm.). Redistillation gave a product with the following constants: b. p. 121–122° (1 mm.), 135–136° (3 mm.), 151–154° (5 mm.); $n^{20}D$ 1.4890; d^{20}_4 1.243; [M]D calcd.,[11] 60.4; found, 60.9.

Anal. Calcd. for $C_{11}H_{19}O_2Br$: C, 50.20; H, 7.28; Br, 30.37. Found: C, 50.98; H, 7.12; Br, 30.11.

Judging from the analysis, the product still contained a trace of γ-methyl-γ-decanolactone, which was extremely difficult to remove completely.

α-Methoxy-γ-methyl-γ-decanolactone (VI).—To a solution of 9.2 g. (0.40 mole) of sodium in 250 cc. of absolute methanol was added 104 g. (0.396 mole) of α-bromo-γ-methyl-γ-decanolactone (V). The solution was allowed to stand at room temperature for ten hours, after which the precipitated sodium bromide was removed by filtration and the excess methanol by distillation *in vacuo*. The residue was poured into 1 liter of water and this was then extracted with two 500-cc. portions of ether. The ether extract was dried over anhydrous calcium sulfate and fractionally distilled in a modified Widmer column to give 64 g. of material boiling at 105–115° (3 mm.). This was redistilled to give 55 g. (65%) of product, b. p. 107–108° (3 mm.); $n^{20}D$ 1.4408; d^{20}_{20} 0.964; [M]D calcd.,[11] 58.6; found, 58.7; saponification equivalent, calcd., 214; found, 216.

Anal. Calcd. for $C_{12}H_{22}O_3$: C, 67.25; H, 10.35. Found: C, 67.94; H, 10.01.

In some runs the yields were lower and small amounts of a higher-boiling isomer were obtained, b. p. 151–170° (3–4 mm.); $n^{20}D$ 1.4710; D^{20}_4 1.020; [M]D calcd.,[11] 58.6; found, 58.8; saponification equivalent, calcd., 214; found, 203.

Anal. Calcd. for $C_{12}H_{22}O_3$: C, 67.25; H, 10.35. Found: C, 66.93; H, 9.85.

Summary

A convenient synthesis of dihydrojasmone is reported.

α-Methoxy-γ-methyl-γ-decanolactone has been prepared and its reaction with phosphorus pentoxide is discussed.

[COMMUNICATION NO. 938 FROM THE KODAK RESEARCH LABORATORIES]

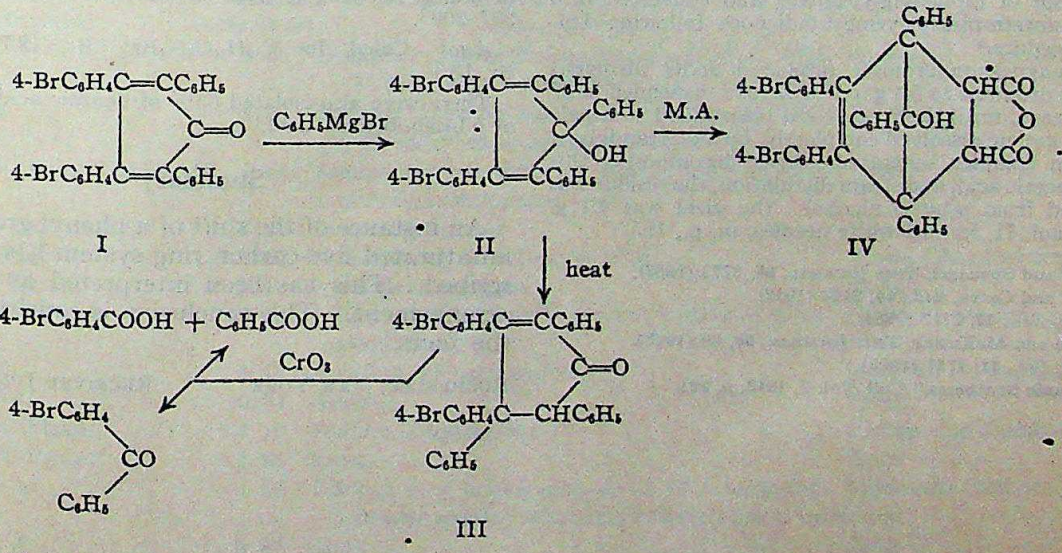
On the 1,3-Rearrangement of a Phenyl Group

BY C. F. H. ALLEN AND J. VANALLAN

The action of phenylmagnesium bromide upon tetraphenylcyclopentadienone gives either a carbinol, formed by 1,2-addition to the carbonyl group, or a ketone, resulting from 1,4-addition to the α,β-unsaturated carbonyl system.[1] Furthermore, the carbinol is converted into the ketone by being heated. This isomerization was accounted for by assuming that there had been a 1,3-rearrangement of the phenyl radical from the carbon atom of the original carbonyl group to one in the β-position of the unsaturated system. The evidence for such a change was the production of benzophenone upon oxidation of the isomerized substance.

All attempts to synthesize this rearranged product were unsuccessful. The use of *p*-methoxyphenylmagnesium bromide, with a view to obtaining *p*-methoxybenzophenone by degradation of the substance resulting from a rearrangement was likewise unsuccessful.[1]

What appears to amount to a positive proof has finally been secured, making use of the known 4,4′-dibromotetraphenylcyclopentadienone, I.[2] The phenyl carbinol, II, which was formed by the action of phenylmagnesium bromide in benzene, was rearranged by heating at 260–265° to the cyclopentenone, III.



The evidence that the carbinol II and ketone III have the structure indicated is important, since rearrangements are assumed to have occurred. The bromine-free pentaphenylcyclopentadienol, to which type II belongs, was first described and its structure proved by Ziegler.[3] In our previous paper,[1] were added the significant data (1) that it adds maleic anhydride, and (2) that it shows one active hydrogen in the Grignard machine. These two observations, plus the formation of a characteristic deep red color, on treatment with concentrated sulfuric acid, afford convenient experimental means for confirming this type of structure. When considering the interaction of a Grignard reagent and tetraphenylcyclopentadienones, it is only necessary to distinguish between 1,2 and 1,4 or 1,6-additions. Since the dibromo carbinol II was obtained by this standard reaction, shows one active hydrogen and no addition, adds maleic anhydride IV, and gives a deep red halochromism with sulfuric acid, there is no reasonable doubt as to its structure. The fact that it is rearranged by heating to form a ketone is also analogous to the behavior of Ziegler's carbinol.[1]

By similar analogies to the corresponding halogen-free ketone,[1] the structure III is assigned to the ketone resulting from the rearrangement. It was formed from the same type of compound by the same sort of reaction. A highly-hindered carbonyl group, such as the one present in the ketone III, is best detected by the Grignard machine, in which it shows one addition. The new ketone III has no active hydrogen, but shows one addition; it also exhibits a yellow halochromism with concentrated sulfuric acid. Upon oxidation by chromium trioxide in acetic acid, it gives 4-bromobenzophenone, 4-bromobenzoic and benzoic acids; this means that in the ketone a phenyl and a 4-bromophenyl are attached to the same carbon atom.

Since the carbinol has been isomerized to a ketone, the phenyl group originally attached to this particular carbon atom must have moved else-

where. But a phenyl group has turned up on the carbon atom originally containing only a 4-bromophenyl group, three carbons away. Hence, it is reasonable to assume that there has been a 1,3-rearrangement of a phenyl.

It may be suggested that the phenyl has undergone two 1,2-shifts, but this means twice as many assumptions. There does not appear to be any certain way of determining whether any 1,3-shift is actually such, or proceeds by two 1,2-rearrangements, but since 1,3-shifts have been generally accepted in other instances, there is no reason why a phenyl group should be an exception.

This is the first instance which appears to be a direct proof for a 1,3-rearrangement of a phenyl group. We have previously pointed out several reactions that appeared to admit of no other interpretation. In addition to the cyclopentadienol mentioned above,[1] there are the bimolecular products formed by the action of acidic dehydrating agents upon anhydracetonebenzil and many of its substitution products,[4,5] and the formation of 2-phenylquinoline from cinnamalaniline.[6]

The *para*-alkylation of benzoyldurene[7] which the authors suggested might be a case of the rarely-observed 1,6-addition of a Grignard reagent to a conjugated system, could equally well be an analogous case—an instance of the common 1,4-addition to the α,β-unsaturated system, followed by a 1,3-shift of the alkyl group.

Experimental

The necessary 4,4′-dibromobenzil was secured by the bromination[8] of diphenylglyoxalone[9] and converted into the dibromotetraphenylcyclopentadienone following Dilthey's procedure.[2]

Phenylmagnesium bromide (prepared under nitrogen) was added dropwise to 5.4 g. of the ketone suspended in 27 cc. of benzene, until the intense red color faded to a pale pink; the ketone dissolved completely, but, on standing, a magnesium complex separated. After decomposing this with iced acetic acid, and steam distillation, the residue was crystallized from *n*-butyl alcohol: the yield was 4.1 g. The carbinol, II, formed white needles, m. p., 195°.

Anal. Calcd. for $C_{35}H_{24}OBr_2$: Br, 25.8. Found: Br, 25.8.

In the Grignard machine it showed one active hydrogen, but no addition. It gives a deep red color with concentrated sulfuric acid.

The maleic anhydride addition product IV was readily formed on heating a mixture of 1 g. of each component at 200° for five minutes, cooling and triturating with methanol. After recrystallization from xylene it melted at 222°.

Anal. Calcd. for $C_{39}H_{26}O_4Br_2$: Br, 22.3. Found: Br, 21.9.

The rearrangement product, the ketone III, was obtained by heating 11 g. of the carbinol at 260–265° (14 mm.) for two hours, cooling, taking up in ether, adding alcohol, and allowing it to stand overnight. A little floating solid matter was removed, and ether added. A new crystalline material soon separated; after filtration, the filtrate was diluted by ligroin—it soon became full of the solid ketone. The analytical sample was recrystallized from *n*-propyl alcohol and, finally, from acetic acid. The yield was 6.1 g., m. p. 178°; it gives a yellow color with concentrated sulfuric acid. (The change in color from red to yellow affords a convenient qualitative method for following the rearrangement.)

Anal. Calcd. for $C_{25}H_{24}OBr_2$: C, 67.8; H, 3.9; Br, 25.8. Found: C, 67.7; H, 3.9; Br, 25.9.

In the Grignard machine it showed no active hydrogen and one addition.

The oxidation was carried out by adding chromium trioxide in small portions to an acetic acid solution of the ketone; the reaction was vigorous. Since some unoxidized material was left after thirty minutes, the whole was refluxed for eight hours. It was then diluted and the ketone steam-distilled. After appropriate manipulation a 53.5% yield of *p*-bromobenzophenone was obtained. It had a melting point of 77–78° after recrystallization from methanol; the mixed melting point with an authentic specimen was 78–79°. The 2,4-dinitrophenylhydrazone separated in orange-red leaflets from dioxane–ethyl alcohol, m. p. 207–209°.

Anal. Calcd. for $C_{19}H_{13}O_4N_4Br$: Br, 12.7. Found: Br, 13.1.

There were also isolated 63% of benzoic acid and 32% of *p*-bromobenzoic acid.

Summary

An instance of the shift of a phenyl group in an unsaturated five-carbon ring system has been described. This has been interpreted as a 1,3-rearrangement. This conclusion is consistent with the facts.

Solubilization and the Colloidal Micelles in Soap Solution

BY J. W. MCBAIN AND K. E. JOHNSON

Solubilization is the power which even dilute aqueous solutions of soaps, detergents and other colloidal electrolytes possess of bringing into thermodynamically stable[1] colloidal solution hydrocarbons, dyes and other substances insoluble in water. The commercial importance of this phenomenon has long been known, but it is only recently that its mechanism has been established as consisting of sorption upon and incorporation within colloidal micelles.[2,3,4]

Conversely, a study of solubilization may now be utilized to throw light upon the nature of the micelles and solutions of colloidal electrolytes. The results here to be presented show that solubilization cannot be accounted for by solution in the hydrocarbon portion of the micelles, and they therefore show that assumed structures such as spherical micelles, in which this is the only mechanism so far proposed, are wholly inadequate. On the other hand, they lend further support to the conception that the solubilized material is placed in layers within the lamellar micelles.

Materials and Method

The dye and methods used were the same as those described in references 3 and 4, namely, 1-*o*-tolylazo-2-naphthol; F. D. and C. orange no. 2; Orange OT, in the form of well-developed crystals. The potassium soaps were prepared by neutralization of Kahlbaum purest fatty acids with Kahlbaum, washed, carbonate-free potassium hydroxide. These were made up in boiled-out distilled water and contained 0.4 equivalent per cent. excess of potassium hydroxide to suppress hydrolysis. Dye was added in only slight excess and the mixture was gently agitated in closed containers in a thermostat until equilibrium was reached. This required at least sixteen to twenty-four hours for more dilute solutions and from seven to ten days for more concentrated solutions of soap. When approaching equilibrium from supersaturation, much longer times were required, presumably on account of the effect of protective action upon the dye separating out. The liquid was then kept motionless in a thermostat for twenty-four hours, or until examination in a strong light showed that all dye particles had settled. Analysis was made by diluting a portion of the liquid with a mixture of acetone and water in such proportion as to keep the dye in solution, and measuring in a Klett–Summerson photoelectric colorimeter with a B-420 blue filter, calibrated against known benzene solutions of dye. The latter gave similar results to dye solubilized in aqueous Aerosol OT.

Some Results with Commercial Detergents

Data for many detergents have been published in reference 4. We may supplement these by the results in Table I.

TABLE I

THE SOLUBILIZATION IN MILLIGRAMS OF DYE PER HUNDRED CC. OF SOLUTION, MADE BY TAKING ONE GRAM OF COMMERCIAL DETERGENT IN ONE HUNDRED CC. OF WATER

Detergent	Mg. of dye	Type of detergent	Manufacturer
Aerosol 18	2.60	Disodium monosulfostearylsuccinamide, 35%, + 65% water and slight turbid impurities	American Cyanamide and Chemical Co.
Aerosol OS	3.65	Sodium isopropyl naphthalene sulfonate, 95% active alkyl naphthalene sulfonate—fairly pure	Same
Ammonium salt of Aerosol OT	1.44	Ammonium salt of dioctyl (2 ethyl hexanol) ester of sodium sulfosuccinic acid	Same
Zinc salt of Aerosol OT	6.56	Zinc salt of above	Same
Alronol (100%)	3.00	Non-electrolytic detergent with	Alrose Chemical Co.
Alronol (90%)	3.4	trivalent nitrogen	Same
Nacconol NRSF	3.23	Sodium alkyl aryl sulfonate, not a sulfated fatty alcohol	National Aniline and Chemical Co.
Nopco 1067	1.17	An alkyl aromatic sulfonate	National Oil Products Co.
Nopco 1086-C	0.44	Same	Same
Orvus W. A. Flakes	3.70	Sodium lauryl sulfate	Procter and Gamble
Orvus W. A. Paste	1.85	Same	Same
Santomerse 1	1.25	Belongs to a homologous series of substituted aromatic sodium sulfonates (alkylated aryl sulfonate)	Monsanto Chemical Co.

centrated solutions of potassium hexoate, and in progressively less concentrated solutions of the higher soaps. Since solubilization of dye is a manifestation of the presence of micelles, it is of great interest to compare the solubilization of dye by various concentrations of typical homologs both to show in how far these are colloidal electrolytes, and also to throw light upon the nature of the colloidal micelles present in different concentrations of different homologs.

Measurements are therefore presented in Tables II, III, IV and V for the solubilization of Orange OT in potassium octoate, decylate, dodecylate and tetradecylate containing the added alkali sufficient to suppress hydrolysis. The results are also shown graphically in Fig. 1. To ensure attainment of the reversible equilibrium from both sides, the measurements with laurate and with myristate are approached from the side of undersaturation and also, by first heating the solution to cause more dye to dissolve, from the side of supersaturation. It is seen from the graphs how closely the corresponding values came together in the time allotted. We may therefore be sure that the true solubilization was actually measured.

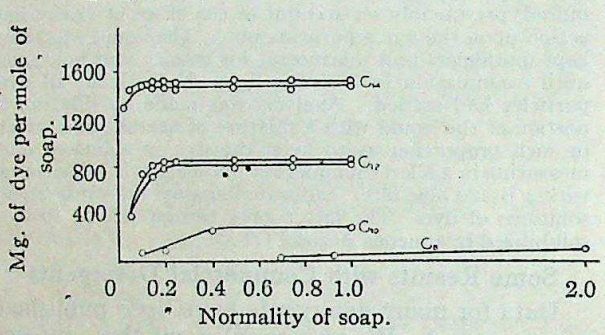

Fig. 1.—The solubility of orange OT in various molalities of aqueous solutions of a homologous series of pure potassium soaps at 25°.

.75	108.4	1445	114.1	1521
1.00	147.4	1474	152.3	1523

It will be seen from the tables and Fig. 1 that the amount of dye solubilized by one mole of each of these four successive homologs of even carbon number stand in the proportions of 1 to 2.34 to 6.77 to 12.04, when the concentration is sufficiently high to ensure full colloidality of the soap. In other words, the solubilizing power per soap molecule in a micelle increases enormously with relatively small increase in the number of carbon atoms in the molecule.

Nevertheless, the soap solutions are strictly comparable because, as Brady has shown,[5] the osmotic coefficients of all straight chain colloidal electrolytes actually coincide when they are plotted on a diagram in which the unit of concentration is in each case taken as the molality at which the osmotic coefficient, g, equals 0.5. The significance of these data will be discussed in a later section.

Next of interest was to ascertain the solubilizing power of equimolar solutions of laurate and myristate. The data given in Table VI and Fig. 2 show that the solubilizing power of the mixture lies not quite midway between that for the two pure soaps separately, namely, 9.09 times the solubilizing power of the caprylate.

In addition to these data for 25°, measurements at 50°, given in Table VII and plotted in Fig. 2, show the very high temperature coefficient of solubilization.

1.00	132.7	175.1	232.9	1327	1751	2329

The solubility has therefore increased between 25 and 50° to an extent corresponding to a negative heat of solubilization amounting to −3830, 3460 and 3830 calories per mole of soap for laurate, for mixture of laurate with myristate, and for myristate, respectively. These are similar to the values calculated from previous work.[3] They have the same order of magnitude as heats of solution or as heats of sorption of the van der Waals type.

The increase in temperature also has a marked effect on the concentration of soap at which the concentration necessary for full colloidality is higher at 50 than at 25°.

Solubilization and the Nature of Micelles.—Solubilization has been shown to be a property of the micelles in solutions of colloidal electrolytes. Conversely, solubilization can throw light upon the nature of these micelles.

The first micelles proposed were the spherical micelles of Reychler, McBain, and later Adam and Hartley. The radius of the spherical micelle is limited by the length of the hydrocarbon chain which is expelled from contact with the water as far as possible. Nevertheless, as Ward[6] points out, seven-tenths of the surface of a spherical micelle containing 50 soap ions of 12 carbon atoms is still hydrocarbon, even if it is assumed possible so to pack the short, thick rods, each length 15 Å., cross section 20–25 sq. Å., without interspaces.

It is an obvious suggestion that the solubilized dye merely dissolves in the hydrocarbon interior of the micelle. This accords well with the positive temperature coefficient of solubilization, and it has been adopted by Hartley in spite of some large numerical discrepancies between the amounts of dyes solubilized and their solubilities in a similar weight of hydrocarbon.

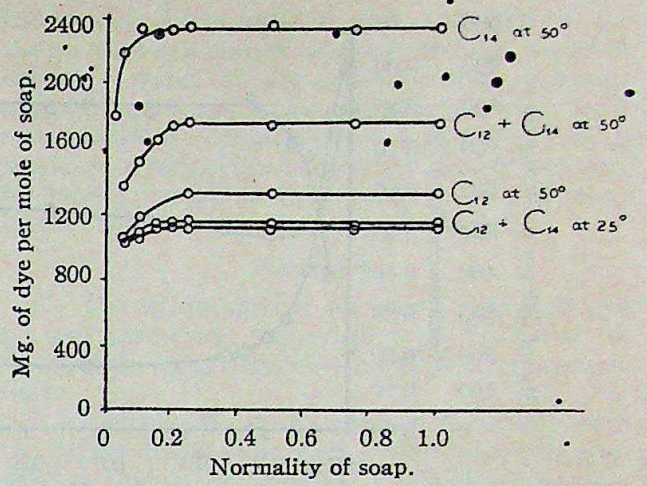

Fig. 2.—The solubility of orange OT in pure potassium soap solutions at 50° and in an equimolar mixture of potassium laurate and myristate at 25°.

The main result of the present communication is to show that the solubilization of the same dye by a homologous series of soaps changes with molecular weight in a manner which does not support the hypothesis that solubilization is solution in the hydrocarbon part of the soap. The results are expressed in milligrams of dye solubilized per mole of soap, because this allows of direct comparison with the number of CH_2 groups per molecule of soap.

The results show that for soaps containing 8, 10, 12 and 14 carbon atoms, respectively, the solubilizations are in the proportions 1:2.34:6.77:12.04.

Thus, for increases of 25, 20 and 16.7% in length of carbon chain, the increases in dye solubilized are 143.5, 190 and 79.5%, respectively. For an increase of 50% in carbon atoms from caprylate to laurate, the solubilization has increased 6.77-fold. The increments of these numbers are, in the same units, 1.34, 4.43 and 5.27 for each added pair of CH_2 groups, instead of being constant. It should be recalled that these numbers were strictly comparable because they refer to concentrations sufficiently high to ensure full colloidality in each case; likewise the numbers were constant for each soap as soon as full colloidality was reached. They are solubilization per molecule in the fully formed micelles.

The only form of micelle for which there is direct evidence is the lamellar micelle, first proposed by McBain. Several investigators[7] have

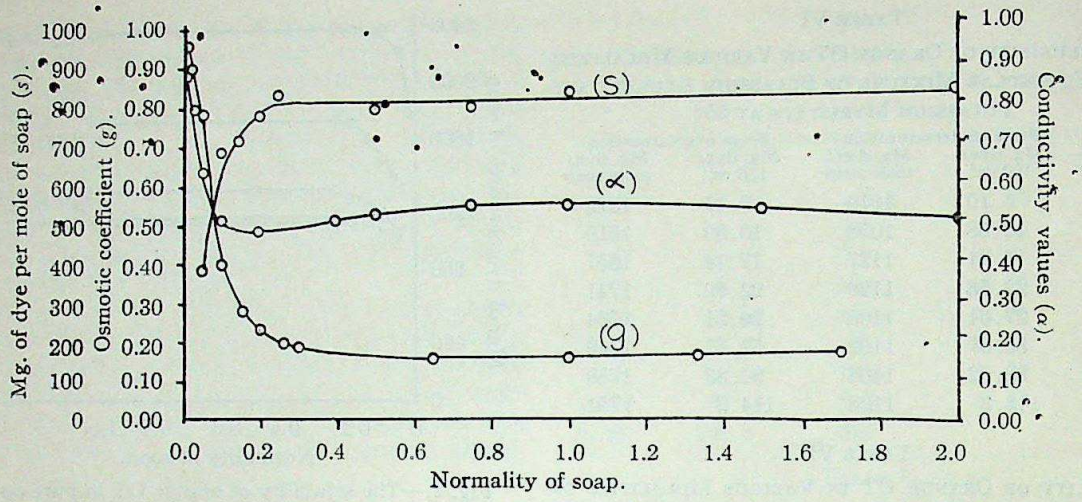

Fig. 3.—Comparison of the solubilization curve (s), the osmotic coefficient curve (g), and the conductivity curve (α) for potassium laurate.

found that the micelles in soaps and synthetic detergent solutions give an X-ray diffraction pattern corresponding to lamellar micelles in which molecules are packed side by side and layer to layer. According to Hess and his collaborators, when benzene is solubilized by the soap solution, spaces between the lamellar planes increase correspondingly. This mechanism, perhaps supplemented by sorption on the exterior of the micelles, would best accord with the present data.

It is of interest to compare the curve of solubilization by the typical soap, potassium laurate, with the corresponding curves for its osmotic coefficient, g, and conductivity ratio, α. This is done in Fig. 3. It is seen that solubilization attains its constant value at 0.25 m, while the osmotic coefficient is still definitely falling; whereas the conductivity has already reached its minimum value at 0.2 m and is on its way to the much higher value at 0.75 m. The changes in the micelles indicated by conductivity and osmotic activity are not reflected by any further change in solubilization. Most authors now agree that there are many sizes of micelles in different concentrations of the same colloidal electrolyte, ranging from "small micelles" or "ionic micelles" that raise the conductivity to larger lamellar micelles that greatly lower it.

A comparison of the relevant data for lauryl sulfonic acid is given in reference 2.

Effect of Added Salts on Solubilization.—McBain and Merrill[3,4] advanced the plausible hypothesis that addition of a salt to a colloidal electrolyte having a common ion would favor formation of micelles in the dilute region where they were not already formed and tend to salt out dye in higher concentrations where the micelles were already completely formed. This they found to be true for solutions of sodium desoxycholate.

Table VIII gives the data for the solubilization of two potassium soaps as affected by the presence of molal potassium chloride in each case, and the results are plotted in Fig. 4. Solutions of 1 m myristate and 1 m and 0.5 m laurate could not be measured, since the dye particles would not settle in such viscous or jelly-like systems.

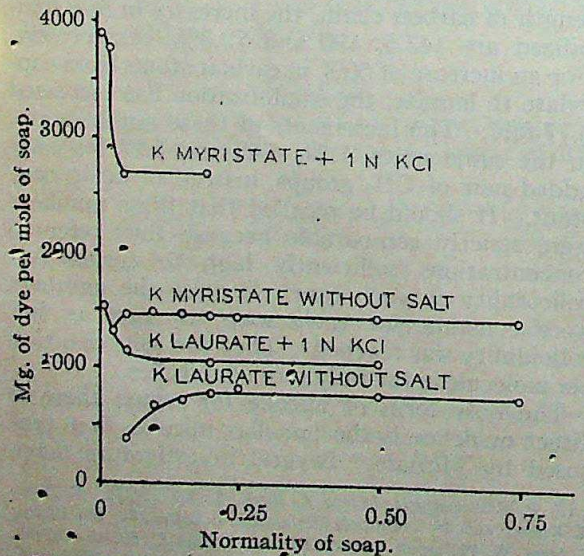

Fig. 4.—The solubility of orange OT at 25° in solutions of potassium laurate and potassium myristate with and without the presence of 1 m potassium chloride.

TABLE VIII

SOLUBILITY OF ORANGE OT IN VARIOUS MOLALITIES OF POTASSIUM LAURATE AND POTASSIUM MYRISTATE AT 25° IN THE PRESENCE OF 1 m POTASSIUM CHLORIDE

solutions, where but little micelle was previously present. Indeed, the micelle so formed appears to have a greatly increased solubilizing power, not only over the ordinary micelle of the same soap, but even over the same micelle in higher concentrations in the presence of the potassium chloride. Furthermore, even in the concentrated solutions, the potassium chloride has increased the solubilization. This is the opposite of the expected salting out effect. Neither can it be reconciled with the hypothesis of solution in the hydrocarbon, which must be unaffected since it is in equilibrium in all cases with solid crystals of dye. We have no adequate explanation either for the improved solubilizing power in concentrated solutions or for its still greater enhancement in dilute solutions. However, a similar effect in dilute solutions was indicated in Hartley's data for cetylpyridinium chloride with sufficient addition of sodium chloride (see reference 2, page 129). Likewise, Merrill found similar effects with pure *n*-(lauryl colamino formyl-methyl)-pyridinium chloride, commercially known as Catol 607, to which potassium chloride was added.

On the other hand, Dr. R. B. Dean in unpublished demonstrations in this Laboratory has shown that potassium chloride reduces the solubilizing power of 0.2 *m* potassium laurate for capryl alcohol. Addition of this chloride to a clear saturated solution of capryl alcohol in 0.2 *m* laurate produces a very evident turbidity, which is cleared by heating or by further addition of potassium laurate solution free from capryl alcohol.

Summary

1. The solubilization of water insoluble dye by four potassium soaps has been measured for equilibrium conditions over a range of concentrations.

2. The solubilization increases so rapidly with the higher soaps as to cast doubt upon the suggestion that it is solution in the hydrocarbon fraction of the molecule, but rather to favor its incorporation between the layers of lamellar micelles.

3. Potassium chloride not only greatly increases the solubilizing power of fully formed micelles, but it produces in dilute solution micelles of still higher solubilizing power.

The Ionization of Strong Electrolytes. II. Ionization, Raman Spectrum and Vibrations of Perchloric Acid

BY O. REDLICH, E. K. HOLT AND J. BIGELEISEN[1]

As discussed in the first paper of this series,[2] the Raman spectrum furnishes a fairly general and unambiguous criterion of the existence of molecules. This criterion, in addition, is cogent if one retains the historical concept of the molecule which characterizes the molecule as a mechanical unit without referring to the nature of the intramolecular forces. The principle of determining the degree of ionization by means of Raman spectra, its history, and some experimental details have also been discussed previously. In the present paper, a refinement of the experimental method and measurements on perchloric acid are reported.

In a check of the Raman frequencies of anhydrous perchloric acid, a previously missing line was discovered by resolution of a doublet. Since this line completes the spectrum of the simplified model, our results for the frequencies of perchloric acid and the perchlorate ion, and an assignment of the frequencies to the vibration forms are included.

The Experimental Method

The spectrograph and the general equipment have been described previously.[2,3] Cells of the smaller type (18 ml.) were used. The front face of the cells was ground and polished. The perchlorate line 931 cm.$^{-1}$, excited by the blue mercury line was used. Because of the instability of the acid, the violet and ultraviolet light was filtered out by a sodium nitrite solution. Exposure times ranged from three minutes with Eastman Kodak Co. plates 103a-O and a slit width of 0.10 mm. to twenty-four minutes with plates II-O and 0.25 mm.

Like the nitrate line, the perchlorate line is fairly sharp and narrow in solutions of sodium perchlorate and in the practically completely ionized acid solutions of moderate concentrations, but considerably broader in concentrated solutions of the acid. Several attempts were made to diminish the error involved in the photographic comparison of the intensity of lines which appreciably differ in width.

For convenience, the usual way of comparing the areas under the microphotometric curves will be called the first method. This method can be considered to be based on two assumptions: (a) that under appropriate experimental conditions, the microphotometric curves of two lines are equal only if the total intensities striking the plate are equal, and (b) that a microphotometric curve is sufficiently characterized by its area.

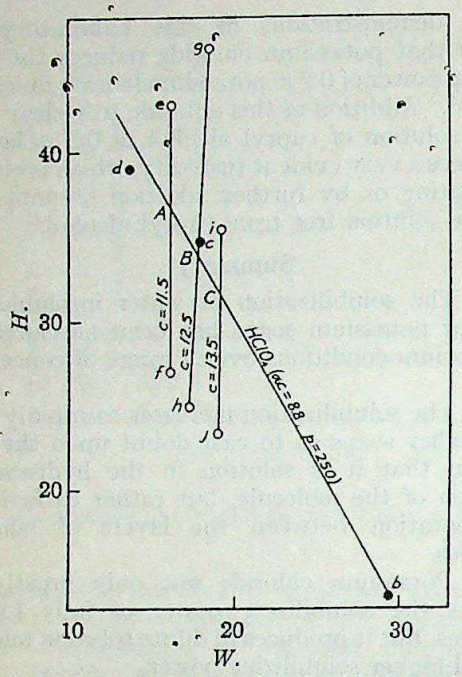

Fig. 1.—Second method: diagram of heights H and widths W of the microphotometric curves.

The first assumption can hardly be dispensed with in any photographic method. The second can be replaced by a less far reaching one: that a microphotometric curve is sufficiently characterized by its height H and width W, measured as usual at the level $H/2$. This assumption is supported by our experience that the area under the curves is practically proportional to the product HW.

The resulting "second method" consists in a comparison of microphotometric curves by interpolation with respect to the two independent variables H and W.

The practical procedure is conveniently described in an example (Fig. 1). The intensity of the light striking the plate is proportional to $I = \alpha cfw$, where αc is the concentration of the perchlorate ion, f the value of the stepfilter before the spectrograph slit, and w the width of this slit. Diffraction at the slit[4] is entirely negligible under the prevailing conditions. The calibration was carried out by means of a perchloric acid solution containing 8.9 moles per liter, corresponding to $\alpha c = 8.8$ according to the smooth curve of Fig. 2 (usually sodium perchlorate solutions were used for calibration). The points b, c and d were taken with different slit widths ($w = 0.250$, 0.323 and 0.595 mm.) but the product $p = fw$ was the same. The points e to j were all taken with $w = 0.250$, but p was 250 for e, g and i, and 194 for f, h, and j.

According to the basic assumptions of the second method, the intensity $I = \alpha cp$ at the crossing point A can be expressed in terms of both the calibrating solution ($\alpha c = 8.8$; $p = 250$) and the "unknown" solution (αc to be determined; $p = p_A$). Thus we have for the "unknown" solution $\alpha c = 8.8 \cdot 250/p_A$ where p_A is to be found by interpolation from the p-values of the points e and f.

The interpolation is to be carried out either linearly with respect to the distances in the diagram or better according to $\log(HW) = k_1 + k_2 \log p$. The values of H and W are read from the diagram and the constants k_1 and k_2 are eliminated by means of the known values of p for the points e and f.

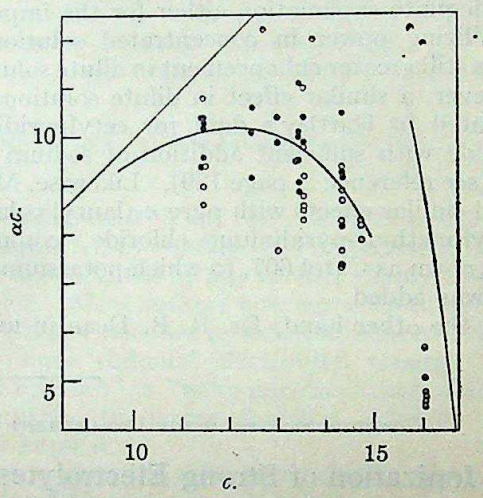

Fig. 2.—Concentration αc of the perchlorate ion in solutions of perchloric acid of the concentration c: ◒, first method, 30°; ○, 53°; ◓, second method, 30°; ●, 53°.

As to be seen from Fig. 2, the results of the second method scatter somewhat less than those of the first. Some additional gain in accuracy would be attained if the lines in a diagram like Fig. 1 were defined by more than two or three points. Practically, however, the number of exposures to be taken in one series and on one plate is limited, even if exposures can be taken as short as with our equipment.

Considerable progress might be achieved by a photoelectric method with the aid of the new photomultiplier tube.[5] The intrinsic difficulties of the photographic method arise from the logarithmic response of the plate. The intensity distribution within the line is necessarily distorted by the logarithmic response of the plate, and again by the influence of the finite width of the microphotometer slit. In addition, the linear response of the microphotometer with respect to the opacity restricts the usable range of the plate to a small interval in which, moreover, the plate is not very efficient. The photoelectric tube with its immediate linear response and large range is free from these disadvantages.

[a] (s) and (b) denote stretching and bending vibrations, respectively.

reliable distillation conditions were established for the preparation of the anhydrous acid.[6] A mixture of 640 ml. chilled sulfuric acid and 160 ml. of chilled perchloric acid (70%) is sealed in a distilling flask and distilled at about 58° in the vacuum of an oil pump. In a period of sixteen hours, approximately 30 ml. of colorless anhydrous acid is collected in a receiver cooled by means of dry-ice. Solutions in the range between 70 and 100% can be prepared only by mixing since the boiling points are so high that the acid decomposes.

Acid of 70% was purified by distillation. Distillates were analyzed by weight titration.

Sodium perchlorate was recrystallized after the solution had been boiled with charcoal. The solutions were analyzed by evaporating in a platinum dish and drying at 150°.

The concentrations were calculated by means of the densities given in the "International Critical Tables," the values of Kohner[7] and two values which we determined with a pycnometer. The density of a solution containing 5.35 moles of sodium perchlorate per kilogram of solution was found to be 1.646 g. per ml. at 25.0°, and 1.618 at 53°.

The concentration range which had to be covered, includes the interval in which solid monohydrate appears at room temperature. Most measurements therefore were carried out at 53 ± 2°. The temperature was maintained by means of an electric hairdryer, the heater being controlled by a resistor.

Results

The results are given in Fig. 2. The straight line in the left part of the diagram indicates the limit of complete ionization. Even the commercial acid (60% or 9 moles per liter) is almost completely ionized.

The slightly curved line in the right part of the diagram indicates the ionization which would be obtained if each water molecule produced a perchlorate ion according to the equation $HClO_4 + H_2O = H_3O^+ + ClO_4^-$. The data of Fig. 2 indicate that a "complete ionization" of this kind might occur in the limit of high acid concentrations. In the case of nitric acid, this possibility was definitely excluded by the experimental data.

Considering the extreme value of the heat of dilution, one has to expect a considerable variation of the ionization with the temperature. Two exposures of moderately concentrated solutions at 30° confirmed this expectation. Similar results on nitric and iodic acids are mentioned in a recent note of Rao.[8]

The concentration range is limited by the decomposition of the acid under mercury light. For the concentration of 16.1 moles per liter, data could be obtained only at the lower temperature.

The calculation of the ionization constant according to the method used in the case of nitric acid has to be postponed, because the activity coefficients are known only in the range of practically complete ionization.

Frequencies and Vibrations

Owing to the rapid decomposition under mercury light, even if filtered, a good spectrum of anhydrous perchloric acid is difficult to secure. After several unsuccessful attempts, we obtained a strong and remarkably clear spectrum in forty minutes on an Eastman plate 103a-O with a slit width of 0.06 mm. One spectrum each of an acid solution (11.6 moles per liter) and of sodium perchlorate (9.06 moles per liter) were measured.

The results, indicated in Table I, agree fairly well with those of previous authors. There is only one significant difference: we were able to resolve a line in the spectrum of the anhydrous acid[9] into a doublet, namely, the sharp line 572 and the weaker and broader line[10] 585 $cm.^{-1}$.

This result affords a basis for revising and completing Fonteyne's interpretation of the perchloric acid spectrum. As pointed out by Fonteyne, the perchlorate ion has the tetrahedral symmetry T_d, and the acid has the trigonal symmetry C_{3v} provided the hydroxyl group is considered as a mechanical unit. This simplification implies that the three hydrogen frequencies are not taken into account.

The symmetry types according to Placzek and the interpretation of the vibrations are given in Table I. A_1 and A denote the totally symmetric types, E double, and F triple frequencies. In the transition from the acid to the ion, one hydroxyl stretching and two oxygen stretching vibrations become identical and coalesce into a triple vibration. The same holds true for bending vibrations. Thus the relations between the vibrations of the acid and the ion are unambiguously determined.

According to Fonteyne, the lines 1032 and 738 of the acid are polarized; they belong, therefore, to type A_1. The third line of this type undoubtedly is the stronger and sharper line of the doublet, namely, 572.

(6) We are indebted to Mr. L. E. Nielsen for extensive preparatory work.

(7) H. Kohner, *Z. physik. Chem.*, B1, 427 (1928).

(8) C. S. Rao, *Current Sci.*, 11, 428 (1942).

(9) (a) R. Fonteyne, *Nature*, 138, 886 (1936); (b) *Natuurwet. Tijdschr.*, 20, 112 (1938); (c) A. Simon and H. Reuther, *Naturwissenschaften*, 25, 477 (1937); (d) A. Simon, H. Reuther and G. Kratzsch, *Z. anorg. allgem. Chem.*, 239, 329 (1938).

(10) Actually the two lines are partially superimposed. Fonteyne (ref. 10b) in his Fig. 1 also indicates an asymmetric structure similar to our observation.

The assignment of line 931 of the ion is based on its intensity and polarization. This frequency results from a stretching of four oxygen bonds which can be interpreted as the result of resonance between one single and three double bonds. The corresponding symmetric oxygen frequency of the acid must be higher, the hydroxyl frequency lower; in addition, the ratio of these two frequencies resulting from double and single bonds, respectively, should be approximately $\sqrt{2}:1$. The frequencies 1032 and 738 satisfy these conditions. The same argument has been used before by Chédin[11] in the case of nitric acid.

The remaining frequency 572 of type A_1 results from a bending vibration of the oxygen atoms.

Oxygen frequencies in the range around 1200 necessarily correspond to stretching vibrations. It happens frequently that antisymmetric or degenerate stretching frequencies are higher than the symmetric ones.

Thus all stretching vibrations have been assigned and none is left for another frequency of the acid near 1200, as assumed by Fonteyne on account of a doublet found in this region in the spectrum of chlorine heptoxide.[12] This doublet, one vibration symmetric, the other antisymmetric with respect to the twofold axis of the simplified chlorine heptoxide molecule, is to be expected in the spectrum of the oxide, but not in that of the acid.

(11) J. Chédin, *J. phys. radium*, **10**, 445 (1939).

(12) R. Fonteyne, *Natuurwet. Tijdschr.*, **20**, 275 (1938).

The assignment of the degenerate bending vibrations 585 and 425 is fairly safe. The hydroxyl group produces the weaker restoring force and therefore is to be correlated to the lower frequency. The two bending vibrations 572 (A_1) and 425 (E) of the acid condense to the frequency 462 (F) of the ion, while 585 (E) corresponds to 631 (E).

A very weak and uncertain line 277 in the spectrum of the anhydrous acid, 297 in the acid solution, could not be satisfactorily interpreted.[13]

The assignment presented here is consistent with Fonteyne's results on deuterium perchlorate.[14]

Summary

1. A refined photographic method of comparing the intensities of spectral lines of unequal width has been developed.

2. The degrees of ionization of perchloric acid have been determined. As to be expected, perchloric acid is ionized to a much greater extent than nitric acid. The ionization constant could not be calculated as the activity coefficients are not known in the range of high concentrations.

3. The Raman spectra of anhydrous perchloric acid and concentrated solutions of the acid and of sodium perchlorate have been measured. Fonteyne's interpretation of the vibration spectrum of the acid has been revised and completed.

(13) Simon, *et al.* (ref. 9d), found 284 in the anhydrous acid. The line might represent the restricted internal rotation.

The Heat Capacity, Heats of Transition, Fusion and Vaporization, Vapor Pressure and Entropy of 1,1,1-Trifluoroethane

BY HORACE RUSSELL, JR., D. R. V. GOLDING AND DON M. YOST

Part of the low temperature calorimetric research program of this Laboratory has been the careful determination of the entropy of simple compounds in which hindered rotation about single bonds would be expected and for which straightforward and reliable statistical mechanical calculations can be made. Of the compounds available, ethane and similar molecules with two symmetrical groups on a common axis seem best suited for study both because of their convenient boiling points and because their configurations and normal frequencies can be readily determined. The existence of a barrier of about 3000 cal./mole hindering internal rotation in ethane was established by Kemp and Pitzer and Kistiakowsky, Lacher and Stitt.[1] Work by Rubin, Levedahl and Yost[2] indicates a barrier of about 2700 cal./mole for 1,1,1-trichloroethane, CH_3CCl_3. From the results reported in this paper the barrier in 1,1,1-trifluoroethane is about 3400 cal./mole. The fact that the values for these three molecules are the same within experimental error points to the interesting and significant possibility that the barrier is a function of the type bonds formed by the carbon atom but is independent, to a first approximation at least, of the nature of the attached atoms.

Purification of CH_3CF_3 or Freon "F-143."—The material used for the measurements was part of a redistilled sample furnished through the courtesy of Dr. A. F. Benning of the Jackson Laboratory of the du Pont Co. The material was carefully dried with phosphorus pentoxide, pumped to remove a small amount of dissolved air, and then fractionally distilled at a reflux ratio of about 40:1 through a 150-cm. vacuum jacketed column packed with glass helices.

From the 316-g. sample a 60-g. first fraction was taken and a 94-g. main fraction, leaving a 152-g. last fraction as the most probable impurities are higher boiling. There was no detectable drift in the pressure of 695 ± 2 mm. at 224.00°K. during the distillation of most of the first fraction and all of the main fraction. The presence of a transition only five and a half degrees below the melting point made it impossible to determine the solid-insoluble liquid-soluble impurity by Raoult's law in a completely satisfactory way. However, several attempts indicated 0.02–0.05 mole % impurity and we believe that this is approximately correct. The final sample was weighed in a small steel bomb from which it was transferred into the calorimeter. The weight of the sample checked to 0.01% on its removal from the calorimeter.

The Heat Capacity and Density.—All thermal measurements except that of the heat of vaporization were made in a new adiabatic calorimeter (gold plated, copper calorimeter II). The construction of this calorimeter is similar to one already described[3] except that greater pains were taken to prevent condensation in the filling tube. This tube is wound with No. 30 constantan wire down to the thermal anchor to the ring and the winding is covered with 0.00025 in. Al foil. A radiation shield soldered to the ring prevents the coil in the filling tube from radiating heat to the hydrogen tank. Thermocouple junctions at several points allow close control of the tube temperature. A further change was the installation of condenser plates within the calorimeter with which it is planned to make dielectric constant measurements in the future. A strain-free platinum resistance thermometer of laboratory designation[3] CT-7 was used for temperature measurements. The defined calorie of 4.1833 international joules is used throughout; the ice point is taken as 273.16°K.

The results of the heat capacity measurements are presented in Table I. There were 1.1183 moles in the calorimeter. Values at even temperatures read from a smooth curve are given in Table II; the points between the transition at 156.35° and the melting point are purely arbitrary and are given because they were assumed to arrive at our heat of fusion. The error in the heat capacities may be as high as 2% at 15°K. but decreases rapidly and above about 30°K. (except for the transition region) is about ±0.1%. The temperature interval used may be estimated from the spacing of the points in a single series as the final temperature of one point was the beginning temperature of the next. Corrections for vaporization were made using the observed vapor pressure and density. The maximum correction was 0.11%.

The density of the liquid under its own vapor pressure was determined by observing the volume of a weighed amount of CH_3CF_3 in a calibrated Pyrex bulb immersed in a stirred alcohol-bath. The four observed points are reproduced to better than 0.1% by the equation

$$d = 1.7374 - 0.00254\ T \quad (197°K. < T < 217°K.,\ d \text{ in g./ml.})$$

The absolute accuracy is estimated to be ±0.5%.

The Melting Point and the Heats of Transition and Fusion.—The results of the melting point determination are given in Table III. The only previously reported melting point is −107°.[4]

The heat capacity curve of solid CH_3CF_3 begins to bend upward at about 130°K. The heat capacity rises steadily but gradually until about 155.8°K. where it abruptly rises to very high values. At 158°K. the heat capacity has decreased to a relatively low value but the melting

TABLE III

THE MELTING POINT OF 1,1,1-TRIFLUOROETHANE

0°C. = 273.16°K.

Approx. % melted	Time since energy supplied	$T_{obs.}$, °K.
4	1 hr. 49 min.	161.614
27	1 hr. 26 min.	161.772
54	59 min.	161.797
81	58 min.	161.800

M. P. this sample = 161.80 ± 0.02°K.
M. P. pure compound = 161.82 ± 0.04°K. (−111.34°C.)

point of 161.82°K. is so close that reliable values cannot be obtained in this region. The observed values are shown in Table I. It is evident that a transition occurs with a relatively small latent heat; the maximum of the heat capacity curve lies at 156.35 ± 0.1°K. and may be taken as the transition point. There seems to be little hysteresis in the transition as no supercooling was observed and the heat capacity measurements were quite reproducible up to 155°K. As some premelting may have occurred any value for the heat of transition is somewhat arbitrary. That given was obtained by drawing a curve through the observed heat capacity up to 159.7°K. ignoring the high values at 155.8–156.8°K. The heat added in excess of that included under the curve is taken as the heat of transition and is shown in Table IV.

TABLE IV

THE HEAT OF TRANSITION IN 1,1,1-TRIFLUOROETHANE

Temp. interval, °K.	Total heat added to compound, cal./mole	$\int C_p dT$, cal./mole	Transition below starting temp., cal./mole	$\Delta H_{Trans.}$[a] cal./mole
155.352–157.205	115.88	45.49	0.21	70.60
155.486–157.379	117.43	46.79	0.28	70.92

[a] The absolute value depends on the interpretation of the heat capacity curve.

The two values do not agree well and this is probably because the transition is not quite complete at the upper temperature. The higher value is then more nearly correct and is taken as the heat of transition; from the method of calculation it represents a lower limit. The exact value is of little importance for the entropy calculation as the over-all energy input in this region is very precisely known.

The uncertainty in the heat of transition and the fact that the heat capacity of the high temperature form of the solid is not known prevents calculation of a unique value for the heat of fusion. The method of evaluation was as follows: a temperature interval starting below the transition and extending into the liquid range was selected; the heat of transition, 70.92 cal./mole, was subtracted from the total heat added; an arbitrary straight line (values in Table II) was drawn from 156.35 to 161.82°K. to represent the heat capacity of the high temperature form of the solid; and finally the heat represented by the area under the heat capacity curve and that absorbed by the calorimeter were subtracted from the total heat. Table V gives the value of the heat of fusion obtained in this way.

TABLE V

THE HEAT OF FUSION OF 1,1,1-TRIFLUOROETHANE

Temp. interval, °K.	Total heat added to compound, cal./mole	$\int C_p dT$, including transition, cal./mole	ΔH_{Fusion} at 161.82°K., cal./mole
155.002–166.876	1832.2	352.2	1480.0
150.045–164.953	1896.4	416.4	1480.1
155.486–163.866	1747.5	267.5	1480.0
		Av.[a]	1480 ± 75

[a] The indicated uncertainty is due to the difficulties of interpreting the heat capacity curve rather than to experimental error.

The total elapsed time in the runs shown varied from one hour and forty-five minutes to eight hours and twenty-three minutes; the measurements were made over a period of two weeks. The melting points in Table IV when combined with the heat of fusion given show a 0.02 mole % impurity. Our observations seem to be best correlated by this value but it is pointed out that by assuming a different amount of impurity and a different heat capacity curve for the high temperature solid the value for the heat of fusion may be changed as much as one hundred calories. The effect on the entropy would be less than 0.02 cal./deg./mole, however.

The Vapor Pressure and Heat of Vaporization.—A non-adiabatic calorimeter previously described[3] was used for these measurements. The vapor pressure was observed with a 13.5-mm. diameter mercury manometer read against a Gaertner steel meter bar suspended inside the manometer case. The results, corrected for capillary depression,[5] temperature of the mercury, and to g = 980.665, are given in Table VI. The error in the measurements is believed to be not greater than ±0.1 mm.

TABLE VI

THE VAPOR PRESSURE OF 1,1,1-TRIFLUOROETHANE

0°C. = 273.16°K.

The heat of vaporization measurements were made by collecting the vaporized gas in a thick-walled glass trap cooled in liquid air. A constant pressure was maintained by means of a 20-liter buffer of dry nitrogen separated from the calorimeter system by a mercury bubbler. The trap containing the condensed gas was sealed off and weighed at room temperature under pressure. In this way the same accuracy was achieved as on substances boiling at room temperature or above. Two measurements of the heat of vaporization of 1,1,1-trifluoroethane at 224.40°K. and 0.9339 atm. gave values of 4582 and 4583 cal./mole. About one-tenth mole was vaporized in each measurement and the heat exchange correction amounted to less than one per cent. of the heat added. The absolute accuracy is estimated as ±5 cal./mole. Calculated from the modified Berthelot equation with $P_c = 42$ atm.[6] and $T_c = 344.6$°K.,[4] the heat of vaporization is 4625 cal./mole. Correction for gas imperfection = −180 cal.

The Entropy from Calorimetric Data.—The only uncertainty in the calculation of the entropy arises in the transition–fusion region. The method used was indicated in discussing the heats of transition and fusion; it seems a direct and reasonable one. Other methods could be used involving the assumption of a different heat capacity curve for the high temperature solid form and possibly more premelting but the difference in entropy between the two methods would almost surely be less than 0.03 cal./deg./mole. The extrapolation from 12 to 0°K. was made by using a Debye function plus an Einstein function, each for three degrees of freedom. The combined functions fit the observed values to at least 25°K. within a few tenths of a per cent. The entropy calculation is summarized in Table VII.

[a] $S_{ideal} - S_{real} = \frac{27RT_c^3P}{32T^3P_c}$, $T_c = 344.6$°K.,[4] $P_c = 42$ atm.[6]

(6) Estimated by the method of H. P. Meissner and E. M. Redding, *Ind. Eng. Chem.*, **34**, 521 (1942).

The Entropy from Molecular Data.—Standard statistical mechanical formulas were used for the entropy calculations. The physical constants given by Birge[7] were used in conjunction with the defined calorie. The moments of inertia were calculated from the results of an unpublished electron diffraction investigation by Mr. William Shand and Dr. R. A. Spurr at this Institute. The C–F bond distance is 1.37 ± 0.02 Å., the C–C distance 1.52 ± 0.02 Å. the C–C–F angle 112°10′ ± 2°, and the F–C–F angle 107° 32′ ± 2°. A tetrahedral methyl group with a C–H distance of 1.09 Å. was assumed. The principle moments of inertia are $I_x = 150.4 \times 10^{-40}$ g. cm.^{2}, $I_y = I_z = 166.7 \times 10^{-40}$ g. cm.^{2} The entropy due to the internal rotation was evaluated from the table of Pitzer and Gwinn[8]; the reduced moment of the methyl group is 5.125×10^{-40} g. cm.^{2} The normal vibrations were assigned from the Raman lines given by Hatcher and Yost.[9] The original notebooks and plates were examined and two slight changes made. There was a typographical error in the lowest frequency published which should be 368 cm.$^{-1}$ instead of 358 cm.$^{-1}$ The line 2792 cm.$^{-1}$ was assumed to be scattered from the 4047 Å. Hg line; it seems equally reasonable to assign it to the 4358 Å. Hg line with a value of 1025 cm.$^{-1}$ and this aids considerably in the analysis. The 1025 cm.$^{-1}$ frequency scattered from the 4047 Å. Hg line would overlap another line. By comparison with ethane and 1,1,1-trichloroethane a reliable assignment of the observed frequencies to normal modes can be made. The frequencies and their degeneracies are: 368 (2), 541 (2), 603 (1), 829 (1), 968 (1), 1025 (2), 1279 (2), 1450 (1), 1450 (2),

TABLE VIII

THE ENTROPY OF 1,1,1-TRIFLUOROETHANE FROM MOLECULAR DATA

Ideal Gas at 224.40°K. and 0.9330 atm.

2975 (1), 3040 (2) cm.$^{-1}$. A summary of the entropy calculation is given in Table VIII. The best value for the barrier to internal rotation is seen to be 3450 cal./mole.

This work adds to the evidence from thermodynamic measurements and other sources[10] that rotation about single carbon–carbon bonds is restricted considerably. Although the method used in this work is the most accurate now available for the determination of the magnitude of the barrier, the possible experimental error is always rather high, being probably in no case less than ±200–300 cal./mole. This is because the quantity of interest, *i. e.*, the contribution of the internal rotation to the entropy, is the small difference between two essentially experimental quantities each burdened with its own errors. It should also be remembered that the height of the barriers is of significance only in connection with the potential function assumed for the rotation. The tables used[8] assume a potential $\varphi = (V/2)(1 - \cos 3X)$; this is used largely because of the mathematical simplification introduced and its correctness has no conclusive support, either theoretical or experimental. Other assumptions as to the potential would give different barrier heights. For example Charlesby[11] has shown that for ethane the assumption of a rectangular barrier 1700 cal./mole high and 1.35 radians wide also gives a fit with available data. The cosine potential is more reasonable, however, and is quite satisfactory for comparing different molecules.

We believe that the values for ethane, 1,1,1-trichloroethane, and 1,1,1-trifluoroethane of 2700–3000, 2700, and 3450 cal./mole, respectively, do not differ enough to allow any reliable ordering as to magnitude, although the higher value of 1,1,1-trifluoroethane is probably significant. However, the important fact that the values are so nearly the same, should stimulate work on a fundamental theory of hindered rotation. Until such a theory is developed, a serious gap exists in our knowledge of simple molecular structures.

We wish to thank Mr. William Shand and Dr. R. A. Spurr for the use of their unpublished electron diffraction data for 1,1,1-trifluoroethane and Professor Alexander Goetz for supplying us with liquid hydrogen.

Summary

1. The heat capacity, heats of transition, fusion and vaporization, and vapor pressure of 1,1,1-trifluoroethane have been measured in the temperature range 13–226°K. From these data the calorimetric entropy has been calculated.

2. The Raman spectrum data have been reconsidered and slightly revised. From this and other molecular data, the entropy of the compound has been calculated statistically. Comparison of the calculated and observed entropies indicates a barrier of 3450 ± 400 cal./mole hindering the internal rotation of the molecules.

Concerning Racemic α-Hydroxy-β,β-dimethyl-γ-butyrolactone (Pantolactone)[1a]

BY JARED H. FORD

Glaser[1b] reported that he obtained pantolactone by vacuum distillation in the form of a transparent crystalline mass, m. p. 55°, that appeared under the microscope as clumps of prismatic needles. Stiller and co-workers[2] obtained a glassy product on vacuum distillation which on recrystallization from ether–petroleum ether gave clusters of fine colorless needles, m. p. 56–58°. Reichstein and Grüssner[3] and Carter and Ney[4] also obtained glassy products, but they reported melting points of 75–78° and 75–80°, respectively.

In the present investigation racemic pantolactone was obtained by vacuum distillation as a colorless transparent solid which became translucent at 80° and which melted at 89.8–91.0°. The melting point was not changed by recrystallization from a benzene–cyclohexane mixture. The melting point of 89.8–91.0° is practically the same as that reported for optically active pantolactone.[4a] On comparison, (−)-pantolactone ($[\alpha]^{25}D$ −49.2° in water; C = 2%) was found to melt at 89.9–91.1°, and a mixture of approximately equal parts of racemic and (−)-forms was found to melt at 89.8–91.0°. Thus it appears that the *d* and *l* forms of this compound form a racemic solid solution which, when partly melted, has the same composition in the liquid and solid phases.[5] The 56° melting form reported by previous investigators[1,2] is probably a racemic compound.

(1a) This name has been suggested by Barnett and Robinson [*Biochem. J.*, **36**, 357 (1942)] for α-hydroxy-β,β-dimethyl-γ-butyrolactone, the lactone half of pantothenic acid.

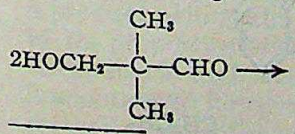
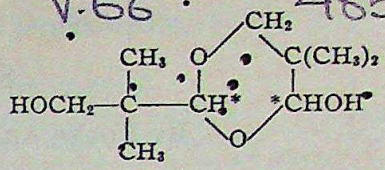
The racemic pantolactone, m. p. 89.8–91.0°, described in this communication, was prepared from α,α-dimethyl-β-hydroxypropionaldehyde[6] that had been recrystallized once from ethyl acetate and once from 95% ethanol. The cyanohydrin reaction was carried out with calcium chloride and sodium cyanide[3,4], and the resulting cyanohydrin was hydrolyzed with hydrochloric acid.[1,2] When the synthesis was carried out with crude α,α-dimethyl-β-hydroxypropionaldehyde as reported by Carter and Ney,[4] the melting point of the resulting pantolactone was in good agreement with the value reported by these investigators (75–80°) and by Reichstein and Grüssner[3] (75–78°). Fractional distillation of the impure material, using a 2-ft. column packed with Raschig rings, gave a product melting at 85–88°.

In order to obtain pure racemic pantolactone it is essential that the intermediate aldol, α,α-dimethyl-β-hydroxypropionaldehyde, be free from certain impurities, but the melting point was found to be a poor criterion of its purity. It usually melts over a range of 2 to 5 degrees. Melting points from 79–82° to 100–103° have been obtained on samples that were recrystallized several times from alcohol. Furthermore, some samples of crude aldol were found to have melting points within this range. The recrystallized samples differ from the crude ones in that they are substantially odorless and give clear solutions when dissolved in 10 parts of hot water.

Since three recrystallized samples having melting points of 79–82°, 82–84° and 100–103°, respectively, were found to give high yields of pure racemic pantolactone, it is believed that they were substantially pure. Melting points of 89–90°[6] and 96–97°[2] have been previously reported for this compound.

Wessely[6] has determined the molecular weight of crystalline α,α-dimethyl-β-hydroxypropionaldehyde and found it to be dimeric. By analogy with the structure proposed by Späth and Schmid[7] for the dimer of aldol it appears likely that the dimer of α,α-dimethyl-β-hydroxypropionaldehyde has the following structure





Since this structure contains two different asymmetric carbon atoms, the compound should exist in two racemic modifications. This affords a logical explanation of the fact that samples having different melting points may give equally good yields of pantolactone. The above structure requires only the splitting of hemiacetal linkages to convert the dimeric into the monomeric form.

The author wishes to thank Messrs. Harold Emerson and William Struck of these Laboratories who carried out the analyses.

Experimental

α,α-Dimethyl-β-hydroxypropionaldehyde.—The proportions of reactants were the same as those described by Wessely,[6] but the temperature was held at approximately 25° by means of an ice-bath. A mechanical stirrer was used. After being recrystallized once from ethyl acetate and once from 95% ethanol, the product melted at 78–81°. The yield of crude aldol was 80%. Each recrystallization caused a loss of about 50% in the yield.

Pantolactone.—To a mechanically stirred mixture of 128.8 g. of α,α-dimethyl-β-hydroxypropionaldehyde (passed through a 12-mesh sieve), 400 g. of chopped ice, and 400 g. of water was added a solution of 111.0 g. of calcium chloride dihydrate (Mallinckrodt) in 100 ml. of water. A solution of 71.0 g. of sodium cyanide in 125 ml. of water was then added rapidly, and the stirring was continued for one hour. Concentrated hydrochloric acid (500 ml.) was then added, and the resulting clear solution was heated for eighteen hours on the steam-bath. The lactone was separated from the aqueous solution by continuous extraction with chloroform. The chloroform was removed, and the residue was vacuum distilled, using an ordinary Claisen flask. The lactone boiled at 117–121° (10 mm.) and was a sticky, wax-like semi-transparent solid, melting at 89.6–91.0°. The yield was 155.5 g. (95%). On redistillation a middle fraction (b. p. 120–121° (11 mm.)) was obtained which melted at 89.8–91.0°.[8]

Anal. Calcd. for $C_6H_{10}O_3$: C, 55.35; H, 7.75; sap. eq., 130.1. Found: C, 55.39; H, 8.05; sap. eq., 130.4, 130.4.

The saponification equivalent was determined by dissolving the sample in an excess of normal alkali, warming to 80° for fifteen minutes, cooling to 0° and titrating with normal acid at 0 to 5°.

Summary

1. Racemic pantolactone has been obtained as a solid solution which has the same melting point as the optically active forms.

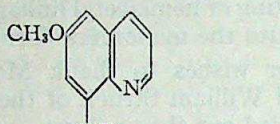
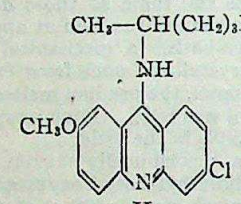
Substituted Aminobenzofuroquinolines

BY ROGER ADAMS, J. H. CLARK,[1] NATHAN KORNBLUM AND HANS WOLFF

The intensive search in many laboratories to find an anti-malarial with more favorable properties than plasmochin (I) or atabrine (II) has led us to a study of certain aminobenzofuroquinolines. These compounds resemble plasmochin in their basic structure.

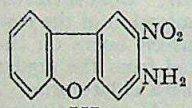


I



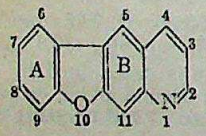
II

The failure of Kirkpatrick and Parker[2] to isolate a nitroquinoline from a Skraup reaction involving 2-nitro-3-aminodibenzofuran (III) made

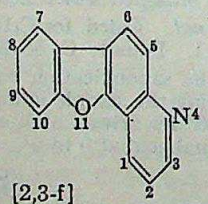


III

it appear advisable to prepare the desired nitrobenzofuroquinolines by nitration of the previously described[2,3] benzofuroquinolines, IV and V.



[3,2-g]
IV

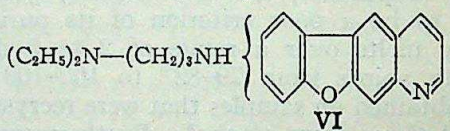


[2,3-f]
V

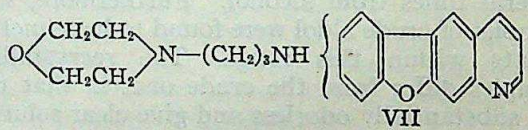
These latter compounds were synthesized following the method of Mosettig and Robinson,[3] and the isomers were isolated taking advantage of the contrasting solubility relationships of the free bases and their sulfates.

The pure quinolines were nitrated by treating the crystalline material with a large excess of fuming nitric acid followed by immediate dilution of the reaction mixture with water. A single isomer was isolated readily from the compound IV but some difficulty was encountered with compound V. In this latter case a mixture resulted from which two pure isomeric mononitrobenzofuroquinolines were finally isolated. It has not been possible, as yet, to determine the position at which nitration occurred in any of the three cases.

Owing to the tediousness of separation of the isomeric mononitro compounds from V, only the derivative of IV was studied from the standpoint of obtaining a substance with antimalarial activity. The corresponding amine was condensed with 3-chloro-N,N-diethylpropylamine hydrochloride to give compound VI and with N-(3-chloropropyl)-morpholine hydrochloride to give compound VII. Neither of these substances showed antimalarial activity.

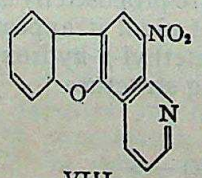


VI

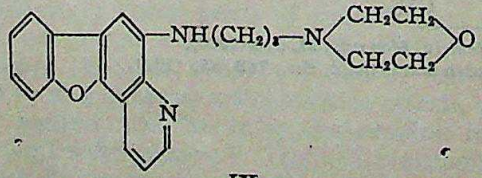


VII

Further efforts were turned toward the synthesis of compounds of unquestionable structure in which the side chain would be attached to the quinoline portion of the benzofuroquinoline nucleus. Contrary to the experience of Kirkpatrick and Parker, it was found possible to prepare 5-nitrobenzofuro[2,3-f]quinoline (VIII) from 2-nitro-3-aminodibenzofuran (III). This compound was reduced and the morpholinylpropyl group introduced to give compound IX. This also showed no antimalarial properties.



VIII



IX

An isomer of the amine from which this derivative IX was obtained is shown in XIII. This resembles much more closely the base from which the plasmochin molecule is derived. Its synthesis was accomplished from the 3-benzenesulfon-

amido-2-nitrodibenzofuran (X) which was prepared by the action of benzenesulfonyl chloride on compound III. In this case the dibenzenesulfonamido derivative was formed very easily and, therefore, it was preferable to prepare compound X by nitration of 3-benzenesulfonamidodibenzofuran. Upon reduction the corresponding amine

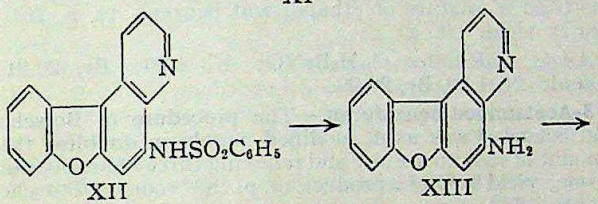
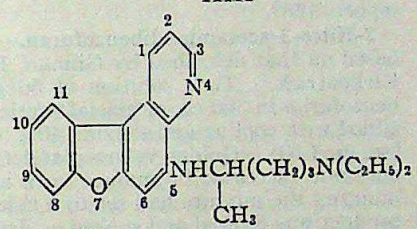
XI



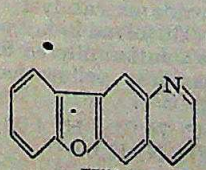
XII XIII



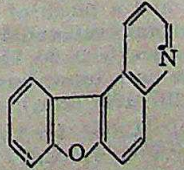
[3,2-f]
XIV

(XI) resulted; by means of a Skraup synthesis this yielded the benzofuroquinoline derivative (XII). Hydrolysis gave the aminobenzofuroquinoline (XIII). Alkylation of compound XIII proved to be unusually difficult and an absolutely pure product (XIV) was not isolated.

From a Skraup synthesis on 2-aminodibenzofuran, Kirkpatrick and Parker[2] have obtained two isomeric benzofuroquinolines, presumably having the structures of XV and XVI. These two products, to which individual structures were not assigned, melted at 185–186° and 160.5–161.5°. It was anticipated that replacement of the amino group in compound XIII by hydrogen would give a product having the structure XVI and identical in its properties with one of those obtained by Kirkpatrick and Parker. The benzofuroquinoline obtained, however, melted at 82–83.5°. The method used in the preparation of this compound would seem to leave no doubt as to its structure; no explanation for this discrepancy presents itself.



XV



XVI

By diazotization and treatment with sodium bromide, the two aminobenzofuro[2,3-f]quinolines were converted to the corresponding bromo derivatives.

Experimental

Benzofuro[3,2-g]quinoline (linear compound) (IV) and Benzofuro[2,3-f]quinoline (angular compound) (V).—The procedure of Mosettig and Robinson[3] was used with slight variations. It was found advantageous to use crude 3-aminodibenzofuran sulfate in the quinoline synthesis since the amine is isolated more readily in this form.[4]

The crude reaction product was distilled without any attempt at fractionation, b. p. around 200° (1 mm.); yield, 74%. The two isomers, linear and angular, were separated by the following procedure. Crystallization of 59 g. of the distilled material from 300 cc. of 95% ethanol gave 13 g. of crude linear polymer, m. p. 160–167°. The mother liquor was diluted to 600 cc. with 95% ethanol, and 15 cc. of concentrated sulfuric acid in 50 cc. of ethanol was added. At the end of fifteen minutes a heavy precipitate had formed. This was collected on a filter, washed with hot ethanol to remove the more soluble linear isomer and dissolved in water. The base, freed with concentrated aqueous ammonia, separated as an oil but solidified on standing. It was collected on a filter, dissolved in boiling petroleum ether (b. p. 60–110°), filtered hot and allowed to crystallize. In this way 10 g. of crude angular isomer was obtained, m. p. 100–106°.

The mother liquor from the sulfate of the angular isomer was evaporated to a thick sirup, treated with aqueous ammonia to free the base, diluted with water to a volume of 600 cc. and digested on a hot plate for thirty minutes. The solid was collected on a filter and recrystallized from ethanol to obtain more of the linear isomer. Repetition of this whole procedure four times gave 24.4 g. of angular isomer, m. p. 100–106°, and 24 g. of linear isomer, m. p. 160–166°. Residual material melting below 95° was discarded.

Two further crystallizations of the linear isomer from ethanol gave 21 g. (26%) of material, m. p. 168–169° (cor.), a value in agreement with that previously reported.[2,3]

Three crystallizations of the sulfate of the angular isomer from ethanol were necessary to give 19.5 g. (24%) of free base, m. p. 106–106.5° (cor.) which agrees with the value reported by Mosettig and Robinson.[3]

Nitrobenzofuro[3,2-g]quinoline.—To 9.6 g. of benzofuro[3,2-g]quinoline (IV) was added 30 cc. of fuming nitric acid (sp. gr. 1.50). A vigorous reaction with evolution of oxides of nitrogen ensued and the solid dissolved within thirty seconds. The reaction mixture was diluted immediately with 400 cc. of water and the product, a solid pasty mass, filtered and digested on a steam-bath with excess aqueous ammonia. The precipitate was filtered, sucked as dry as possible, suspended in 800 cc. of xylene, boiled until all the water was removed and filtered hot through a fluted filter. Upon cooling, a cream-colored crystalline product separated which was essentially pure, m. p. 267–268° (cor.); yield, 9.6 g. (84%).

Anal. Calcd. for $C_{15}H_8N_2O_3$: N, 10.60. Found: N, 10.68.

Aminobenzofuro[3,2-g]quinoline.—A suspension of 5 g. of nitrobenzofuro[3,2-g]quinoline in 150 cc. of 95% ethanol was reduced with 3 g. of Raney nickel and hydrogen at 2-3 atmospheres pressure. At the end of about sixteen hours the reduction was complete. The reaction mixture was heated to boiling, filtered from catalyst and then cooled. Recrystallization from ethanol gave yellow needles, m. p. 236.5–237° (cor.); yield, 3.9 g. (88%).

Anal. Calcd. for $C_{15}H_{10}N_2O$: N, 11.96. Found: N, 12.19.

(3-Diethylaminopropylamino)-benzofuro[3,2-g]quinoline (VI).—A mixture of 16 g. of aminobenzofuro[3,2-g]quinoline and 30 g. of 3-chloro-N,N-diethylpropylamine hydrochloride in 75 cc. of pure *n*-butanol was heated in an oil-bath at 140° with stirring for sixty hours. After evaporation of the ethanol an excess of 10% aqueous sodium

Digitized by Arya Samaj Foundation Chennai and eGangotri

hydroxide was added to liberate the base. It was extracted with benzene. The product, a viscous yellow oil, was obtained by high vacuum (0.02 mm.) distillation; bath temperature, 250–260°; yield 11.5 g. (48%).

Anal. Calcd. for $C_{22}H_{25}N_3O$: C, 76.05; H, 7.25; N, 12.09. Found: C, 76.16; H, 7.26; N, 11.87.

The product could not be crystallized and no crystalline salts were found. A large excess of 3-chloro-N,N-diethylpropylamine hydrochloride is necessary if a pure product is to be obtained.

[3-(4-Morpholinyl)-propylamino]-benzofuro[3,2-g]quinoline (VII).—A mixture of 15 g. of aminobenzofuro[3,2-g]-quinoline, 20 g. of N-(3-chloropropyl)-morpholine hydrochloride and 100 cc. of pure *n*-butanol was heated in an oil-bath at 140–150° with stirring for fifteen hours. The butanol was distilled and the residual gummy solid washed with three 50-cc. portions of absolute ethanol-ethyl acetate mixture (1:2). The solid was recrystallized once from glacial acetic acid to give a pale pink powder which appeared to be a mixture of the hydrochlorides of the base. Upon dissolving in water and treating with excess of aqueous ammonia, a yellow solid separated. It was purified by recrystallization from petroleum ether (b. p. 60–110°); yellow needles, m. p. 120° (cor.); yield, 7.5 g. (32%).

Anal. Calcd. for $C_{22}H_{23}N_3O_2$: C, 73.10; H, 6.42; N, 11.63. Found: C, 72.96; H, 6.24; N, 11.81.

Nitration of Benzofuro[2,3-f]quinoline.—The same procedure was used as in the nitration of the isomer. The crude reaction product from 9 g. of starting material was treated with aqueous ammonia, filtered, sucked dry, treated with 400 cc. of xylene, boiled until all the water was removed, treated with Norite and filtered hot. Evaporation of the solvent gave 9.5 g. of yellow solid. This material was suspended in about 200 cc. of ethanol, the mixture boiled for ten minutes and filtered hot through a preheated fluted filter. The ethanol-insoluble material remaining on the filter amounted to 6 g. and the ethanol-soluble 3.5 g. No pure compounds could be obtained from the soluble portion.

The ethanol-insoluble product was recrystallized six to eight times from glacial acetic acid. Cream-colored needles were obtained thus, m. p. 297–298° (cor.).

Anal. Calcd. for $C_{15}H_8N_2O_3$: C, 68.18; H, 3.05; N, 10.60. Found: C, 68.07; H, 3.28; N, 10.66.

The residues from the glacial acetic acid filtrate after removal of the solvent were extracted thoroughly four times with cold 5% aqueous hydrochloric acid to remove any isomer, m. p. 297–298°, which was present. They were then treated with aqueous ammonia and recrystallized from toluene; yellow needles, m. p. 282° (cor.).

Anal. Calcd. for $C_{15}H_8N_2O_3$: C, 68.18; H, 3.05; N, 10.60. Found: C, 68.13; H, 3.02; N, 10.48.

Aminobenzofuro[2,3-f]quinolines.—A suspension of 15 g. of pure nitrobenzofuro[2,3-f]quinoline, m. p. 297–298°, in 150 cc. of ethanol, was reduced with hydrogen at 3 atmospheres pressure using 3 g. of Raney nickel catalyst. The product was crystallized from toluene; yellow needles, m. p. 200° (cor.); yield, 10 g. (75%).

Anal. Calcd. for $C_{15}H_{10}N_2O$: C, 76.91; H, 4.30; N, 11.96. Found: C, 77.25; H, 4.54; N, 12.16.

Reduction of the nitro isomer, m. p. 282°, gave the corresponding amine. It was purified from benzene; yellow platelets, m. p. 233° (cor.).

Anal. Calcd. for $C_{15}H_{10}N_2O$: N, 11.96. Found: N, 12.15.

Bromobenzofuro[2,3-f]quinoline from Aminobenzofuro[2,3-f]quinoline, m. p. 200°.—To a boiling suspension of cuprous bromide prepared from 6.3 g. of copper sulfate, 20 g. of copper turnings, and 15.4 g. of sodium bromide according to the method given in "Organic Syntheses,"[5] was added the diazonium bromide prepared from 2 g. of aminobenzofuro[2,3-f]quinoline, m. p. 200°, 15 cc. of 42% hydrobromic acid, 35 cc. of water, and 0.65 g. of sodium nitrite. The mixture was refluxed for thirty minutes, cooled, and 100 cc. of benzene added, followed by an excess of aqueous ammonia. The aqueous layer was removed and the benzene solution washed three times with water. The washings were discarded.

The benzene layer was then extracted four times with an excess of dilute hydrochloric acid. The aqueous layer contained a pink solid in suspension. This aqueous suspension was removed and heated to drive off traces of benzene and then made alkaline with aqueous ammonia. A yellow solid separated which was dissolved in toluene, treated with Norite and concentrated to give white needles, m. p. 180–182° (cor.); yield, 1.28 g.

Anal. Calcd. for $C_{15}H_8BrNO$: C, 60.43; H, 2.70; N, 4.70. Found: C, 60.45; H, 2.74; N, 5.00.

Bromobenzofuro[2,3-f]quinoline from Aminobenzofuro[2,3-f]quinoline, m. p. 233°.—This compound, prepared from 0.45 g. of aminobenzofuro[2,3-f]quinoline, m. p. 233°, by the method previously described, formed white platelets from a mixture of ethanol and benzene, m. p. 204° (cor.); yield, 0.05 g.

Anal. Calcd. for $C_{15}H_8BrNO$: N, 4.70; Br, 26.81. Found: N, 4.52, Br, 26.20.

3-Acetaminodibenzofuran.—The procedure of Borsche and Schacke[6] was used, modified merely in doubling the amount of sodium acetate and refluxing three hours instead of one; yield 92% of a product, m. p. 183° (cor.). Borsche reports 178°.

2-Nitro-3-acetaminodibenzofuran.—The procedure was based on that described by Gilman, Brown, Bywater and Kirkpatrick.[7] To a solution of 56 g. of 3-acetaminodibenzofuran in 300 cc. of glacial acetic acid was gradually added with cooling and stirring 40 g. of fuming nitric acid (sp. gr. 1.50). Golden yellow platelets appeared almost at once and increased in amount until at the end of twenty minutes, the mixture had set to a thick pasty mass. The product was filtered and sucked as dry as possible; yellow platelets from glacial acetic acid, m. p. 205° (cor.); yield 49 g. (73%). Gilman, *et al.*, report 196°.

Dilution of the filtrate from the reaction mixture caused the precipitation of a dirty yellow solid. It was composed of a little impure starting material and a compound which crystallized from boiling xylene in the form of silky yellow needles, m. p. 261–262° (cor.). This compound was not investigated further.

2-Nitro-3-aminodibenzofuran.—The method of Borsche and Schacke[7] was employed. The product was purified from xylene; orange needles, m. p. 232–233° (cor.); yield, 86%. Borsche reports m. p. 222°.

5-Nitrobenzofuro[2,3-f]quinoline (VIII).—To a mixture of 32 g. of 2-nitro-3-aminodibenzofuran and 21 g. of arsenic acid ($H_3AsO_4 \cdot {}^1/_2H_2O$) was added 32 g. of dry glycerol followed by 41 g. of concentrated sulfuric acid in small portions. The mixture was heated in an oil-bath at 130–140° for five hours and then poured over cracked ice. The product, a black tar, was extracted three times with 600-cc. portions of 10% sulfuric acid, then with boiling xylene. From the xylene solution were obtained yellow crystals which were pure after one recrystallization from the same solvent, m. p. 206–207° (cor.); yield, 9 g. (24%).

Anal. Calcd. for $C_{15}H_8N_2O_3$: C, 68.18; H, 3.05; N, 10.60. Found: C, 68.10; H, 3.09; N, 10.55.

5-Aminobenzofuro[2,3-f]quinoline.—The product was formed by reducing 5.7 g. of the nitro compound in ethanol at 50° and 3 atmospheres pressure, with Raney nickel and a pinch of platinum oxide as catalyst. The solvent was evaporated, the residue dissolved in hot petroleum ether (b. p. 60–110°) and the solution filtered hot to remove dark brown insoluble impurities; yellow needles, m. p. 197–198° (cor.); yield, 4.4 g. (87%).

Anal. Calcd. for $C_{15}H_{10}N_2O$: C, 76.91; H, 4.30; N, 11.96. Found: C, 77.28; H, 4.30; N, 11.67.

5-[3-(4-Morpholinyl)-propylamino]-benzofuro[2,3-f] quinoline (IX).—A suspension of 13 g. of 5-aminobenzofuro[2,3-f]quinoline and 30 g. of N-(3-chloropropyl)-morpholine hydrochloride in 100 cc. of *n*-butanol was stirred at 145° for twenty-four hours. At this point 5 cc. of 3-(4-morpholinyl)-1-propanol was added to free any of the 5-aminobenzofuro[2,3-f]quinoline which may have been in the form of hydrochloride. The reaction mixture became much less viscous. Heating was continued for twenty-four hours more and a part of the butanol then removed on the steam cone under an air jet.

To the resulting brick red, pasty product was added a mixture of 60 cc. of methyl acetate and 30 cc. of methanol. Most of the product dissolved leaving in suspension fine, cream-colored needles which were found to be the hydrochloride of 5-aminobenzofuro[2,3-f]quinoline. The recovered material amounted to 2 g. The solvent was evaporated and a thick brown oil resulted. This was made alkaline with aqueous sodium hydroxide and extracted with benzene. The solvent was evaporated and the product distilled at a pressure of 0.03 mm. About 2 cc. of an oil distilling at 80–100° was not investigated further. It was probably a polymer of chloropropylmorpholine. An additional 0.5 g. of unchanged 5-aminobenzofuro[2,3-f]quinoline distilled at about 200°. It was necessary to stop the distillation and remove this solid from the sidearm of the distilling flask.

The desired product distilled as an orange-yellow, semi-solid resin, b. p. 238–240° (0.03 mm.) (bath temperature 265–275°).

Anal. Calcd. for $C_{22}H_{23}N_3O_2$: C, 73.10; H, 6.42. Found: C, 72.98; H, 6.75.

3-Benzenesulfonamidodibenzofuran.—A mixture consisting of 2 g. of 3-aminodibenzofuran, 25 cc. of 10% aqueous sodium hydroxide and 2.5 cc. of benzenesulfonyl chloride was shaken vigorously for five to ten minutes. The white solid was filtered and sucked as dry as possible.

The sodium salt thus obtained was added to 800 cc. of boiling water and filtered. The solution was then acidified with hydrochloric acid and digested on the steam-bath for one-half hour. The precipitate was dissolved in 95% ethanol, treated with Norite, concentrated and cooled. The white needles which separated were recrystallized from aqueous ethanol, m. p. 162–163° (cor.). The product is soluble in hot chloroform and hot glacial acetic acid.

Anal. Calcd. for $C_{18}H_{13}NO_3S$: C, 66.87; H, 4.02; N, 4.33. Found: C, 66.52; H, 4.14; N, 4.07.

2-Nitro-3-benzenesulfonamidodibenzofuran (X).—A. (Used for preparation.) A solution of 0.5 g. of 3-benzenesulfonamidodibenzofuran in 15 cc. of hot glacial acetic acid was cooled to 18° and while stirring and cooling, 0.17 cc. of nitric acid (sp. gr. 1.5) was added dropwise. The mixture was maintained at 18°. After a few minutes the nitro compound started to precipitate and was filtered with suction after ten minutes of standing. The yellow solid was sucked as dry as possible and then recrystallized from pyridine; yellow needles, m. p. 226–227° (cor.); yield, 0.26 g.

Anal. Calcd. for $C_{18}H_{12}N_2O_5S$: C, 58.69; H, 3.26. Found: C, 58.68; H, 3.19.

Hydrolysis of this compound was accomplished by refluxing for sixty hours 0.085 g. of 2-nitro-3-benzenesulfonamidodibenzofuran with 250 cc. of 25% hydrochloric acid. The mixture was filtered hot and the filtrate made alkaline. The precipitate was dried and recrystallized from xylene; orange needles, m. p. 232–233° (cor.). A mixed melting point with an authentic sample of 2-nitro-3-aminodibenzofuran showed no depression.

B.—A solution of 2.25 g. of 2-nitro-3-aminodibenzofuran in 100 cc. of pyridine was treated with 1.5 cc. of benzenesulfonyl chloride and immediately refluxed for seven and one-half hours. By addition of water a precipitate formed (1.85 g.). To remove any unchanged amine the crude material was dissolved in nitrobenzene and dry hydrogen chloride passed in. A small amount of precipitate was filtered and discarded. The nitrobenzene was distilled off and the residue purified from pyridine; orange crystals, m. p. 226–227° (cor.).

Anal. Calcd. for $C_{18}H_{12}N_2O_5S$: C, 58.69; H, 3.26. Found: C, 58.70; H, 3.29.

This product was identical with that obtained by nitrating 2-benzenesulfonamidodibenzofuran. It was always difficult to obtain it in a pure state by use of procedure B.

In several experiments the preparation B just described was not duplicated. Thus, in some cases, upon dilution of the reaction mixture, a yellow solid separated which was purified twice from xylene followed by two purifications from pyridine; yellow crystals, m. p. 263–265° (cor.) with decomposition and evolution of gas. It proved by analysis to be a disulfonamido derivative.

Anal. Calcd. for $C_{24}H_{16}N_2O_7S_2$: C, 56.69; H, 3.15; N, 5.51. Found: C, 56.83, 56.98; H, 3.21, 3.24; N, 5.52.

2-Amino-3-benzenesulfonamidodibenzofuran (XI).—To a suspension of 7.2 g. of 2-nitro-3-benzenesulfonamidodibenzofuran in 150 cc. of 95% ethanol, 0.05 g. of platinum oxide catalyst was added and the reduction carried out at 2–3 atmospheres pressure. The color of the material changed from deep yellow into a very light gray. The suspended amine and catalyst were refluxed with toluene. The resulting solution was filtered from the catalyst and the toluene cooled, giving asbestos-like needles; m. p. 227–228° (cor.); yield, 5.1 g.

Anal. Calcd. for $C_{18}H_{14}N_2O_3S$: C, 63.89; H, 4.18. Found: C, 63.94; H, 4.10.

5-Benzenesulfonamidobenzofuro[3,2-f]quinoline (XII).—To 60 g. of the 2-amino-3-benzenesulfonamidodibenzofuran, 68 g. of nitrobenzene and 73.1 g. of freshly distilled glycerol, 41.6 g. of concentrated sulfuric acid was added and the mixture was heated on a steam cone for one hour. Heating was continued in an oil-bath, the temperature of which was gradually raised to 145–150° and maintained at that temperature for five hours. The excess of nitrobenzene was separated by steam distillation and the remaining black residue was filtered, washed with water and dried. A black powdery material remained which was refluxed with 1 liter of xylene, filtered and the process repeated with the solid residue. On cooling, a slightly brown-colored material crystallized. The quinoline thus obtained was purified from xylene; brownish yellow crystals, m. p. 197–198° (cor.); yield 30 g. (45%).

Anal. Calcd. for $C_{21}H_{14}N_2O_3S$: C, 67.35; H, 3.77; N, 7.49. Found: C, 67.59; H, 3.73; N, 7.45.

5-Aminobenzofuro[3,2-f]quinoline (XIII).—To 7 g. of the sulfonamide, 17 cc. of sulfuric acid (prepared from 3 volumes of concentrated sulfuric acid and 1 volume of water) was added and the mixture was heated for twenty minutes in an oil-bath at 145° (bath temperature). Water was added after cooling and the red solution made alkaline and refluxed. After cooling, the amine was filtered, dried and purified by recrystallization from petroleum ether (b. p. 60–110°); yellow crystals, m. p. 139–140° (cor.); yield, 3.3 g. (78%).

Anal. Calcd. for $C_{15}H_{10}N_2O$: C, 76.91; H, 4.30; N, 11.96. Found: C, 77.18; H, 4.45; N, 11.44.

Concentrated hydrochloric acid with or without glacial acetic acid, sodium in liquid ammonia or sodium amide were all unsatisfactory reagents for hydrolysis.

5-[4-Diethylamino-1-methylbutylamino]benzofuro[3,2-f]quinoline (XIV).—A mixture of 4.7 g. of 5-aminobenzofuro[3,2-f]quinoline and 4.2 g. of 4-chloro-N,N-diethylamylamine hydrochloride was heated in an atmosphere of nitrogen to 180°. When the temperature reached about 100° the mixture liquefied and was thoroughly shaken. On raising the temperature a red paste was obtained which was heated for two hours at 180°. After cooling the material was transferred into a three-necked flask with 30 cc. of *n*-butanol. Another 10 g. of 4-chloro-N,N-diethylamylamine hydrochloride was added and 3 g. of anhydrous potassium carbonate and the mixture heated with mechanical stirring for thirty hours at 140–150°. At this point 2 cc. of 1-diethylamino-4-pentanol was added. Heating and stirring were continued for another thirty hours. The solvent was evaporated and the residue shaken with 10% aqueous sodium hydroxide and extracted with

Digitized by Arya Samaj Foundation Chennai and eGangotri

benzene. The benzene layer was washed with water several times. The residue obtained by evaporation of the benzene was boiled with 500 cc. of petroleum ether (b. p. 60–110°) and filtered. On cooling, the unreacted aminoquinoline was obtained as yellow crystals. More of this starting amine was obtained on concentrating the petroleum ether solution. The product was distilled at 0.01 mm. The excess 1-diethylamino-4-pentanol was much lower boiling than the desired alkylated amine which was distilled at a bath temperature of 230–250°. The distillate was dissolved in 80 cc. of petroleum ether and more of the unalkylated amine separated after cooling at 4° for twenty-four hours. The petroleum ether again was evaporated and the resulting viscous material distilled at 0.01 mm. The first few drops of the distillate were discarded because they contained most of the starting amine still present. Finally 1.8 g. of product was obtained as a red viscous oil which still contained a small amount of unalkylated amine.

Anal. Calcd. for $C_{24}H_{29}N_3O$: C, 76.67; H, 7.78. Found: C, 77.14; H, 7.63.

The presence of potassium iodide did not improve the yield of alkylated amine.

Deamination of 5-Aminobenzofuro[3,2-f]quinoline (XIII).—The amine (0.2 g.) was dissolved in 35 cc. of hot concentrated hydrochloric acid and the resulting solution cooled to 0°. The suspension thus obtained was diazotized rapidly with 0.088 g. of sodium nitrite in 5 cc. of water. After five minutes at 0–3°, the diazonium solution was filtered quickly and to the clear filtrate 35 cc. of ice-cold 50% aqueous hypophosphorous acid was added. The reaction mixture was allowed to stand in the refrigerator for twelve hours, followed by an additional twelve hours at room temperature. The solution was made alkaline with aqueous sodium hydroxide and the precipitate which formed was filtered, washed with a little water and dried.

After two "short path" distillations at a pressure of 2 mm. and a bath temperature of 100–120°, 0.090 g. of needles which melted at 81–82° was obtained. The product was recrystallized from petroleum ether (b. p. 35–60°); very pale yellow needles, m. p. 82–83.5° (cor.). The melt solidified and remelted at the same value. The product is insoluble in Claisen potash solution and gives a negative ferric chloride test and a negative Beilstein test for halogens.

Anal. Calcd. for $C_{15}H_9NO$: C, 82.17; H, 4.14; N, 6.39. Found: C, 82.13; H, 4.42; N, 6.41.

Summary

1. Benzofuro[3,2-g]quinoline was nitrated to a single mononitro derivative. By reduction the corresponding amino compound was synthesized and converted into 3-diethylaminopropylamino and 3-(4-morpholinyl)-propylamino derivatives. Neither showed antimalarial activity.

2. Benzofuro[2,3-f]quinoline yielded two difficultly separated mononitro derivatives. The corresponding amines and, through them, the corresponding bromo compounds were synthesized.

3. 5-Nitrobenzofuro[2,3-f]quinoline was synthesized from 2-nitro-3-aminodibenzofuran. It was then reduced, and the morpholinylpropyl derivative prepared. This latter compound had no antimalarial activity.

4. 3-Benzenesulfonamido-2-nitrodibenzofuran was reduced to the corresponding amine which, in turn, was converted by means of a Skraup synthesis to the benzenesulfonamidobenzofuroquinoline. This last compound was hydrolyzed to the aminobenzofuroquinoline and attempts made to substitute the amino group with appropriate alkyl radicals.

Studies on Lignin and Related Compounds. LXXIV. Relation of Wood Ethanolysis Products to the Hibbert Series of Plant Respiratory Catalysts. Allylic and Dismutation Rearrangements of 3-Chloro-1-(3,4-dimethoxyphenyl)-2-propanone and 1-Bromo-1-(3,4-dimethoxyphenyl)-2-propanone

BY ARTHUR M. EASTHAM,[1] H. E. FISHER,[1] MARSHALL KULKA AND HAROLD HIBBERT

In previous communications[2,3] on the origin and function of lignin in the plant, a comparison was drawn between the Szent-Györgyi animal cell system of hydrogen-transporting respiratory catalysts[4] and a suggested analogous system composed of assumed lignin progenitors capable of functioning in a similar manner in the plant cell (Scheme 1).

SCHEME 1

Szent-Györgyi System (Animal)	Hibbert System (Plant)
A. $COOH—CH_2—CO—COOH$	A′. $R—CH_2—CO—CH_2OH$
B. $COOH—CH_2—CHOH—COOH$	B′. $R—CH_2—CHOH—CH_2OH$
C. $COOH—CH=CH—COOH$	C′. $R—CH=CH—CH_2OH$
D. $COOH—CH_2—CH_2—COOH$	D′. $R—CH_2—CH_2—CH_2OH$

(R = 4-hydroxy-3-methoxyphenyl)

The third member of the Hibbert system, coniferyl alcohol (C′) (corresponding to fumaric acid in the animal system), is known to be present in practically all plants in the early stages of growth.[5] The non-appearance of this and the other three members among the lignin fission products isolated in the ethanolysis of wood is assumed to be due to their very labile character, resulting in their ready conver-

sion, under the influence of the extraction medium, into stabilized end-products.

It was suggested[3] that possibly only the first and second members (A′ and B′) actually are present (probably as dimers) in native lignin, in view of the pronounced oxidizing character of the postmortal plant cell environment. Moreover, it was predicted that the first member of the series, namely, 3-hydroxy-1-(4-hydroxy-3-methoxyphenyl)-2-propanone, should exist in equilibrium with its enol form, oxyconiferyl alcohol, and that the latter should readily undergo an allylic rearrangement to give a more stable benzoin type. There existed the further probability that this benzoin would form an equilibrium mixture with its ene-diol and dismutation isomers.

$$R{-}CH_2{-}CO{-}CH_2OH\ (A') \rightleftharpoons$$
$$R{-}CH{=}C(OH){-}CH_2OH \rightleftharpoons$$
$$R{-}CHOH{-}C(OH){=}CH_2 \rightleftharpoons$$
$$R{-}CHOH{-}CO{-}CH_3 \rightleftharpoons$$
$$R{-}C(OH){=}C(OH){-}CH_3 \rightleftharpoons R{-}CO{-}CHOH{-}CH_3$$

In preceding communications[6] the isolation of the isomeric benzoin dismutation forms as their ethyl ethers from the ethanolysis products of spruce wood is described, and in the present paper experimental proof is given of the above theoretical conceptions.

It is a well-known fact that aromatic and aliphatic substituted allyl halides, such as cinnamyl chloride[7] and crotyl chloride[8] readily undergo rearrangement when the halide is replaced by hydroxyl, ethoxyl or acetate groups. Thus, when cinnamyl chloride is treated with aqueous or alcoholic alkali, or potassium acetate in glacial acetic acid, equilibrium mixtures of cinnamyl and phenylvinylcarbinyl alcohols, -ethyl ethers and -acetates are formed. The treatment of either crotyl chloride or methylvinylcarbinyl chloride with potassium or silver acetate gives a mixture of crotyl- and methylvinylcarbinyl acetates, the extent of rearrangement being determined by the type of solvent used.[8]

This communication deals with (i) the synthesis of the four new products 1-bromo-, 1-hydroxy- and 1-acetoxy-1-(3,4-dimethoxyphenyl)-2-propanone (Series II), and 3-acetoxy-1-(3,4-dimethoxyphenyl)-2-propanone (Series I), and (ii) the rearrangements (see below) occurring when the halogen atoms in 1-bromo-1-(3,4-dimethoxyphenyl)-2-propanone (Series II, X = Br) and 3-chloro-1-(3,4-dimethoxyphenyl)-2-propanone (Series I, X = Cl) are replaced by hydroxyl, ethoxyl and acetate groups.

$$R'{-}CH_2{-}CO{-}CH_2X \underset{\text{rearr.}}{\overset{\text{allylic}}{\rightleftharpoons}}$$

SERIES I

$$R'{-}CHX{-}CO{-}CH_3 \underset{\text{rearr.}}{\overset{\text{dismutation}}{\rightleftharpoons}}$$

SERIES II

$$R'{-}CO{-}CHX{-}CH_3$$

SERIES III

(R′ = 3,4-dimethoxyphenyl- and X = —Br or —Cl, —OH, —O—CO—CH_3 or —OC_2H_5)

Synthesis of Members of the Series I, II and III.—In order to study the rearrangement reactions involved in the conversion of the halides of Series I, II and III to the corresponding alcohols, acetates and ethyl ethers, it was necessary to have available twelve pure reference compounds, namely: **Series II:** 1-bromo-1-R″; 1-hydroxy-1-R″; 1-acetoxy-1-R″; 1-ethoxy-1-R″.[9] **Series I:** 3-chloro-1-R″[10]; 3-hydroxy-1-R″; 3-acetoxy-1-R″; 3-ethoxy-1-R″.[9] **Series III:** 2-bromo-1-R‴[6c]; 2-hydroxy-1-R‴[6b,6c]; 2-acetoxy-1-R‴[6b,6c]; 2-ethoxy-1-R‴.[6b,6d]

(R″ = (3,4-dimethoxyphenyl)-2-propanone; R‴ = (3,4-dimethoxyphenyl)-1-propanone)

Synthesis of Members of Series II.—The derivatives of Series II (X = Br, —OH, —O—CO—CH_3 and —OC_2H_5) were synthesized from 1-(3,4-dimethoxyphenyl)-2-propanone by the following type reactions[11]

$$R'{-}CHO + NO_2{-}CH_2{-}CH_3 \longrightarrow$$
$$R'{-}CH{=}C(NO_2){-}CH_3 \longrightarrow$$
$$R'{-}CH_2{-}C(=NOH){-}CH_3 \longrightarrow$$
$$R'{-}CH_2{-}CO{-}CH_3 \xrightarrow{Br_2} R'{-}CHBr{-}CO{-}CH_3 \xrightarrow[aq.]{KOAc} R'{-}CHOH{-}CO{-}CH_3$$
$$\text{Also } R'{-}CH_2{-}CO{-}CH_3 \xrightarrow{Pb(OAc)_4} R'{-}CHOAc{-}CO{-}CH_3$$

(R′ = 3,4 dimethoxyphenyl-)

In an attempt to synthesize 3-hydroxy-1-(3,4-dimethoxyphenyl)-2-propanone (Series I) from the corresponding halide (Series I) rearrangement reactions resulted, no normal product being formed, the latter evidently undergoing rapid transformation into a mixture of members of Series II and III (Scheme 2)

Synthesis of Members of Series I.—3-Acetoxy-1-(3,4-dimethoxyphenyl)-2-propanone (Series I) was synthesized from homoveratric acid[12] by treatment of the acid chloride with diazomethane and interaction of the resulting diazomethyl ketone with acetic acid as applied by Wolfrom.[13]

$$R'{-}CH_2{-}COOH \xrightarrow{SOCl_2} R'{-}CH_2{-}COCl \xrightarrow{CHN_2}$$

$$R'-CH_2-CO-CHN_2 \xrightarrow{HOAc} R'-CH_2-CO-CH_2-O-CO-CH_3$$

The method of Hahn, Stiehl and Schultz[12a] for the preparation of homoveratric acid was slightly modified, in that α-chlorohomoveratric amide was converted to homoveratric amide by use of hydriodic acid in glacial acetic acid instead of by catalytic hydrogenation.

Members of Series III.—These have been synthesized previously.[6b,d] The physical constants of the three series of reference compounds (I, II and III) are summarized in Table I. The fourth isomeric series ($R'-CO-CH_2-CH_2-X$)[14] is included for comparative purposes.

TABLE I

PHYSICAL CONSTANTS OF REFERENCE COMPOUNDS

M. p. °C., if solid or $n^{25}D$ if liquid

Compound	Bromide	Alcohol	Acetate	Ethyl ether
1-Substituted-1-R″	87–88	77–78	1.5260	1.5160
3-Substituted-1-R″	44–45	....	55–56	1.5215
2-Substituted-1-R‴	88–89	1.5590	65–66	81–82
3-Substituted-1-R‴	107–108	83–84	100–101	50–51

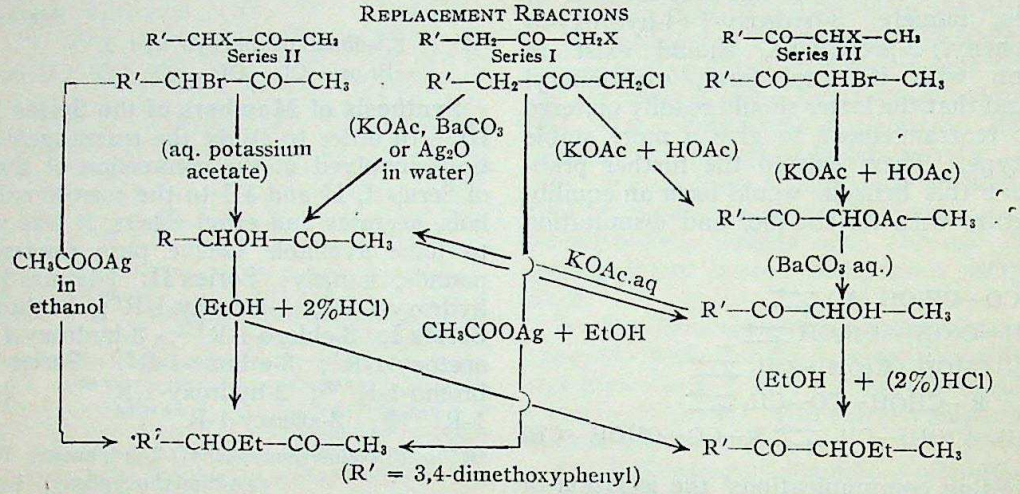
R″ = (3,4-dimethoxyphenyl)-2-propanone; R‴ = (3,4-dimethoxyphenyl)-1-propanone.

Since the three bromides of Series I, II and III were prepared by standard methods and also were found to be different from each other, it was assumed that the formulas assigned them according to the method of preparation were correct and that no rearrangements had taken place. The structures of the alcohols, acetates and ethyl ethers were arrived at in a similar manner. Further proof of structure in certain cases was obtained from absorption spectra studies.[15]

Replacement Reactions.—The attempted replacement of halogen in the halides, $R'-CHBr-CO-CH_3$ (Series II) and $R'-CH_2-CO-CH_2Cl$ (Series I), by hydroxyl, acetate or ethoxyl groups resulted in some cases in a complete, in other cases a partial, rearrangement whereby a mixture of the normal and abnormal products was obtained. These replacement reactions are summarized in Scheme 2.

SCHEME 2

REPLACEMENT REACTIONS



(R′ = 3,4-dimethoxyphenyl)

Treatment of the bromide (Series II) with silver acetate in ethanol gave the normal ethyl ether, namely, 1-ethoxy-1-(3,4-dimethoxyphenyl)-2-propanone in yield of 88%; no ethyl ethers of I or III could be detected. On the other hand, treatment of the 1-hydroxyketone (II) with 2% hydrogen chloride in ethanol yielded a mixture of the dismutation rearrangement products, namely, 2-ethoxy-1-(3,4-dimethoxyphenyl)-1-propanone (III) (60%) and the normal 1-ethyl ether (II) (30%). The replacement of bromine by the hydroxyl group on treatment of II (X = Br) with aqueous potassium acetate yielded the normal 1-hydroxyketone (II), some unchanged bromide and a small amount of the 2-hydroxyketone (III) formed as the result of a dismutation rearrangement.

Members of Series III showed, as far as could be ascertained, no tendency to rearrangement[6b,d] and also the 1-hydroxyketone (II) was found to be quite stable toward dilute acid. On the other hand, members of I proved to be very reactive and underwent rearrangements frequently. Thus treatment of the chloroketone (I) with aqueous potassium acetate, barium carbonate or silver oxide gave the 1-hydroxyketone (II) in 70% yield (as the result of an allylic rearrangement), and a small amount of the diketone, 1-(3,4-dimethoxyphenyl)-1,2-propanedione. Treatment of the chloroketone (I) with silver acetate in ethanol yielded the 1-ethyl ether (II) in approximately 60% yield together with a high alkoxyl-containing compound not further investigated. Refluxing the same chloroketone (I) with potassium acetate in glacial acetic acid also yielded a mixture of substances one of which was identified as the acetate (III).

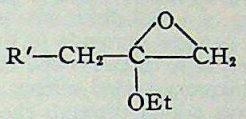
In other attempts to prepare the normal 3-ethyl ether of I, the 3-chloroketone (I) was treated with sodium ethylate and also with potassium hydroxide in ethanol solution. In both cases the reaction product was a carbonyl-free ethyl ether believed to have the structure[16]



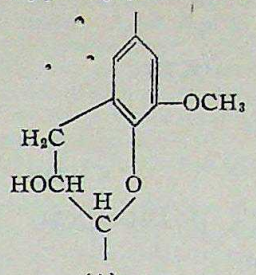
The remarkable ease with which members of Series I rearrange to give types II and III possesses marked significance for the structure of lignin. In the former type (I) there are no terminal methyl groups, in contrast to the presence of these in each of the latter (II and III). Moreover, members of Series III, when subjected to ethanolysis conditions, do not readily undergo rearrangement, while under similar treatment members of Series II are partially converted to type III.

It follows that if native lignin contains structures of the type Series I these might very well rearrange during ethanolysis to give products containing $-CH_3$ groups and belonging to Series II and III.

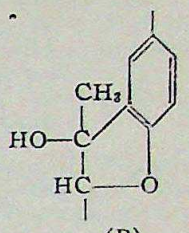
Previous work on the hydrogenation of lignin and of wood under high pressure[17] has demonstrated the presence in native lignin of large amounts of products containing terminal $-CH_2OH$ or $-CH_2-O-CH_2-$ groupings. In a following communication[18] it is shown by a chromic acid oxidation technique that native lignin contains no terminal methyl groups as postulated by Freudenberg, so that the present experimental evidence permits of the conclusion that the ethanolysis products from wood, R—CHOH—$COCH_3$[7]; R—CO—CHOH—CH_3 and R—CO—$COCH_3$ (R = 4-hydroxy-3-methoxyphenyl- or 4-hydroxy-3,5-dimethoxyphenyl-), represent stabilized end products derived from a more reactive lignin progenitor[3b], namely, the keto form of oxyconiferyl alcohol. The present experimental observation that hydrolysis with aqueous barium carbonate or potassium acetate of the chloroketone R—CH_2—CO—CH_2Cl (Series I) yields a small amount of the diketone, R—CO—$COCH_3$, in addition to the main product R—CHOH—$COCH_3$, is of marked significance in this connection.

The present experimental results bring into contrast the marked divergence of theoretical views on the structure of lignin advocated by Freudenberg and by Hibbert.

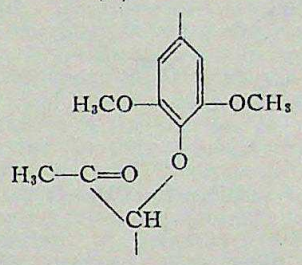
According to the former investigator[19] native spruce lignin consists of the polymeric forms of propylphenol units (A) and (B) essentially derived by condensation reactions from the two building stones R—CHOH—CHOH—CH_2OH and R—CHOH—CO—CH_3 (R = 4-hydroxy-3-methoxyphenyl).



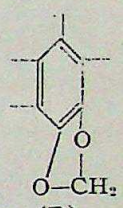
(A)



(B)



(C)



(D)

Freudenberg considers that five out of eight units in spruce lignin belong to types (A) and (B), two units contain methylenedioxy groups, type (D), and one is of the pyrogallol type (C).

Hibbert has pointed out repeatedly[20,21] the complete lack of experimental evidence supporting Freudenberg's claim of the presence of the piperonyl type (D) (based on the amount of formaldehyde formed on hydrolysis of an "extracted" lignin[18]) and has suggested "that the formaldehyde (1–4%) is formed from an aromatic side-chain, possibly one existing as part of a complex present in lignin condensation polymers and similar to cinnamyl alcohol."[21]

Freudenberg has now accepted this explanation[22] in his very recent abandonment of type (D) as part of the native lignin aggregate. His type (B) is characterized by the presence of terminal methyl groups while type (A) could give rise to a minor amount of free primary alcohol groups. No adequate experimental evidence is available indicating the presence in spruce lignin of his type (C)—syringyl component—in other than minute quantity. Up to the present Freudenberg has not been successful in isolating any propylphenol lignin units.

Hibbert regards native lignin as a mixture of polymers derived by condensation reactions from a different type of propylphenol building unit, oxyconiferyl alcohol ($\beta\gamma$-dioxyisoeugenol) the keto form of which is R—CH_2—CO—CH_2OH.

Polymer formation is assumed to occur by one or more of three mechanisms (E), (F), (G).

The syringyl lignin building unit R′—CH_2—$COCH_2OH$ (R′ = 4-hydroxy-3,5-dimethoxyphenyl) is assumed by Hibbert to be present in

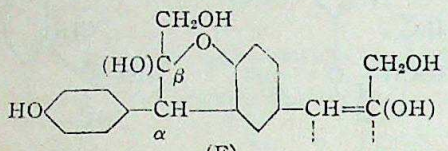
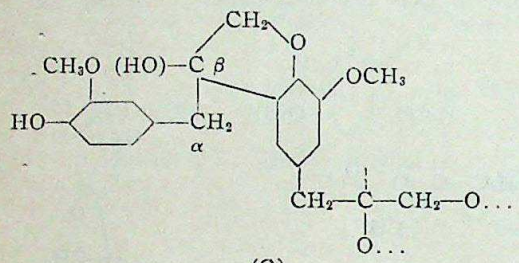
(E)



(F)



(G)

the native lignin of all angiosperms and is probably present as the initial monomeric building-stone since the blocking by methoxyl groups of both positions ortho to the phenol group would prevent polymerization proceeding in the manner indicated above.

(E) and (F) represent condensation polymers of dehydro-di-(dioxyisoeugenol), while (G) is related to the furan series. Available experimental evidence does not permit of a distinction between the three types but it is evident that they differ markedly in structure from those proposed by Freudenberg, and in particular are distinguished by the absence of methyl groups.

Removal of water from the positions (α) and (β) would yield an unsaturated type, capable of forming cross linkages, and such may form part of the native lignin aggregate.

These structural theories of Freudenberg and of Hibbert are still highly speculative in character. The source of the small quantity of monomolecular ethanolysis products obtained in the case of spruce, and of the much larger amount in the case of maple, is still unknown. That they are derived from oxyconiferyl and oxysyringyl alcohols now seems reasonably certain, but the actual form in which the latter are present in native lignin, whether as mono- or diglucosides, phenol ethers, ketals involving the carbonyl and phenol groups, or as readily reversible dimers of the truxillic acid type is, as yet, quite unknown. It would seem somewhat unlikely they are formed from polymers of the type depicted above.

Experimental

1-(3,4-Dimethoxyphenyl)-2-nitro-1-propene.—This was synthesized by the condensation of veratric aldehyde with nitroethane.[23]

(23) Kaufmann, *Ber.*, **52**, 1431 (1919).

1-(3,4-Dimethoxyphenyl)-2-propanone.—1-(3,4-Dimethoxyphenyl)-2-nitro-1-propene was reduced to the oxime by treatment with a mixture of iron dust, ferric chloride and hydrochloric acid and the oxime hydrolyzed to the ketone[11]; yield, 70%; b. p. 118° (0.2 mm.); $n^{25}D$, 1.5330. *Anal.* Calcd. for $C_{11}H_{14}O_3$: C, 68.0; H, 7.2; OCH_3, 32.0. Found: C, 67.8; H, 7.1; OCH_3, 32.0.

1-Bromo-1-(3,4-dimethoxyphenyl)-2-propanone (Series II).—To a solution of 1-(3,4-dimethoxyphenyl)-2-propanone (10.14 g.) and benzoyl peroxide (0.1 g.) in chloroform (100 cc.), contained in a three-necked flask fitted with a dropping funnel, mercury-sealed stirrer and drying tube, bromine (9.6 g.) was added through the dropping funnel over a period of ninety minutes. The temperature of the reaction mixture was kept below 10° by means of an ice-bath. At the conclusion of the addition, the reaction mixture was allowed to attain room temperature and then stirred for two hours. The chloroform solution was washed, successively, twice with cold water, twice with cold 1% bicarbonate solution and finally with water, then decolorized with charcoal and dried over sodium sulfate. Removal of the solvent under reduced pressure yielded a dark oily product, convertible to a white crystalline solid from a mixture of ether and petroleum ether (b. p. 30–50°), m. p. 87–88°; yield 8.5 g. (58%). *Anal.* Calcd. for $C_{11}H_{13}O_3Br$: C, 48.4; H, 4.8; OCH_3, 22.7; Br, 29.3. Found: C, 48.5; H, 4.9; OCH_3, 22.7; Br, 29.5.

Semicarbazone of 1-Bromo-1-(3,4-dimethoxyphenyl)-2-propanone.—Fine white crystals from water, m. p., 201.5–202.5°. *Anal.* Calcd. for $C_{12}H_{16}O_3N_3Br$: C, 43.6; H, 4.9; OCH_3, 18.8. Found: C, 43.8; H, 5.0; OCH_3, 18.7.

1-Hydroxy-1-(3,4-dimethoxyphenyl)-2-propanone (Series II).—1-Bromo-1-(3,4-dimethoxyphenyl)-2-propanone (2.0 g.) was dissolved in 5% potassium acetate (200 cc.) and the solution heated on the steam-bath for four hours. The reaction mixture was extracted with chloroform, the extract dried over sodium sulfate and the solvent removed. The residual oil distilled at 135–145° bath temperature (0.1 mm.); yield of light-yellow distillate which soon solidified, 1.27 g.; recrystallized from a mixture of ether and petroleum ether as white plates, m. p. 76–77°; yield, 0.84 g. (55%). *Anal.* Calcd. for $C_{11}H_{14}O_4$: C, 62.8; H, 6.7; OCH_3, 29.6. Found: C, 63.0, H, 6.8; OCH_3, 29.5

Semicarbazone of 1-Hydroxy-1-(3,4-dimethoxyphenyl)-2-propanone.—White crystals from water, m. p. 155–156°. *Anal.* Calcd. for $C_{12}H_{17}O_4N_3$: C, 53.9; H, 6.4; OCH_3, 23.2. Found: C, 53.8; H, 6.4; OCH_3, 23.0.

Action of Aqueous Potassium Acetate on 1-Hydroxy-1-(3,4-dimethoxyphenyl)-2-propanone (Series II).—The hydroxyketone (0.5 g.) was heated twelve hours (100°) with 5% aqueous potassium acetate (50 cc.) in an atmosphere of carbon dioxide. The reaction mixture was extracted with chloroform and the solvent removed, leaving a yellow oil which distilled at 125–135° bath temperature (0.02 mm.). The distillate quickly solidified and was recrystallized from ether-petroleum ether (b. p. 30–50°). 1-Hydroxy-1-(3,4-dimethoxyphenyl)-2-propanone (0.205 g.) (45%) was recovered, m. p. 76–77°. On evaporation of the mother liquors, a yellow oil (0.230 g., 50%) $n^{25}D$ 1.5610 was obtained. The semicarbazone of this oil when mixed with that of 2-hydroxy-1-(3,4-dimethoxyphenyl)-2-propanone showed no depression in melting point.

Synthesis of 1-Acetoxy-1-(3,4-dimethoxyphenyl)-2-propanone (Series II)

(a) Acetylation of 1-Hydroxy-1-(3,4-dimethoxyphenyl)-2-propanone.—The hydroxyketone was acetylated with acetyl chloride and pyridine,[24] yield, 1.6 g. (89%); $n^{25}D$ 1.5260. Fractional distillation showed that this acetate was a pure homogeneous product. *Anal.* Calcd. for $C_{13}H_{16}O_5$: C, 61.9; H, 6.4; OCH_3, 24.6. Found: C, 62.0; H, 6.3; OCH_3, 24.6.

2,4-Dinitrophenylhydrazone of 1-Acetoxy-1-(3,4-dimethoxyphenyl)-2-propanone.—Orange crystals from ethanol, m. p. 149–150°. *Anal.* Calcd. for $C_{19}H_{20}O_8N_4$: C,

52.8; H, 4.7; OCH_3, 14.4. Found: C, 52.5; H, 4.8; OCH_3, 14.5.

(b) **Treatment of 1-(3,4-Dimethoxyphenyl)-2-propanone with Lead Tetraacetate.**—1-(3,4-Dimethoxyphenyl)-2-propanone (2.3 g.) was dissolved in glacial acetic acid (80 cc.) and freshly prepared lead tetraacetate (7 g.)[25] added. The mixture was heated for eight hours at 88° in a two-necked flask equipped with a mercury-sealed stirrer and a condenser. The solution was decanted into water (400 cc.) and the aqueous solution extracted with ether. The ether extract was washed with 5% sodium bicarbonate, then with water, and dried over sodium sulfate. Removal of the solvent left a dark-colored oil which distilled at 160–190° bath temperature (0.1 mm.); yield 2.2 g. (74%); $n^{25}D$ 1.5290. On fractional distillation (0.2 mm.) the greater part of this material distilled over as pure 1-acetoxy-1-(3,4-dimethoxyphenyl)-2-propanone. Its 2,4-dinitrophenylhydrazone when mixed with that prepared from the pure synthetic product (previous experiment) showed no depression in melting point.

Homoveratric Acid.—α-Chloro-homoveratric amide[12a] (6.0 g.) was dissolved in glacial acetic acid (20 cc.) and constant-boiling hydriodic acid (8 cc.) added. After standing for fifteen hours at room temperature the reddish-purple crystalline precipitate (22 g.) was filtered, dried *in vacuo* and added to a well-stirred, saturated solution of sodium bisulfite. Addition of ammonium hydroxide to the bisulfite solution precipitated the homoveratric amide (4.2 g., 82%) m. p. 141–144°. The amide was then hydrolyzed to homoveratric acid.[12a]

3-Bromo-1-(3,4-dimethoxyphenyl)-2-propanone (Series I).—Homoveratric acid was converted to the acid chloride, the latter treated with diazomethane and the resulting diazomethyl ketone allowed to react with hydrogen bromide in ether. The method used was identical with that employed for the preparation of 3-chloro-1-(3,4-dimethoxyphenyl)-2-propanone (Series I),[10] X = Cl. Yield of the bromide 80%; recrystallized from a mixture of ether and petroleum ether, m. p. 44–45°. *Anal.* Calcd. for $C_{11}H_{13}O_3Br$: OCH_3 22.7. Found: OCH_3, 22.5.

3-Acetoxy-1-(3,4-dimethoxyphenyl)-2-propanone (Series I).—Homoveratric acid (1.4 g.) was treated with pure thionyl chloride (2.0 cc.) for fifteen minutes at room temperature and then at 70° for an additional thirty minutes. The excess thionyl chloride was removed under reduced pressure and the residual product freed from last traces by two additions and removals of benzene. The light orange-colored oil was dissolved in ether and the solution added gradually to a cold solution of diazomethane in ether (prepared from 4 g. of nitrosomethyl urea). After standing at 0° for three hours, the ether was distilled off and the residual diazomethyl ketone refluxed with glacial acetic acid (20 cc.) for fifteen minutes. The acetic acid was removed under reduced pressure and the residue distilled at 165–190° (bath temperature) (0.1 mm.); yield of light-yellow oil, which solidified with difficulty, 1.44 g. (85%); white needle-like crystals from a mixture of ether and petroleum ether, m. p. 55–56°. *Anal.* Calcd. for $C_{13}H_{16}O_5$: C, 61.9; H, 6.4; OCH_3, 24.6. Found: C, 62.0; H, 6.4; OCH_3, 24.8.

Semicarbazone of 3-Acetoxy-1-(3,4-dimethoxyphenyl)-2-propanone.—White crystals from water and from ethanol–petroleum ether, m. p. 128–129°. *Anal.* Calcd. for $C_{14}H_{19}O_5N_3$: C, 54.4; H, 6.3; OCH_3, 20.1. Found: C, 54.4; H, 6.3; OCH_3, 20.2.

Synthesis of 1-(3,4-Dimethoxyphenyl)-1,2-propanedione.—To a hot solution of copper sulfate (1.45 g.) dissolved in pyridine (2.4 cc.) and water (1.2 cc.), was added 1-hydroxy-1-(3,4-dimethoxyphenyl)-2-propanone (Series II, X = −OH) (0.50 g.) and the resulting solution heated on the steam-bath for two hours. The reaction mixture was poured with stirring into 3 *N* hydrochloric acid (14 cc.) and the acid solution extracted with ether. Removal of the ether yielded a yellow solid (0.30 g.); recrystallized from a mixture of ether and petroleum ether, m. p. 69–70°. *Anal.* Calcd. for $C_{11}H_{12}O_4$: OCH_3, 29.8. Found: OCH_3, 29.7°. Oxidation of 2-hydroxy-1-(3,4-dimethoxyphenyl)-1-propanone (Series III), in a similar manner, yielded the same diketone.

Semicarbazone of 2-Hydroxy-1-(3,4-dimethoxyphenyl)-1-propanone.—A solution of 2-hydroxy-1-(3,4-dimethoxyphenyl)-1-propanone[5a] (0.1 g.), semicarbazide hydrochloride (0.1 g.) and potassium acetate (0.2 g.) in water (5 cc.) was heated at 70° for two hours and then allowed to stand at room temperature for one week; white crystals from water, m. p. 154–155°. *Anal.* Calcd. for $C_{12}H_{17}O_4N_3$: C, 53.9; H 6.4; OCH_3, 23.2. Found: C, 53.8; H, 6.5; OCH_3, 23.1.

Reaction of 1-Bromo-1-(3,4-dimethoxyphenyl)-2-propanone (Series II) with Silver Acetate and Ethanol.—1-Bromo-1-(3,4-dimethoxyphenyl)-2-propanone (2.0 g.) was dissolved in ethanol (150 cc.) and silver acetate (2.0 g.) added. The suspension was refluxed for twelve hours in an atmosphere of carbon dioxide. The silver bromide was filtered, the filtrate taken to dryness under reduced pressure and the residue distilled at 140–150° bath temperature (0.1 mm.); yield, 1.53 g. (88%). The 2,4-dinitrophenylhydrazone of this product, m. p. 141–142°, when mixed with the 2,4-dinitrophenylhydrazone of 1-ethoxy-1-(3,4-dimethoxyphenyl)-2-propanone[8] showed no depression, but when mixed with that of 2-ethoxy-1-(3,4-dimethoxyphenyl)-1-propanone showed a marked depression.

Reaction of 3-Chloro-1-(3,4-dimethoxyphenyl)-2-propanone (Series I) with Silver Acetate and Ethanol.—3-Chloro-1-(3,4-dimethoxyphenyl)-2-propanone was treated with silver acetate and ethanol in a similar manner. The resulting product was fractionally distilled (0.2 mm.) yielding 1-ethoxy-1-(3,4-dimethoxyphenyl)-2-propanone (Series II, X = $-OC_2H_5$) (approx. 60%) and a high alkoxyl-containing compound (alkoxyl, 43.5%) which was not investigated further.

Behavior of 1-Hydroxy-1-(3,4-dimethoxyphenyl)-2-propanone (Series II) toward 2% Ethanolic Hydrogen Chloride.—1-Hydroxy-1-(3,4-dimethoxyphenyl)-2-propanone (1.5 g.) was dissolved in a 2% solution of hydrogen chloride in ethanol (150 cc.) and the mixture refluxed for forty-eight hours under an atmosphere of carbon dioxide. The reaction product was neutralized with solid sodium bicarbonate, filtered and the filtrate taken to dryness under reduced pressure. The residual oil was dissolved in ether and the ether solution extracted with 10% sodium bisulfite. The ether solution was then dried and the solvent removed. The residue distilled at 120–130° bath temperature (0.05 mm.); yield of pale-yellow distillate, which soon solidified, 1.406 g. The product was treated with a small amount of warm petroleum ether, and the insoluble material (0.792 g.) filtered off and washed; recrystallized from dilute ethanol, m. p. 81–82°; no depression in melting point when mixed with an authentic sample of 2-ethoxy-1-(3,4-dimethoxyphenyl)-1-propanone (Series III).

The combined petroleum ether filtrate and washings were taken to dryness and the residual oil (0.561 g.) converted to the 2,4-dinitrophenylhydrazone; recrystallized from ethanol, m. p. 141–142°; no depression in melting point when mixed with the 2,4-dinitrophenylhydrazone of 1-ethoxy-1-(3,4-dimethoxyphenyl)-2-propanone (Series II).

The bisulfite extract from the original ether solution was neutralized, the sulfur dioxide removed, and the resulting solution extracted with ether. Removal of the ether left a small amount of bisulfite-soluble material (0.04 g.) which was not investigated.

Reaction of 3-Chloro-1-(3,4-dimethoxyphenyl)-2-propanone (Series I) with Aqueous Potassium Acetate, Barium Carbonate and Silver Oxide.—The chloroketone (3.3 g.) was refluxed with 5% aqueous potassium acetate (250 cc.) for five hours and the solution then extracted with chloroform. The extract was dried over sodium sulfate and the solvent removed. The residue was recrystallized from ether, yielding white crystalline material (1.5 g.), m. p., 76–77°; no depression in melting point when mixed with an authentic sample of 1-hydroxy-1-(3,4-dimethoxyphenyl)-2-propanone (Series II, X = −OH). The filtrates from the recrystallizations were taken to dry-

ness and the residue (A) fractionally distilled in the Cooke-Bower fractionating column[26] at 0.1-mm. pressure. About 20% (0.35 g.) of the starting material (A) was obtained as a yellow crystalline solid and after recrystallization from ether melted at 68–69°. A mixed melting point determination, with 1-(3,4-dimethoxyphenyl)-1,2-propanedione showed no depression. The remainder of the material was not identified.

Reaction of 3-Chloro-1-(3,4-dimethoxyphenyl)-2-propanone (Series I) with a Mixture of Potassium Acetate and Glacial Acetic Acid.—The chloroketone (8.0 g.) was dissolved in glacial acetic acid (35 cc.), freshly-fused potassium acetate (21 g.) added, and the resulting solution heated for eight hours at 90–100°. The reaction mixture was diluted with water (300 cc.), neutralized with sodium carbonate, and extracted with chloroform. The extract was dried, the solvent removed and the residue fractionally distilled under reduced pressure. Each of the fractions obtained was semicrystalline. The crystalline material (40%) was separated on a porous plate and recrystallized from a mixture of ether and petroleum ether, m. p. 65–66°; no depression when mixed with an authentic sample of 2-acetoxy-1-(3,4-dimethoxyphenyl)-2-propanone (Series III).

Reaction of 1-Hydroxy-1-(3,4-dimethoxyphenyl)-2-propanone (Series II) with 5% Sulfuric Acid.—The hydroxyketone (0.4 g.) was heated at 70–80° with 5% sulfuric acid (100 cc.) for three and one-half hours and the solution extracted with chloroform. The chloroform extract was dried and the solvent removed. The residue was recrystallized from ether yielding the pure unchanged 1-hydroxy-1-(3,4-dimethoxyphenyl)-2-propanone (0.35 g.).

Reaction of 2-Hydroxy-1-(3,4-dimethoxyphenyl)-1-propanone (Series III) with Aqueous Potassium Acetate.—The hydroxyketone (0.5 g.) was refluxed for four hours with 5% aqueous potassium acetate (75 cc.). From the solution the starting material was recovered as the semicarbazone (m. p. 153–155°) in 40% yield. No 1-hydroxy-1-(3,4-dimethoxyphenyl)-2-propanone could be detected.

Reaction of 3-Chloro-1-(3,4-dimethoxyphenyl)-2-propanone (Series I) with Methanolic and Ethanolic Alkali.—The chloroketone (2.5 g.) was dissolved in methanol (15 cc.) and a solution of sodium (0.32 g.) in methanol (16 cc.) added dropwise at room temperature. The alkaline solution was acidified very slightly with hydrochloric acid, and then neutralized by addition of solid sodium bicarbonate, filtered and the filtrate taken to dryness under reduced pressure. The residue (1.75 g.) was recrystallized from petroleum ether (b. p. 30–50°) and then from aqueous ethanol; m. p. 40–41°. *Anal.* Calcd. for $(CH_3O)_2$—C_6H_3—$C_3H_4O(OCH_3)$: C, 64.3; H, 7.1; OCH_3, 41.5; mol. wt., 224. Found: C, 64.2; H, 7.0; OCH_3, 41.7; mol. wt. (Rast), 234.

Treatment of the same chloroketone with *methanolic* potassium hydroxide yielded the same compound in 80% yield.

The substitution of *ethanol* for *methanol* and sodium *ethylate* for sodium *methylate* in this experiment yielded the corresponding ethyl ether; b. p. 104° (0.04 mm.); $n^{25}D$ 1.5150; alkoxyl, calcd. for $(CH_3O)_2$—C_6H_3—$C_3H_4O(OC_2H_5)$, 39.1. Found, 39.2.

Treatment of these reaction products with semicarbazide or acidified 2,4-dinitrophenylhydrazine yielded no carbonyl derivatives.

Summary

1. Four new substances, namely, 1-bromo-, 1-hydroxy-, 1-acetoxy- and 3-acetoxy-1-(3,4-dimethoxyphenyl)-2-propanone have been synthesized.

2. The allylic and dismutation rearrangement reactions attendant upon the conversion of the two halides, 1-bromo-1-(3,4-dimethoxyphenyl)-2-propanone and 3-chloro-1-(3,4-dimethoxyphenyl)-2-propanone to the corresponding alcohols, acetates and ethyl ethers have been studied under a variety of conditions.

3. The ease with which these rearrangements occur provides valuable confirmation of the theory of Hibbert that the ethanolysis products from wood are in reality stabilized end-products formed from more reactive lignin progenitors of the type represented by oxyconiferyl alcohol (β,γ-dioxyisoeugenol) or its keto isomer, and provides strong support for his views on the structure of native lignin.

Studies on Lignin and Related Compounds. LXXV. Alkaline Nitrobenzene Oxidation of Plant Materials and Application to Taxonomic Classification[1]

BY R. H. J. CREIGHTON, R. DARNLEY GIBBS AND HAROLD HIBBERT

The two types of classification recognized by botanists for higher plants are (1) an *artificial* classification, or "key," compiled merely for the purpose of identification and based on any *obvious* characteristic, such as flower or leaf morphology, convenience being the sole criterion; (2) a *natural* one in which all available criteria should be employed[2] to indicate true relationships between species, genera, etc. In general, flower morphology is the most suitable basis for classification, but many other criteria (*e. g.*, morphology of other parts, cytology, comparative anatomy and chemistry) have been employed occasionally for its support.

Chemical methods have been employed in clarifying the relationships of many closely related species. Thus, Manske[3] has pointed

out that the structures of the alkaloids present in closely-related plants may serve to distinguish between species regarded as identical on the basis of morphology.

Miller[4] found the essential oils of three species of *Pycnanthemum*, *P. tullia*, *P. incanum* and *P. lanceolatum* (plants between which it is difficult to differentiate on morphological grounds) to differ markedly.

McNair's[5] studies of the essential oils from eighty-seven plants and families led him to conclude that their structure is closely related to the position of the plant in the phylogenetic scale.

Cole and Cardoso[6] isolated from members of the family *Flacourtiaceae* the five-membered ring fatty acids, gorlic acid, chaulmoogric acid, and several of the lower homologs of the latter. Of the eleven tribes or subfamilies which comprise the family *Flacourtiaceae*,[7] it is only from the *Oncobeae* (which according to Gilg is the central tribe) and the closely-related *Pangieae* that these acids have been isolated and identified. They contain an asymmetric carbon atom, and other members of the *Oncobeae* and *Pangieae* whose fatty acids have not yet been studied in detail have also yielded optically active fatty acids.

Reichert[8] has examined the starch grains from a large number of plant species and concludes that they "constitute a strictly scientific basis for the classification of plants." Both Reichert[8] and Carles[9] have carried out extensive investigations of the family *Iridaceae* which, as now classified, contains a number of genera, some of which (*e. g.*, *Moraea* and *Homeria*) differ so widely in the reactions of their starches as to suggest misclassification. In general, their results support the earlier classification of Tournefort[10] rather than the more modern one.[11]

A close relationship exists between the proteins in certain plant extracts and the plant species,[12] in that, as the degree of relationship between species diminishes, the number of common proteins present in the plant extracts decreases proportionately. Mez and co-workers[13] on the basis of their serological investigations have constructed a "family tree" of the vegetable kingdom. The indicated phylogenetic relationships are in general accepted by taxonomists. Where differences occur Mez's results may sometimes express the truer phylogenetic relationships, though some of his serological relationships are obviously false.

The role of lignin in plant taxonomy has been confined largely to lignin color reactions, of which the Mäule test[14] has been the most valuable.

Crocker,[15] employing a wide variety of botanical groups, found that the three genera included in the *Gnetales*, namely, *Gnetum*, *Ephedra* and *Welwitschia*, all gave strongly positive Mäule tests. In general, all of the *Coniferales* gave the expected negative test, but one of the *Podocarpus* species, namely, *P. amarus*, gave a strongly positive test. Crocker's work has recently been extended by Gibbs[16] and some of his findings are included here for comparison with the present results obtained by nitrobenzene oxidation.

Analytical data have shown that a marked difference exists between the lignins isolated from the gymnosperms or "softwoods" and those isolated from the angiosperms or "hardwoods." The lignins of the former type contain 14–16% methoxyl and the latter up to 20–22%. Holmberg,[17] employing thioglycolic acid as the lignin extraction agent, investigated the extracted lignins from over fifty plant species. His results showed that, while the lignins from all of the higher plants were essentially uniform in type, the carbon analyses of lignins isolated from the gymnosperms were generally 3–5% higher than those from the angiosperms, the oxygen values of the latter lignins being correspondingly higher, even in the case of certain monocotyledons in which low methoxyl values (16.9 to 17.1%) were found. Similar results were obtained by Klason,[18] in his analyses of β-lignin sulfonic acids from various woods. He found that the lignins from gymnosperms had the formula $C_{10}H_{10}O_3$ and those from angiosperms the formula $C_{10}H_{10}O_4$. More recently further confirmation of chemical differences between the lignins from gymnosperms and angiosperms, respectively, has been secured in analyses of products obtained in the ethanolysis of wood by Hibbert and co-workers.[19] They showed that the lignin from angiosperms differs from that from gymnosperms in that in the former there are present both the 4-hydroxy-3-methoxyphenyl and the 4-hydroxy-3,5-dimethoxyphenyl nuclei, whereas in the latter the 4-hydroxy-3-methoxyphenyl nucleus only is present. Thus spruce wood, when subjected to ethanolysis, yields a mixture of 2-ethoxy-1-(4-hydroxy-3-methoxyphenyl)-1-propanone (I), 1-ethoxy-1-(4-

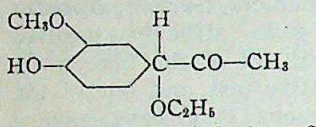
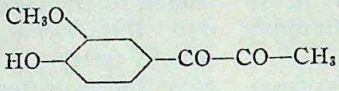
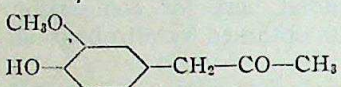
I. 2-Ethoxy-1-(4-hydroxy-3-methoxypheny)-1-propanone



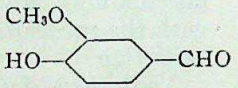
II. 1-Ethoxy-1-(4-hydroxy-3-methoxyphenyl)-2-propanone



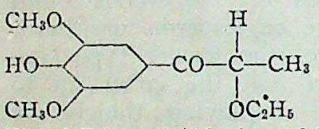
III. 1-(4-Hydroxy-3-methoxyphenyl)-1,2-propanedione



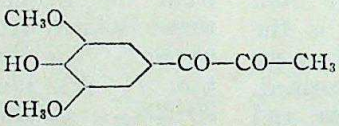
IV. 1-(4-Hydroxy-3-methoxyphenyl)-2-propanone



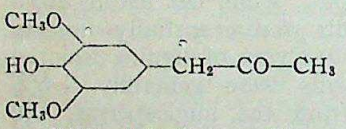
V. Vanillin



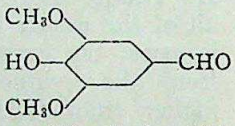
VI. 2-Ethoxy-1-(4-hydroxy-3,5-dimethoxyphenyl)-1-propanone



VII. 1-(4-Hydroxy-3,5-dimethoxyphenyl)-1,2-propanedione



VIII. 1-(4-Hydroxy-3,5-dimethoxyphenyl)-2-propanone



IX. Syringaldehyde

hydroxy-3-methoxyphenyl)-2-propanone (II), 1-(4-hydroxy-3-methoxyphenyl)-1,2-propanedione (III), 1-(4-hydroxy-3-methoxyphenyl)-2-propanone (IV) and vanillin (V). Maple wood on similar treatment gives, in addition, the corresponding syringyl analogs (VI, VII, VIII and IX), the combined yields of pure products from angiosperms and gymnosperms amounting to 9.7 and *ca.* 3%, respectively. With certain monocotyledons, the presence of the syringyl compounds could not be definitely established.[19c]

More recently, employing the nitrobenzene oxidation technique of Freudenberg[20] spruce is found to give only vanillin upon oxidation, in a yield of 24% based on the initial Klason lignin, while maple and other dicotyledons give a combined yield of a mixture of vanillin and syringaldehyde of as high as 49%.[21] The ratio of vanillin to syringaldehyde in the isolated mixture was shown to be approximately 1:3. The monocotyledons investigated (consisting of several grasses) gave slightly lower yields of aldehydes (up to 30%), and the ratio of vanillin to syringaldehyde was approximately 1:1. A more recent investigation shows that the vanillin fraction isolated from these monocotyledons (all belonging to the grasses) contains a mixture of vanillin and *p*-hydroxybenzaldehyde.[22]

In the present investigation the above alkaline nitrobenzene oxidation technique has been applied to over fifty plant species and the results confirm in general those obtained in the earlier work. Certain exceptions were found, however, which suggest that the method may provide a possible aid to the taxonomist in establishing the true phylogenetic relationships of certain plant species.

The procedure was essentially that previously outlined.[21] Due to the difficulty in obtaining sufficiently large quantities of material in certain cases, a reduction in the amount of starting material was found necessary. In these cases the time of reaction could be reduced from three to two hours, and the tedious step of steam distillation eliminated, when only the bisulfite soluble fraction called for investigation. The mixture of aldehydes obtained in the case of the angiosperms was separated by means of fractional sublimation of the crude mixture.[21]

Whenever possible, fresh plant material was employed, although in certain cases, notably with *Podocarpus amarus*, *P. pedunculatus* (see below), *Paulownia imperialis*, *Drimys winteri*, *Trochodendron sp.*, *Zygogynum vieillardi* and *Belliolum haplopus* (Burtt), A. C. Smith, museum specimens were used. In all cases the air-dried chips were ground to 40-mesh in a Wiley mill and solvent-extracted before use.

Podocarpus pedunculatus is not recognized by Pilger[23] but is regarded as synonymous with *P. amarus*. The close agreement found in this investigation between the two species (Table I) lends support to his views.

The results of the alkaline nitrobenzene oxidation of fifty species are shown in Tables I, II and III.

Unless otherwise specified, the air-dried wood chips were ground to 40-mesh in the Wiley mill, the resulting wood meal extracted successively with 50:50 ethanol–benzene (forty-eight hours), ethanol (twenty-four hours) and hot water (twelve hours), then air-dried, and the moisture content determined by drying a 2-g. sample overnight at 105°. The Klason lignin was determined on the oven-dried sample by the method of Ritter, Seborg and Mitchell[24] involving the use of 72% sulfuric acid.

The commonly accepted gymnosperms (Table I, Expts. 1–12) gave only vanillin, in yields of 15–24% calculated on the Klason lignin content

7	*Saccharum officinarum*	16.4	16.3	5.3	9.0	1:1.7	+

[a] Based on dry wood weight. [b] Based on weight of initial Klason lignin. [c] "Vanillin fraction" consists of vanillin plus *p*-hydroxybenzaldehyde. [d] Ethanol–benzene extracted meal was used for these tests (all other Mäule tests were on *untreated* plant material).

of the wood, while the dicotyledons (Table II, Expts. 1–24) yielded 35–51% of a mixture of vanillin and syringaldehyde in an approximate ratio of 1:3. The monocotyledons (Table III, Expts. 1–7) gave lower yields of mixed aldehydes (16.3 to 37.1%). In the grasses (Table III, Expts. 4 and 6) (excepting *Saccharum officinarum*) the presence of a third non-methoxyl-containing aldehyde, admixed with the vanillin, was indicated from the lower methoxyl values. As shown in the following communication, the aldehyde was *p*-hydroxybenzaldehyde.

A number of interesting exceptions were found to the above chemical differentiation between gymnosperms and angiosperms. Three species belonging to the *Coniferales*, namely, *Podocarpus amarus*, *P. pedunculatus* and *Tetraclinis articulata* (Table I) and also members of all the genera included in the *Gnetales* (Table I, Expts. 19–22) were found to give not only vanillin but also high yields of syringaldehyde. These species also gave a positive Mäule test, and a comparison of the results of this with the nature of the aldehydes formed on oxidation shows that a close correlation exists between the occurrence of the syringyl nucleus in the lignin of plants and the red coloration obtained in the positive Mäule test. From *Podocarpus macrophyllus v. maki*, which was found to give a very weakly positive Mäule test, the presence of the syringyl grouping could not be definitely established. In one experiment (Table I, Expt. 12) fractional crystallization of the *m*-nitrobenzoylhydrazone of the last sublimation fraction gave a trace (0.003 g.) of a hydrazone (m. p. 191–193°) which showed no mixed melting point depression with the *m*-nitrobenzoylhydrazone of syringaldehyde (m. p. 192–193°). In repeating this experiment with larger amounts of material (from a different source) (Table I, Expt. 13) and fractionating the bisulfite fraction in a semi-micro Cooke–Bower fractionating column[25] no syringaldehyde could be found. It should be emphasized, however, that the Mäule test was only *very* faintly positive with this species. The case of *Tetraclinis articulata* is particularly interesting. It has recently been separated from *Callitris* by the taxonomists and this separation is clearly supported by the chemical evidence (Table I, Expts. 16 and 17).

With *Belliolum haplopus* and *Zygogynum vieillardi* (Table II, Expts. 25, 26) the ratio of vanillin to syringaldehyde was found to be 1:1.1 and 1:1.2, respectively, proving to be, in this respect, the sole exception met with in a wide variety of dicotyledons. Both species were found to contain large amounts of Klason lignin (35 and 37%, respectively), while the yields of aldehydes based on same were only 29.6 and 32.8%. The results are of interest since these two species belong to a group of primitive angiosperms comprising the families *Magnoliaceae*, *Winteraceae* and *Trochodendraceae*, all of which are characterized by the absence of vessels. According to the most recent classification of these groups, *Belliolum* and *Zygogynum* are included, along with *Drimys winteri* (Table II, Expt. 24) in the Winteraceae while *Liriodendron* (Table II, Expt. 22) and *Trochodendron* (Table II, Expt. 23) are placed in the Magnoliaceae and Trochodendraceae, respectively. The very marked difference in the chemical behavior of *Belliolum* and *Zygogynum*, as compared with *Drimys* and also with *Trochodendron* and *Liriodendron*, suggests that further work is necessary to clarify the classification of this group of plants.

Of marked interest concerning lignin structure are the many high yields of mixed aldehydes (ratio vanillin to syringaldehyde 1:3) obtained from angiosperms amounting to 51% of the Klason lignin in the case of silver maple. If, as suggested by one of us (H. H.), native maple lignin is derived essentially from a dimeric and polymeric mixture of oxyconiferyl and oxysyringyl alcohols, and assuming the dimer units are formed by the loss of a molecule of water, the above percentage in terms of these anhydropropylphenol building units would amount to approximately 61%. This provides substantial support for the view that native maple lignin is derived *entirely* from propylphenol building units, the variations in yield between the different species being due to variations in the amounts of the polymeric forms present.

The very marked parallelism between the red color obtained on testing with the Mäule reagent and the definitely proven presence of the syringyl radical indicates the possibility of using the oxidation technique as a chemical means for checking taxonomic classification.[26]

Acknowledgment.—The authors wish to thank the numerous friends who so kindly provided much of the plant material used in this investigation and to express their appreciation of the valuable assistance rendered by Miss Jean Rosten in the preparation and analysis of the wood samples. One of us (R. H. J. C.) also desires to thank the Canadian Pulp and Paper Association for their financial assistance.

Summary

1. Alkaline nitrobenzene oxidation of forty-seven widely varying accepted forms of gymnosperms and angiosperms has shown that in practically all cases the former yield only vanillin, while the latter give both vanillin and syringaldehyde. This confirms the earlier findings of Hibbert and co-workers.

2. The yields of vanillin, in the case of the gymnosperms, vary between 15 and 24%, based on the Klason lignin. With the angiosperms the combined yield of vanillin and syringaldehyde amounts to 35–51%, the ratio of the former to the latter being approximately 1:3.

3. Considering the highest combined aldehyde yield (silver maple 51%) obtained, this amounts to 61% of the Klason lignin based on the assumption that the native maple lignin is derived essentially from a mixture of anhydro polymeric forms of coniferyl and syringyl alcohols.

4. Exceptions to the above ratio (1:3) of mixed aldehydes were found in the case of certain primitive angiosperms characterized by the absence of vessels, the ratio in this case being 1:1.

5. All genera of the *Gnetales* (a group of uncertain position) gave both vanillin and syringaldehyde on oxidation, a result in harmony with their high lignin and methoxyl values and behavior with the Mäule reagent. Their relationship to the angiosperms rather than to the gymnosperms is thus indicated.

6. Only a very few members of the *Coniferales* were found to yield, on oxidation, an aldehyde mixture containing *both* vanillin and syringaldehyde and to give a definite Mäule reaction.

7. The behavior on oxidation of all the plants investigated is in complete agreement with their color reaction (or its absence) when tested with the Mäule reagent, and thus offers a new chemical procedure for taxonomic classification.

(26) It is the authors' intention to isolate the red coloring matter obtained by treatment of angiosperms with the Mäule reagent with the object of establishing therein the presence of the syringyl nucleus.

Studies on Lignin and Related Compounds. LXXVI. Alkaline Nitrobenzene Oxidation of Corn Stalks. Isolation of *p*-Hydroxybenzaldehyde

BY R. H. J. CREIGHTON[1] AND HAROLD HIBBERT

Alkaline nitrobenzene oxidation of a wide variety of woods[2] has been shown to give high yields of vanillin from gymnosperms and of a mixture of vanillin and syringaldehyde from dicotyledons.

Certain monocotyledons, notably corn (cobs and stalks), bamboo and rye straw, yielded, in addition to vanillin and syringaldehyde, a non-methoxylated carbonyl derivative which could not be separated from vanillin by sublimation. The absence of methoxyl was indicated in the much lower values found for the crude *m*-nitrobenzoylhydrazones derived from the bisulfite fraction[2] isolated from the oxidation products.

The bisulfite fraction from the nitrobenzene oxidation of corn stalks has been reinvestigated and a separation of the unknown product from vanillin effected, based on solubility differences

in cold benzene. The non-methoxyl-containing constituent has been identified as *p*-hydroxybenzaldehyde. The yields of the three aldehydes obtained in the oxidation of corn stalks are summarized in Table II.

TABLE II

SUMMARY OF YIELDS FROM THE ALKALINE NITROBENZENE OXIDATION OF CORN STALKS

Fraction	Crude product % Klason lignin	Recrystallized product % Klason lignin
Total aldehydes determined as *m*-nitrobenzoylhydrazones	18.7	
Crude bisulfite soluble oils	16.7	
Total distillable oils	10.3	
Vanillin	5.3	4.5
p-Hydroxybenzaldehyde	1.8	1.4
Syringaldehyde	3.2	2.6

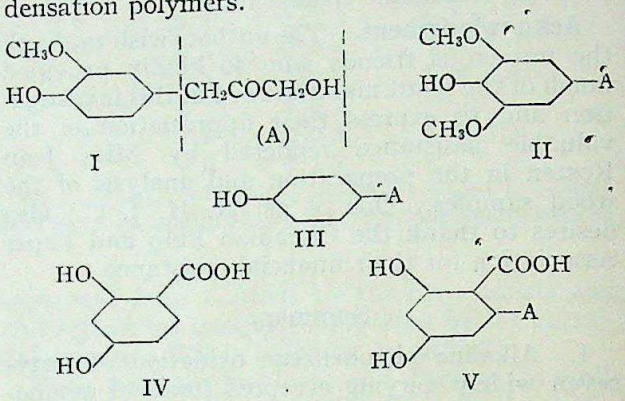
The presence of the *p*-oxyphenylmethane (—O—C_6H_4—C—) grouping in corn cob lignin has been shown previously by Phillips and Goss[3] who isolated anisic acid from the oxidation products of a methylated alkali corn-cob lignin, but obtained only oxalic acid from the unmethylated lignin. Phillips[4] also claims to have obtained anisic acid by permanganate oxidation of a fraction isolated from the dry distillation of an alkali corn cob lignin, presumably unmethylated. It seems likely that one of the products obtained in this same investigation, and characterized by them as a dimethoxycarboxylic acid, $C_8H_6O_2(OCH_3)_2$, was in reality acetosyringone, this having the same empirical composition and melting point, 120.5–121.5°.[5]

The experimental results may provide a means of distinguishing between mono- and dicotyledons. Substantial experimental evidence has been obtained by Hibbert and co-workers to show that the lignin complex in gymnosperms is derived from I; that in angiosperms from I and II.

It is possible that all monocotyledons may contain, in addition to lignins derived from I and II, a new type derived from III, oxidation of which would give *p*-hydroxybenzaldehyde.

On the other hand Raistrick's metabolic products obtained by the action of molds (*Penicillium brevi-compactum*) on glucose as sole substrate[6] contain the aromatic nucleus IV and presumably are also stabilized end products arising from V, the —COOH group being introduced as a secondary type reaction.

A common feature of all plants would seem to consist in their ability to synthesize metabolic products containing a similarly-functioning propyl side-chain (A) attached to a varying type of aromatic phenol unit. The products I, II, III, V, etc., may exist as such or in the form of condensation polymers.



Experimental

Corn-stalk meal (previously extracted successively with ethanol–benzene, ethanol and hot water) (50.0 g. containing 10.0 g. of Klason lignin), nitrobenzene (30 cc.) and aqueous sodium hydroxide (600 cc. of 2 *N*) were heated for three hours at 160° with vigorous agitation as outlined in the previous paper[2]; yield of crude bisulfite soluble oils, 1.503 g.

Separation of Syringaldehyde.—The crude oil (1.503 g.) on distillation yielded two crystalline fractions; (1) b. p. 130–160° (0.2 mm.); 0.825 g.; OCH_3 (of different portions) 12–17%; (2) b. p. 210–230° (0.25 mm.); 0.284 g. The second fraction was recrystallized from water and gave syringaldehyde; m. p. 110–112°; no mixed melting point depression.

Isolation of Vanillin and *p*-Hydroxybenzaldehyde.—Fraction (1) (0.825 g.) was mixed with 10 cc. of dry benzene and stirred for one hour at 20°, the mixture then centrifuged, the benzene-soluble portion evaporated to dryness and re-treated similarly with a further 5 cc. of benzene. The final benzene-soluble fraction left after the second treatment was recrystallized from water, and gave 0.451 g. of pure vanillin; m. p. 81–82°.

The benzene-insoluble fractions from the two treatments were combined, and recrystallized from water; yield, 0.126 g.; white crystalline product, m. p. 116–117°. A mixed melting point with *p*-hydroxybenzaldehyde showed no depression, as was also the case with the phenylhydrazones.

Summary

Oxidation of corn stalks by nitrobenzene and alkali gives, as actual pure products, vanillin, syringaldehyde and *p*-hydroxybenzaldehyde in yields of 4.5, 2.6 and 1.4%, respectively, based on the Klason lignin content of the corn stalks, the crude yields being 5.3, 3.2 and 1.8%, respectively.

This represents the first isolation of *free p*-hydroxybenzaldehyde from lignin. Its presence may serve as a distinguishing characteristic between the mono- and dicotyledons.

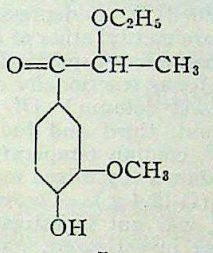
Studies on Lignin and Related Compounds. LXXVII. Re-investigation of the Ethanolysis Products of Maple Wood

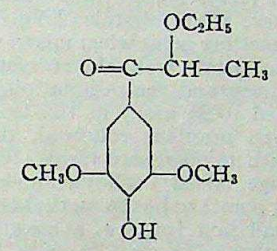
BY MARSHALL KULKA, HERBERT E. FISHER, SAMUEL B. BAKER AND HAROLD HIBBERT

Treatment of maple wood with a 2% solution of hydrogen chloride in ethanol yields around 25–30% of the lignin as a mixture of water-soluble, largely monomeric, propylphenol derivatives (termed ethanolysis oils) which are separable into bisulfite-soluble, alkali-soluble and neutral fractions.[1] The alkali-soluble fraction[2] consists of α-ethoxypropiovanillone [2-ethoxy-1-(4-hydroxy-3-methoxyphenyl)-1-propanone] (I) and α-ethoxypropiosyringone [2-ethoxy-1-(4-hydroxy-3,5-dimethoxyphenyl)-1-propanone] (II). The amount of these two compounds isolated (approximately 5% based on the Klason lignin present in the original wood) constituted only about a third of the total alkali-soluble fraction of the ethanolysis oils.



I

2-Ethoxy-1-(4-hydroxy-3-methoxyphenyl)-1-propanone



II

2-Ethoxy-1-(4-hydroxy-3,5-dimethoxyphenyl)-1-propanone

The purpose of this re-investigation was to separate the components more completely and to identify the unknown components. While (I) and (II) have been isolated in increased yield (3.1 and 3.2%, respectively, based on the Klason lignin present in the original maple wood), due to the complexity of the remaining material no other components could be identified. The improved technique adopted provides a method applicable to a wide variety of plant products and is outlined in Chart I. Fraction D on rectification gave 2-ethoxy-1-(4-hydroxy-3-methoxyphenyl)-1-propanone (I) and 2-ethoxy-1-(4-hydroxy-3,5-dimethoxyphenyl)-1-propanone (II) in yields of 0.7 and 3.2%, respectively.[3] The latter (II), previously isolated as a liquid, was now obtained as a light-colored crystalline compound. Since fraction E decomposes on distillation it was methylated with diazomethane, then fractionally distilled and heterogeneous fractions refractionated in a smaller column. The "crystalline fractions" isolated were identified as the methyl ether of (I) and represented 2.4% based on the Klason lignin present in the original wood.

An investigation of the ether-ammonia-soluble fraction (F) (methoxyl value 15.1%; ethoxyl value 22.8%) showed that only about one-half was precipitable as the 2,4-dinitrophenylhydrazone. This had an indefinite melting point and could not be purified by recrystallization; no other crystalline derivative could be isolated. The product (F) was not readily distillable at low pressures (0.001 mm.) but treatment with diazomethane gave a distillable methylated product from which, however, no pure products could be prepared. Attempts to effect a fractionation of (F) into homogeneous carbonyl- and non-carbonyl-containing fractions by oximation[4] followed by extraction with 10%

Experimental

Separation of the Components of the Alkali-soluble Fraction of Maple Wood (Chart I).—The alkali-soluble ethanolysis oils (31.6 g.) were dissolved in cold absolute ethanol (0°, 450 cc.) and the solution saturated with dry ammonia gas. The cream-colored ammonium salt (A) (10.9 g.) was filtered, washed with a solution of dry ammonia in absolute ethanol and dried *in vacuo*. The solvent was removed from the combined filtrate and washings under reduced pressure at room temperature, the residual oil dissolved in cold anhydrous ether (0°, 250 cc.) and the solution saturated with ammonia at 0°. The ammonium salt (B) was filtered, washed with a solution of anhydrous ammonia in ether and dried *in vacuo*. The ammonium salts (A) and (B) were each dissolved separately in water, the solutions acidified and extracted with benzene. Removal of the solvents yielded three oily fractions, the ethanol-ammonia-insoluble fraction (D) (10.1 g.), the ether-ammonia-insoluble fraction (E) (13.0 g.) and the ether-ammonia-soluble fraction (F) (7.0 g.).

Investigation of the Ethanol–Ammonia-insoluble Fraction (D).—The oil (10.1 g.) was fractionally distilled in the Cooke–Bower column[7] at a pressure of 0.25 mm. Eight fractions were obtained of which the first three (bath temperature range, 161–172°, column temperature range, 100–105°) were light-colored oils and the last five (bath temperature range, 178–193°, column temperature range, 107–112°) were crystalline solids. Each of the crystalline fractions was recrystallized from a mixture of ether and petroleum ether, and from dilute ethanol, m. p. 73–74°; *p*-nitrobenzoyl ester, m. p. 143.5–144.5°; no depression in melting point when mixed with the *p*-nitrobenzoyl ester of 2-ethoxy-1-(4-hydroxy-3,5-dimethoxyphenyl)-1-propanone (II). The first three oily fractions were each again fractionally distilled from a smaller fractionating column (five plates), the resulting fractions methylated with diazomethane and the methylated products recrystallized from petroleum ether, m. p. 80–81°; no depression in melting point when mixed with the methyl ether of 2-ethoxy-1-(4-hydroxy-3-methoxyphenyl)-1-propanone (I). The amounts of each of the components found present in the ethanol-ammonia-insoluble fraction (D) were (I), 1.30 g.; (II), 6.35 g.; unidentified, 0.95 g.

Investigation of the Ether–Ammonia-insoluble Fraction (E).—The oil (E) (13.0 g.) was methylated with diazomethane and to insure complete reaction the non-methylated material was extracted with 5% sodium hydroxide and remethylated. The total methylated product was distilled and yielded two fractions, the first at bath temperature 150–200° (0.05 mm.) (8.6 g.) and the second at bath temperature 200–260° (0.025 mm.) (1.1 g.). The second fraction, a resinous oil, was not investigated further. The first fraction solidified on scratching the container and was recrystallized from a mixture of ether and petroleum ether; white crystals (2.5 g., m. p. 80–81°); no depression in melting point when mixed with pure methyl ether of (I). The filtrate from the recrystallization was evaporated to dryness and the residual oil (6.1 g.) was fractionally distilled (0.25 mm.) in the Cooke-Bower column.[7] Of the seven fractions collected, the second, third and fourth (bath temperature range, 168–180°, column temperature range, 90–92°) solidified and were shown (by mixed melting point) to be the methyl ether of (I) (2.4 g.). The very small first fraction, a colorless oil, was not investigated further. The last fraction, also not investigated, was a high-boiling resinous material probably dimeric or polymeric in type. The fifth and sixth fractions were combined and refractionated in a smaller column. The resulting fractions were of uniform composition ($n^{25}D$ 1.5200; alkoxyl (calcd. as methoxyl), 44.3%), but the 2,4-dinitrophenylhydrazone could not be purified by recrystallization and no other crystalline derivative could be isolated. The amounts of the components of the ether–ammonia–insoluble fraction (E) present were: (I), 4.9 g. (isolated as the pure methyl ether); unidentified, 3.8 g.; the remainder decomposed during fractionation.

Investigation of the Ether–Ammonia-soluble Fraction (F)

(a) **Fractional Distillation.**—The ether–ammonia-soluble fraction (F) (7.0 g.) was methylated completely with diazomethane and the methylated product (6.86 g.) distilled at 160–250° bath temperature (0.25 mm.); yield of light-colored distillate, 4.95 g. or 71%. This distillate (F′) was fractionally distilled (0.25 mm.) in the Cooke–Bower column.[7] The refractive indices of the fractions (F″, F‴, F⁗, etc.) thus obtained varied from 1.5200 to 1.5098 to 1.5312 at 25° and the alkoxyl values from 36.0 to 45.8%. Refractionation of several of these fractions in a smaller column failed to yield products of uniform composition.

(b) **Permanganate Oxidation.**—Portions (0.3 g.) of the different fractions F′, F″, F‴, etc., obtained in the above separation (a) were oxidized at 90–100° by slow addition of a 3% solution of potassium permanganate (50 cc.). The lower-boiling fractions yielded veratric acid (identified by mixed melting point) and the higher-boiling fractions yielded 3,4,5-trimethoxybenzoic acid (similarly identified) in yields of 20–25% by weight. The ratio of lower-boiling to higher-boiling material was approximately 1 to 3.

known components, 2-ethoxy-1-(4-hydroxy-3-methoxyphenyl)-1-propanone and 2-ethoxy-1-(4-hydroxy - 3,5 - dimethoxyphenyl) - 1 - propanone have been increased to 3.1% and 3.2%, respectively, based on the Klason lignin present in the original wood.

2. 2-Ethoxy-1-(4-hydroxy-3,5-dimethoxyphenyl-1-propanone previously reported as being a liquid was isolated in pure form and found to be a well-defined crystalline solid.

3. The material left after removal of the two known components from the alkali-soluble fraction of the ethanolysis oils was found to be a complex mixture, inseparable by fractional distillation, the methylated product containing the 3,4-dimethoxyphenyl- and 3,4,5-trimethoxyphenyl- nuclei in the ratio of 1 to 3.

4. A summary of the work on ethanolysis of maple wood shows that the yield of *pure* compounds isolated was 9.8% of the Klason lignin present in the original wood. In view of the experimental difficulties involved in their separation and isolation this percentage represents a very conservative figure, the *actual* value undoubtedly being appreciably higher.

Studies on Lignin and Related Compounds. LXXVIII. Chromic Acid Oxidation of Lignin-type Substances, Wood Ethanolysis Products and Wood[1]

BY W. S. MACGREGOR, T. H. EVANS AND HAROLD HIBBERT

The importance in lignin chemistry of propylphenol (C_6—C—C—C) units related to coniferyl alcohol is evident from recent reviews on the subject.[2] This is exemplified in the isolation of a considerable amount of wood lignin as hydroxylated propylcyclohexane derivatives from the hydrogenation products of wood;[3] in the isolation from spruce wood ethanolysis products of 2 - ethoxy - 1 - (4 - hydroxy - 3 - methoxyphenyl)-1 - propanone[4] (I), 1 - (4 - hydroxy - 3 - methoxyphenyl)-1,2-propanedione[5] (II), 1-ethoxy-1-(4-hydroxy-3-methoxyphenyl)-2-propanone[6] (III), 1-(4-hydroxy-3-methoxyphenyl)-2-propanone[7] (IV) and, in addition to these, the 4-hydroxy-3,5-dimethoxyphenyl analogs of I, II and IV from maple wood.

Theories concerning the mode of linkage of the propylphenol building-units in native lignin[2,8] are represented on the one hand by the Freudenberg[2a,8] postulate of spruce lignin as a mixture of polymers of the dehydrodiisoeugenol type and, on the other, by Hibbert's theory[2d,8] of native lignins as a series of polymers of dehydrodi-(oxyconiferyl alcohol) [dehydrodi-(β,γ-dioxyisoeugenol)] and dehydrodi-(oxysyringyl alcohol). Freudenberg's polymers are characterized by the presence of terminal methyl groups in the propyl side chains, while in Hibbert's the terminal groups are either primary alcohol groups or ether linkages —O—CH_2—O—, methyl groups being absent. Upon cleavage of these latter types of polymers the side chains would become free to rearrange from the labile —CH_2—$COCH_2OH$ form to the more stable configurations isolated (I-IV). The actual presence of terminal carbinol groups, or end —CH_2—O—CH_2— linkages in native lignin, is proven by the isolation of 1-(4-hydroxycyclohexyl)-3-propanol[3a,3b] and of 1-cyclohexyl-3-propanol[3c] upon hydrogenation of wood. Further, the ease with which the postulated rearrangements of RCH_2COCH_2OH to units I-IV (the latter characterized by the presence of terminal methyl groups)[8] are known to occur also forms supporting evidence for the views of Hibbert[2d,8] that these latter represent stabilized end-products formed from the more reactive R—CH_2COCH_2OH type.

By oxidizing organic substances containing methyl groups with hot, concentrated, aqueous chromic acid and simultaneous steam distillation of the acetic acid formed, Kuhn and l'Orsa[9] were able to account for the total carbon in many compounds as carbon dioxide, or as acetic acid, the yield of the latter being above 85% of theoretical for many structures containing methyl groups, such as CH_3COCH_2—, $CH_3CHOHCH$-OH—, CH_3CH_2O—, and CH_3CH=CH—. Freudenberg[10] oxidized spruce "cuproxam lignin" by the same method and obtained a 6% yield of acetic acid. This low yield, amounting to only twenty per cent. of that theoretically obtainable from his structural lignin polymer,[2a,8] was regarded by him as due to the inadequacy of the experimental technique employed.

In the present investigation the chromic acid oxidation technique has been applied to lignin-type substances, wood ethanolysis products, extracted lignins and woods, in order to obtain further information concerning the structures of native and isolated lignins, and especially to determine the amount of terminal methyl groups present, if any, in the two latter.

17	2-(3,4-Dimethoxyphenyl)-2-propanol	11.1 13.6	36 44
18	Acetophenone[9]		10

As shown in Table I, oxidation with chromic acid of (4-hydroxy-3-methoxyphenyl)-propane derivatives containing a terminal methyl group (Expts. 1–9) yields, in agreement with the observations of Kuhn and l'Orsa,[9] at least 80% of the theoretical amount of acetic acid. The ethoxyl group is also oxidized practically quantitatively to acetic acid (Expts. 7, 8, 10 and 11). Where the terminal methyl group either is replaced by carbinol (Expts. 12 and 13) or is absent (Expts. 14 and 15) no acetic acid is obtained. The procedure is therefore suitable for the detection of terminal methyl groups in lignin-type compounds.

The effect of aromatic ring stability on yield of acetic acid is shown clearly in Expts. 16, 17 and 18 where, in each case, the methyl group is attached to a carbon atom in the position α to the ring. Where the ring is *stable* (Expt. 18), oxidation results in formation of aromatic carboxylic acids in good yield with accompanying oxidation of the methyl group to carbon dioxide and water. However, as the stability of the ring *decreases* (Expts. 16 and 17) oxidation is accompanied by ring opening permitting of cleavage and formation of acetic acid.

With the remaining products of Table I, the methyl group (where present) is part of the skeletal form $R-\overset{|}{\underset{|}{C}}-\overset{|}{\underset{|}{C}}-\overset{|}{\underset{|}{C}}-$, the methyl group being attached to a carbon atom in the position β to the ring. Since the tendency to cleave is through the α position (carboxylic acid formation) the yield of acetic acid will be high even in the case of $R-CH_2-CH_2-CH_3$.

The acetic acid yield from similarly situated methyl groups appears to be the same irrespective of whether the structure be mono- or polymolecular. This is evidenced in the high yield of acetic acid from dehydrodiisoeugenol (Table I, Expt. 2), the yield in this case being enhanced by the labilizing effect of the phenolic hydroxyl group (that is, oxidation of dehydrodiisoeugenol parallels that of acetovanillone). On the other hand, it is to be expected that this same effect will be inhibited in a chain polymer of the dehydrodiisoeugenol type due to the phenolic ether linkages (with the exception of the methyl group attached to the terminal member) so that yields of 40–50% of theoretical are to be anticipated (*cf.* Table I, Expt. 17). On this basis a polymer of the Freudenberg type V should give at least 40–50% of the theoretical amount of acetic acid, or approximately twice the amount found by Freudenberg, and it is very likely that the acetic acid obtained in his experiment originated solely from methyl groups on terminal units.

When spruce and maple woods (previously extracted successively with benzene–alcohol and water) were oxidized (Table II, Expts. 4 and 5), the acetic acid obtained was that due solely to the ester acetyl groups. Thus native lignin in these woods contains only a small percentage (if any) of end methyl groups. Cellulose and holocelluloses (Expts. 1, 2 and 3) gave no acetic acid other than that from the acetyl groups present.

The yields of acetic acid from the lignin ethanolysis products from spruce and maple woods were determined in similar fashion (Table II, Expts. 6, 7, 8, 9, 10). The low molecular weight lignin water-soluble ethanolysis oils from these two woods yielded 7.3 and 10.8% acetic acid, respectively, in excess of that arising from the introduced ethoxyl groups (Table II, Expts. 7 and 10). By chemical fractionation of the same oils, methyl-containing C_6-C_3 units have been isolated in quantity sufficient to account for 68% of the acetic acid from the spruce ethanolysis

Maple ethanolysis oils			
2-Ethoxy-1-(4-hydroxy-3-methoxyphenyl)-1-propanone	11.8	5.9	2.9
2-Ethoxy-1-(4-hydroxy-3,5-dimethoxyphenyl)-1-propanone	8.5	3.7	1.8
1-(4-Hydroxy-3-methoxyphenyl)-1,2-propanedione + 1-(4-Hydroxy-3,5-dimethoxyphenyl)-1,2-propanedione	8.3	2.1	2.1
1-(4-Hydroxy-3,5-dimethoxyphenyl)-2-propanone	0.6	0.1	0.1
1-(4-Hydroxy-3-methoxyphenyl)-2-propanone	0.3	0.1	0.1
Total	29.5	11.9	7.0

[a] Calculated from the yields of acetic acid obtained upon oxidation of the pure compounds (Table I), *e. g.* 11.8 × 0.50 = 5.9. [b] The acetic acid (93% of theory) from ethoxyl groups has been deducted.

oils[4,5,6,7] (7.3 × 68/100 = 5.0) and 65% of that from the maple ethanolysis oils[11] (10.8 × 65/100 = 7.0) as shown in Table III. The acetic acid is therefore derived from these isolable units.

The oxidation of amorphous water-insoluble *spruce* and *maple* ethanol lignins varied markedly, in that the former gave a 6.6% yield of acetic acid, derived from terminal methyl groups (Table II, Expt. 6), while the acetic acid derived from the maple water-insoluble lignin fractions is entirely accounted for by ethoxyl groups present in these materials (Table II, Expts. 8 and 9), thus indicating a pronounced difference in structure between the two types. This was further emphasized by the fact that the water-soluble lignin ethanolysis oils from maple wood (Table II, Expt. 10) contained *all* of the constituents characterized by the presence of terminal methyl groups. Occasionally, due to variations in the ethanolysis reaction, cleavage of the native maple lignin polymers was not always complete and in one case a *water-insoluble* maple ethanol lignin fraction yielded, upon oxidation, 1.5% of acetic acid from terminal methyl groups.

Re-ethanolysis of an ether-soluble spruce lignin fraction resulted in only a slight decrease in the methyl groups in the *recovered* petroleum ether-insoluble lignin as shown by the decrease in yield of acetic acid from 6.1 to 5.4% (Table IV). However, the oily, petroleum ether-soluble lignin fraction isolated simultaneously (amounting to 31% of the total re-ethanolysis products) yielded 16.1% acetic acid from terminal methyl groups on oxidation (Table IV). The effect of the re-ethanolysis treatment of the *ether-soluble* spruce ethanol lignin was to increase the yield of acetic acid from end methyl groups from 6.1 to 8.4% (see footnote, Table IV).

This actual formation of methyl groups during ethanolysis of spruce wood lignin is in accord with Hibbert's oxyconiferyl alcohol theory of lignin structure.[2d,8]

TABLE IV

RE-ETHANOLYSIS OF ETHER-SOLUBLE SPRUCE ETHANOL LIGNIN

	Substance	Weight, g.	Acetic acid: Total obtained, %	Acetic acid: From ethoxyl groups, %	Acetic acid: From terminal methyl groups (by diff.), %	Acetic acid: From terminal methyl groups, g.	
I	Spruce ether-soluble ethanol lignin	9.7	22.8	16.7	6.1	0.59	
II	Petroleum ether-*insoluble* fraction from re-ethanolysis of I	6.4	17.6	12.2	5.4	0.35	0.82[a]
III	Petroleum ether-*soluble* fraction from re-ethanolysis of I	2.9	29.2	13.0	16.1	0.47	

[a] 0.82 g. acetic acid represents a combined yield of 8.4% based on the original weight (9.7 g.) of the ether-soluble spruce ethanol lignin.

Experimental

Preparation of Samples.—The wood samples were ground in a Wiley mill to 40-mesh, extracted forty-eight hours with 1:1 alcohol–benzene, twenty-four hours with alcohol, thoroughly washed with water, and dried under reduced pressure. The holocelluloses were prepared from the same wood samples by the procedure of Van Beckum and Ritter.[12] The ethanol lignin fractions were obtained by the standardized procedure used in these Laboratories.[13]

Oxidation.—The sample (0.2–0.5 g.) was placed in a 500-cc. flask fitted with dropping funnel, nitrogen inlet, and distillation outlet.[9] Twenty grams of chromium trioxide in 50 cc. of water was then introduced from the dropping funnel, and a slow stream of nitrogen (1 to 2 bubbles per second) passed through the reaction mixture. Heating in a wax-bath, maintained at 160°, was commenced and 25-cc. portions of water were added at half-hour intervals until all the acetic acid was removed (seven additions were generally sufficient). The distillate, which comprised a solution of acetic acid plus a small amount of acidity derived from chromic acid, was transferred to an Erlenmeyer flask, boiled to remove dissolved carbon dioxide, and titrated with 0.1 *N* sodium hydroxide.

In each analysis the "corrected value" for acetic acid in the distillate was determined as follows: Two cc. excess 0.1 *N* alkali was added to the titrated solution and the solution concentrated to 2 to 4 cc. The acetate in the solution was then determined by the method of Clark.[14] This latter value for acetic acid is recorded in the tables. Blank determinations showed an acidity equivalent to 0.2 cc. of 0.1 *N* sodium hydroxide due to chromic acid.

In the oxidation of wood and holocelluloses 1 to 2 g. samples were taken and oxidized with a solution of 50 g. of chromium trioxide in 70 cc. of water.

Re-ethanolysis of Spruce Ethanol Lignin.—Spruce ether-soluble ethanol lignin (9.7 g.) dissolved in 350 cc. of 2% ethanolic hydrogen chloride was refluxed forty-eight hours in an atmosphere of carbon dioxide. The resulting solution was neutralized with the calculated amount of sodium bicarbonate, filtered and the filtrate concentrated under reduced pressure to 50 cc. This solution was then added in a fine stream to 1500 cc. of petroleum ether (b. p. 60–70°) with rapid stirring, and the amorphous precipitate removed by filtration, giving a brownish powder (6.4 g.). The petroleum ether filtrate was evaporated under reduced pressure, the residual oil dissolved in 25 cc. of benzene, and the benzene distilled to remove any adhering petroleum ether. The process was repeated and the residual oil brought to constant weight under reduced pressure at 70°, removal of the solvent being facilitated by bubbling carbon dioxide through the oil during this process. After a total evaporation time of twelve hours the material reached a constant weight of 3.9 g. The samples for analysis and oxidation were aliquots of this material. 71.2 mg. of this oil was dried thirty hours in an oven at 105°. The final weight was 52.6 mg.; the true yield of oil was, therefore, 2.9 g.

Acknowledgments.—The authors wish to acknowledge the grant of a bursary from the Canadian Pulp and Paper Association to one of them (W. S. M.) during the tenure of which this work was carried out.

Summary

1. Chromic acid oxidation of oxygenated side-chain phenylpropane derivatives related to lignin yielded 80 to 95% of the theoretical amount of acetic acid, thereby providing a method for the quantitative determination of

groupings in such products.

2. Oxidation of spruce and maple woods showed that the native lignin present in each wood contains no appreciable quantity of end methyl groups.

3. A difference between extracted, amorphous spruce and maple ethanol lignins was observed, in that the former was found to contain an appreciable quantity of —C—CH_3 groupings (one for each four or five C_6—C_3 units) whereas the latter contained few or no such groups.

4. Re-ethanolysis of spruce ethanol lignin effected an increase in the proportion of terminal methyl groups.

5. Strong experimental support is thus found for the theory of Hibbert that native lignin is characterized by the absence of terminal methyl groups and that their presence in extracted lignins is the result of intramolecular changes undergone by very reactive side chains such as are present in oxyconiferyl alcohol.

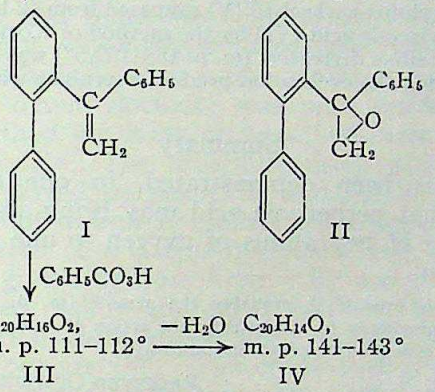
The Anomalous Oxidation of an Ethylene Derivative by Perbenzoic Acid

BY CHARLES K. BRADSHER[1]

The classical reaction of an olefin with perbenzoic acid leads to the formation of an olefin oxide. So well established is this fact, that it forms the basis of a quantitative method for the estimation of olefin linkages.[2]

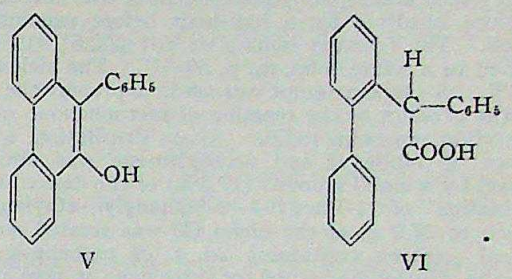
In connection with another problem, we attempted the preparation of the oxide (II) of 1-phenyl-1-(2-biphenylyl)-ethylene by perbenzoic acid oxidation of the corresponding olefin (I).



Despite the use of a 32% excess of the oxidizing agent, after three days standing at 0–10° the solution gave a negative test for perbenzoic acid.[3] Worked up in the usual way, there was obtained a quantity of crystals which, upon analysis, proved to be not the expected oxide, but a compound (III) which apparently contained two oxygen atoms. This "dioxide"[4] (III), upon heating with hydrobromic acid, sulfuric acid or potassium bisulfate, lost one molecule of water to yield a compound (IV) melting at 141–143°. When the dehydration product (IV) was refluxed with acetyl chloride, it gave a derivative melting some 20° higher.

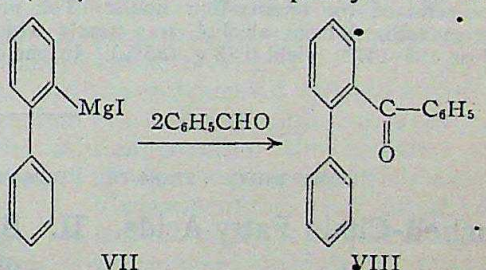
The properties and composition of the dehydration product (IV) correspond to those reported by Koelsch[5] for 9-phenylphenanthrol-10 (V) which he had synthesized by cyclization of the acid chloride of (2-biphenylyl)-phenylacetic acid (VI). A sample of the phenanthrol (V) prepared by Koelsch's directions was found to be identical with the dehydration product (IV) obtained from the "dioxide."

It should be pointed out that though (2-biphenylyl)-phenyl-acetic acid (VI) is isomeric, it



is not identical with the "dioxide" which has no acidic properties and which melts some 60° lower than the acid.

The olefin (I) used in the reaction was prepared from *o*-phenylbenzophenone[6] (VIII) by the action of methylmagnesium iodide essentially as described by Bergmann and Bondi.[7] The *o*-phenylbenzophenone has been prepared in a new way which makes possible the use of commercially available starting materials. The Grignard reagent (VII) from 2-iodobiphenyl was treated



with over two moles of benzaldehyde in benzene solution and the mixture refluxed overnight, resulting in a 69% yield of the desired ketone (VIII). This use of an excess of aldehyde as an oxidizing agent has been much investigated from a theoretical standpoint,[8] but has as yet found little synthetic application.[9]

Experimental

***o*-Phenylbenzophenone.**—A Grignard reagent was prepared from 56 g. of 2-iodobiphenyl and 4.86 g. of magnesium. A solution of 22 cc. of benzaldehyde in 40 cc. of benzene was added slowly. When addition was complete, two-thirds of the ether was distilled off and 100 cc. of benzene and 40 cc. of benzaldehyde added. The mixture was refluxed for twenty-two hours, after which it was decomposed by the addition of ammonium chloride solution. The ether–benzene layer was dried, concentrated, and the residue distilled under reduced pressure. The entire fraction boiling at 195–232° (19 mm.) was collected and crystallized from methyl alcohol giving 35.8 g. (69.5%)

of white crystals, m. p. 86–87°. This material was identical with a sample prepared from the nitrile by the method of Schlenk and Bergmann.[6]

1-Phenyl-1-(2-biphenylyl)-ethylene (I) was prepared as described by Bergmann and Bondi[7] with the exception that the product of the reaction between methylmagnesium iodide and *o*-phenylbenzophenone was heated with potassium bisulfate for a half-hour before vacuum distillation. The fraction boiling at 201–202.5° (12 mm.) solidified to a white solid, m. p. 59–61°. The yields were 56–73%. A single attempt was made to prepare the olefin from the product of the reaction of acetophenone with 2-biphenylylmagnesium iodide. Upon distillation, a large fore-run of biphenyl and acetophenone was obtained, followed by a small amount (17.5%) of the desired olefin.

Oxidation of 1-Phenyl-1-(2-biphenylyl)-ethylene.—A solution of 27.9 g. of the olefin (I) was treated with an ethereal solution containing 20 g. of perbenzoic acid. After the solution had stood for three days, it gave a negative test for excess oxidant. The solution was washed free of acid with sodium bicarbonate solution and dried over sodium sulfate. Upon concentration of the solution and addition of petroleum ether, 14 g. (46%) of nearly colorless crystals was obtained, m. p. 107–109°. An analytical sample was prepared by repeated recrystallization, m. p. 111–112°.

Anal. Calcd. for $C_{20}H_{16}O_2$: C, 83.32; H, 5.60. Found: C, 83.37; H, 5.68.

Dehydration of the "Dioxide" (III).—(a) By hydrobromic and acetic acids: one-half gram of the "dioxide" (III) was suspended in a boiling mixture containing 5 cc. of acetic and 5 cc. of 34% hydrobromic acids and the mixture refluxed for twenty-four hours. The product, once recrystallized from alcohol, was nearly white and melted at 139–141°; yield 0.33 g. (35%). In one case in which the "dioxide" had been heated previously for a few minutes at its boiling point (22 mm.) the yield was 56%.

(b) By the action of potassium bisulfate: one gram of the "dioxide" was heated at 170–180° for ten minutes with 2 g. of potassium bisulfate. The product was extracted with ether and recrystallized as above; yield 0.33 g. (35%).

(c) By the action of concentrated sulfuric acid: one-half gram of the "dioxide" was heated on the steam-bath for two minutes with 3 cc. of concentrated sulfuric acid. Poured into water and once recrystallized, it gave 0.30 g. (64%) of white needles, m. p. 141–143°.

The products obtained by all of these methods were shown to be identical by mixed melting point determinations.

Anal. Calcd. for $C_{20}H_{14}O$: C, 88.86; H, 5.22. Found: C, 88.94, 88.73; H, 5.30, 5.23.

The products were shown to be identical with a sample of 9-phenylphenanthrol-10 (V) prepared from (2-biphenylyl)-phenylacetic acid (VI) by the method of Koelsch.[5]

A crystalline derivative (m. p. 158–159.5°) was obtained by refluxing the cyclization product overnight with acetyl chloride.[10]

Summary

It has been demonstrated, in one case at least, that perbenzoic acid may bring about the addition of two atoms of oxygen to one mole of an olefin.

(10) This product is probably the acetate (m. p. 153–155°) prepared previously by Koelsch[5] by the action of acetic anhydride and sulfuric acid on 9-phenylphenanthrol-10.

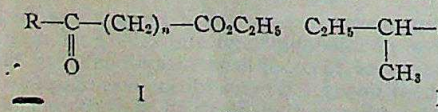
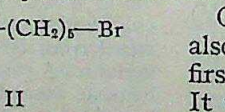
Branched-Chain Fatty Acids. II. Syntheses in the C_{19} and C_{25} Series. Preparation of Keto Esters

BY JAMES CASON AND FRANKLIN S. PROUT[1]

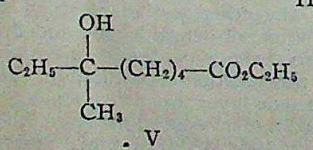
In continuation of the program of synthesizing methyloctadecanoic acids,[2] the 16-methyl isomer has been prepared by the general method used for synthesis of 17-methyloctadecanoic acid.[2] This procedure involves preparation of a keto ester (I) by reaction between a dialkylcadmium



I



II



V

compound and an ω-carbethoxyalkoyl chloride, reduction of the keto ester by the Clemmensen method and hydrolysis of the reduced ester. For synthesis of 16-methyloctadecanoic acid the required alkyl halide is 1-bromo-6-methyloctane (II). This bromide has been prepared by Levene and Marker[3] from the corresponding alcohol which was obtained by reduction of ethyl 6-methyloctoate (IV). These workers prepared 6-methyloctoic acid[4] by extending the chain of 1-bromo-4-methylhexane by use of the malonic ester synthesis.

Our preparation of 1-bromo-6-methyloctane also utilizes ethyl 6-methyloctoate, which was first prepared by us as in the scheme shown. It was hoped that the small amount of isoamyl alcohol present in the *s*-butylcarbinol[5] used as starting material would not interfere with obtaining a pure product in the final stages of the synthesis; however, such was not the case. Reduction of the keto ester, III, by the Clemmensen method proved more difficult than reduction of the 7-methyl isomer[2]; therefore, the concentration of the undesired 7-methyl isomer, arising from isoamyl bromide, was considerably increased at this step. 16-Methyloctadecanoic

IV

acid obtained from 1-bromo-6-methyloctane prepared by this route was contaminated with the less soluble 17-methyloctadecanoic acid and could not be isolated in a pure state.

Ethyl 6-methyloctoate was next synthesized by a method involving no branched-chain starting materials. The procedure used, which has been employed by Schneider and Spielman[6] for synthesis of several 10-methyl acids, depends on the reaction of a Grignard reagent with a keto ester to give a hydroxy ester. By use of ethylmagnesium iodide and ethyl 6-ketoheptoate in this reaction, there was obtained ethyl 6-hydroxy-6-methyloctoate (V). The crude hydroxy ester was dehydrated by heating with iodine and the unsaturated ester was hydrogenated to the desired ethyl 6-methyloctoate. The over-all yield from ethyl 6-ketoheptoate was 19–30%. When 1-bromo-6-methyloctane prepared from this ester was used in the synthesis of 16-methyloctadecanoic acid a readily purified product was obtained. 16-Methyloctadecanoic acid melts at 49.9–50.6°, about seventeen degrees below the 17-methyl isomer.

Since 6-methyl- and 10-methyltetracosanoic acids were desired for biological testing,[7] they have been prepared by the general method of Schneider and Spielman,[6] as described above for preparation of ethyl 6-methyloctoate. The reaction between myristylmagnesium bromide and ethyl 10-ketohendecanoate was carried out essentially as described by Schneider and Spielman; however, the resulting hydroxy ester was used for dehydration, rather than the acid, as used by the above authors. The unsaturated ester was hydrogenated over platinum and, in order to insure as pure a product as possible, the saturated C_{25} ester was distilled through an 18-inch Vigreux type column. The over-all yield of recrystallized 10-methyltetracosanoic acid, obtained after saponification of the ester, was 39%. Schneider and Spielman obtained this acid in 34% yield. 6-Methyltetracosanoic acid was obtained by a similar procedure, starting with octadecyl bromide and ethyl 6-ketoheptoate, in an over-all yield of 26%.

The keto esters prepared in the course of the syntheses described above were obtained by the reaction between a dialkylcadmium compound and an ω-carbethoxyalkoyl chloride. The method of Cason[2] has been improved so that yields of 75–85% were obtained, and this procedure now appears to be the most efficient yet devised for synthesis of aliphatic keto esters. The improvement was effected by removing as much ether as possible from the reaction mixture after preparation of the dialkylcadmium compound from the corresponding Grignard reagent. This process greatly reduces the yield of di-ester, arising from reaction of the ester acid chloride with ether, and the yield of keto ester is nearly doubled. If a dialkylcadmium derivative other than dimethylcadmium is used, the small amount of di-ester may be removed by fractional distillation; however, when dimethylcadmium is used the di-ester and keto ester have nearly identical boiling points. In this case, a pure product may be obtained by distillation of the keto acid.

When the above-described method of running the cadmium reaction was applied to a secondary bromide, 2-bromopentane, the reaction failed completely. However, when the cadmium derivative of 2-bromopentane was prepared in ether at −5 to −7° and allowed to react with β-carbomethoxypropionyl chloride at this temperature a 21.5% yield of methyl 4-keto-5-methyloctoate was obtained.

It has been previously reported[2] that when diisoamylcadmium is allowed to react with succinic anhydride in ether the yield of 4-keto-7-methyloctoic acid is only 5–10%. In a trial run, this reaction was carried out in boiling benzene solution, and a yield of 31% was obtained.

Experimental[8]

Keto Esters and Acids

Methyl 4-Keto-7-methyloctoate.[2]—The Grignard solution prepared in an atmosphere of nitrogen from 7.3 g. of magnesium and 45.3 g. of isoamyl bromide (b. p. 120.0–120.2°) in 150 cc. of ether was cooled in an ice-bath and 29.3 g. of dried C. P. cadmium chloride was added in one portion. After removal of the ice-bath the mixture was stirred for five minutes, then ether was distilled rapidly from the solution by heating on a steam-bath, while stirring was continued. Distillation was continued until a dark semi-solid residue remained, then 100 cc. of dry thiophene-free benzene was added and distillation resumed until benzene had practically ceased to distil. After 100 cc. of benzene had been added to the residue the mixture was stirred and refluxed until the cake had been broken up and dispersed through the mixture. There was then added during ten minutes a solution of 36.1 g. of β-carbomethoxypropionyl chloride[9] in 50 cc. of benzene. After the exo-

thermic reaction had subsided the mixture was refluxed with stirring for one hour.

The organometallic complex was decomposed with ice and sulfuric acid, and the water was separated and extracted twice with benzene. The benzene extracts were washed with water, 5% sodium carbonate solution, water and saturated sodium chloride solution, then filtered through a layer of anhydrous sodium sulfate. After the solvent had been flashed off, the residue was distilled through an 18-inch Podbielniak type column, and the following fractions were obtained

Fraction	B. p. (8 mm.), °C.	Weight, g.
Methyl ethyl succinate[2]	82–89	1.44
Intermediate fraction	89–116.5	0.98
Methyl 4-keto-7-methyloctoate	116.5–117	32.74

The yield of keto ester is 73.5% of theory based on ester acid chloride or 58.8% based on isoamyl bromide.

When this reaction was run as above except that only 29.3 g. of β-carbomethoxypropionyl chloride was used the yield of keto ester was 74–76% based on ester acid chloride or 48.3–49.5% based on isoamyl bromide. When the reaction was carried out in ether, using the above quantities (29.3 g. of acid chloride), there were obtained 3.70 g. of methyl ethyl succinate and 15.40 g. (42.5% based on ester acid chloride) of methyl 4-keto-7-methyloctoate.

4-Keto-7-methyloctoic Acid.[2]—A solution of diisoamylcadmium in 200 cc. of benzene was prepared from 0.3 mole of isoamyl bromide as described in the preparation of methyl 4-keto-7-methyloctoate. After addition of 22.5 g. of succinic anhydride, which had been ground and washed with carbon bisulfide and ether,[9] the mixture was stirred under reflux for four hours. The reaction mixture was decomposed with ice and sulfuric acid, and the benzene phase was separated and extracted with 300 cc. of 5% sodium carbonate solution in four portions. The material obtained from the carbonate extract after acidification was distilled from a Claisen flask at 4 mm. pressure. The entire distillate, consisting of 4-keto-7-methyloctoic acid, boiled at 152–153° and crystallized rapidly in the receiver; yield, 11.9 g. (30.8%).

On working up the benzene solution containing the neutral material from this reaction only 2.0 g. of material was obtained. This yielded, on distillation at 4 mm. pressure, 0.94 g. boiling at 100–110° and 0.93 g. boiling at 147–150°. These fractions were not further investigated.

Ethyl 10-keto-13-methyltetradecanoate was prepared in a 0.3-mole run from isoamyl bromide and ω-carbethoxynonoyl chloride[2,10] by the procedure described for methyl 4-keto-7-methyloctoate, except that the ester acid chloride was added in 100 cc. of benzene. This keto ester was obtained in a yield of 58.2 g. (85% based on acid chloride); b. p. 180–182° (3 mm.).

Anal. Calcd. for $C_{17}H_{32}O_3$: C, 71.80; H, 11.34. Found: C, 71.76; H, 11.66.

Ethyl 6-ketoheptoate,[11] b. p. 143–145° (33 mm.), and **ethyl 10-ketohendecanoate,**[6,12] b. p. 137–138° (2 mm.), were prepared by the procedure described for methyl 4-keto-7-methyloctoate. In both cases the yields in 1.0-mole runs were 76%. Since some dimethylcadmium is lost by volatilization during distillation of benzene and since it is desirable to reduce di-ester formation to a minimum in these cases, only 0.5 mole equivalent of ω-carbethoxyvaleryl chloride[13] and of ω-carbethoxynonoyl chloride were used for these preparations. The purity of these keto esters was indicated to be 80–90% by conversion to semicarbazones. From ethyl 6-ketoheptoate there was obtained an 86.5% yield of semicarbazone, m. p. 100.2–104.2°. After recrystallization from aqueous alcohol and from benzene the m. p. was 104.8–107.0° (Blaise and Koehler[11a] reported this m. p. as 107°). The semicarbazone of ethyl 10-ketohendecanoate was obtained in 89.6% yield (m. p. 90.2–99.4°). After three crystallizations from benzene very fine crystals melting at 110.7–112.8° were obtained.

Anal. Calcd. for $C_{14}H_{27}O_2N_2$: C, 58.92; H, 9.54. Found: C, 59.35; H, 9.70.

A 30-g. sample of ethyl 10-ketohendecanoate was saponified and the product was distilled through an 18-inch Podbielniak type column. There were obtained 1.5 g. of forerun, b. p. 143–145° (2 mm.); 19.7 g. (75%) of 10-ketohendecanoic acid, b. p. 168–169° (1 mm.), m. p. 52–59°; and 3.2 g. of residue. After one crystallization from ether–petroleum ether the keto acid melted at 58–60°. This substance appears to be polymorphic, for it melts at once when placed in a bath at 59°, partially resolidifies and melts completely at 60°. It has been reported as melting at 57.5°,[6] 58.5–59.5°,[14] 53–55°.[15]

The residue (3.2 g.) from the above distillation was extracted with 200 cc. of boiling water, and after considerable salve-like material had been removed by filtration the clear filtrate was concentrated to 100 cc. On cooling there crystallized 0.99 g. of sebacic acid, m. p. 121–129°. After one crystallization from acetone-benzene, this product melted at 131.5–132.5° and gave no depression on mixing with pure sebacic acid of the same melting point. If this weight of sebacic acid is increased by 0.10 g. to allow for that remaining in the mother liquor, it corresponds to 1.4 g. or 4.7% of diethyl sebacate in the sample of keto ester.

The fore-run (1.5 g.) from 10-ketohendecanoic acid solidified when cooled in ice and salt, so it was recrystallized from petroleum ether (b. p. 30–40°). After three crystallizations there was obtained 30 mg. of a substance crystallizing as clusters of feathery needles and melting at 67.4–67.8°. It reacts with 2,4-dinitrophenylhydrazine and the analytical figures suggest that it is **dodecanedione-2,11.** This would arise from reaction of dimethylcadmium with the ester group of ethyl 10-ketohendecanoate.

Anal. Calcd. for $C_{12}H_{22}O_2$: C, 72.71; H, 11.19. Found: C, 72.48; H, 11.28.

Methyl 4-keto-5-methyloctoate could not be obtained by the procedure described above for preparing keto esters, presumably due to the instability of di-(2-amyl)-cadmium. For preparation of this keto ester, the Grignard reagent from 0.3 mole of 2-bromopentane in 150 cc. of ether was cooled to −7° and treated with 29.3 g. of dried cadmium chloride at such a rate as to allow the temperature to remain below −5°. After the resultant mixture had been stirred for one and one-half hours at −5 to −7° a solution of 33.8 g. of β-carbomethoxypropionyl chloride in 75 cc. of ether was added during twenty minutes at −5 to −7°. After addition was complete the reaction mixture was stirred four hours at the same temperature. When the reaction was worked up as described for methyl 4-keto-7-methyloctoate there was obtained 8.07 g. (21.5% based on ester acid chloride) of methyl 4-keto-5-methyloctoate, b. p. 130.5–130.7° (21 mm.). No fraction corresponding to methyl ethyl succinate was obtained.

Anal. Calcd. for $C_{10}H_{18}O_3$: C, 64.50; H, 9.75. Found: C, 63.87; H, 9.93.

16-Methyloctadecanoic Acid

Methyl 4-keto-6-methyloctoate was prepared from 1-bromo-2-methylbutane (b. p. 119–121°) and *p*-carbomethoxypropionyl chloride in the manner described for preparation of methyl 4-keto-7-methyloctoate, except that only about half the ether was distilled after preparation of the cadmium compound; b. p. 132–134° (16 mm.); yield, 60%. When the preparation was carried out in ether solution the yield was only 24–27%.

Since this ester is contaminated with the 7-methyl iso-

(10) By distilling this ester acid chloride at a pressure of 5 mm. or less a yield of 90–95% may be obtained.

mer it was saponified, and the semicarbazone of the resultant 4-keto-6-methyloctoic acid was prepared. It crystallizes from 50% ethanol as thin blades, m. p. 137–138° (dec.). When this semicarbazone was mixed with that from 4-keto-7-methyloctoic acid the m. p. was depressed to 128–131°.

Anal. Calcd. for $C_{10}H_{19}O_3N_3$: C, 52.39; H, 8.35. Found: C, 52.64; H, 8.39.

6-Methyloctoic Acid.[4]—Clemmensen reduction of methyl 4-keto-6-methyloctoate in alcoholic solution[6] gave yields of only 10–16%; so reduction was accomplished in aqueous hydrochloric acid as has been described for the 7-methyl isomer.[2] When reduction of 45.2 g. of keto ester was continued for forty-eight hours there was obtained in the best run 22.4 g. (76.7%, based on keto ester consumed) of 6-methyloctoic acid, b. p. 98–105° (1–2 mm.) and 10.1 g. of 4-keto-6-methyloctoic acid, b. p. 125–129° (1–2 mm.).

6-Methyloctamide was prepared from a sample of pure acid recovered from reduction of the ester (see below). The method used was that previously described for 7-methyloctoic acid.[2] This amide crystallizes from benzene as small plates, m. p. 90.4–91.6°.

Anal. Calcd. for $C_9H_{19}ON$: C, 68.74; H, 12.18. Found: C, 68.52; H, 12.44.

Ethyl 6-Methyloctoate.[3]—A Grignard reagent was prepared from 23.4 g. of ethyl iodide (b. p. 72.5–72.9°) in 100 cc. of ether and forced from the flask under nitrogen pressure into a nitrogen-filled separatory funnel. This solution was added during one hour to a stirred solution of 21.5 g. of ethyl 6-ketoheptoate in 100 cc. of ether, which was cooled in an ice–salt mixture. After addition was complete the mixture was stirred for an additional hour with continued cooling. The Grignard complex was then decomposed in the usual way and the aqueous phase was extracted with two portions of ether. The extracts were washed with water, 5% sodium carbonate solution, water and saturated sodium chloride solution, then filtered through a layer of anhydrous sodium sulfate. The residue remaining after removal of solvent was heated for thirty minutes with a crystal of iodine at 180–190°, and the unsaturated ester was distilled from a Claisen flask, b. p. 83–100° (3 mm.). This ester was readily hydrogenated in 100 cc. of 95% ethanol in the presence of 0.3 g. of platinum oxide catalyst. The resulting ethyl 6-methyloctoate was distilled through an 18-inch Podbielniak type column at 36 mm. pressure; b. p. 125.5–127.5°; yield in the best run, 7.0 g. (30%). The average yield of several runs was 20%.

In an effort to improve the yield, the hydroxy ester was dehydrated by other methods: with phosphorus tribromide followed by alcoholic potassium hydroxide[16] the yield was 21%; with phosphorus pentachloride followed by alcoholic potassium hydroxide[17] the yield was 16%; with phosphorus oxychloride[18] the yield was 17%; and with acetic anhydride the yield was 20.5%. Since these processes are relatively more laborious the use of iodine was adopted as most satisfactory.

1-Bromo-6-methyloctane.[3]—6-Methyloctanol-1 was prepared by reduction of ethyl 6-methyloctoate with sodium and alcohol according to Manske.[19] From 25.9 g. of ester there was obtained 10.8 g. of 6-methyloctanol-1, b. p. 108–111° (22 mm.). Since 7.3 g. of 6-methyloctoic acid, b. p. 139–143° (17 mm.), was recovered the yield on the basis of acid consumed was 83%. By treating 14.5 g. of the alcohol with anhydrous hydrogen bromide[20] there was obtained 13.0 g. (62.5%) of bromide, b. p. 105–108° (21 mm.). There was 1.0 g. of lower-boiling material and 1.8 g. of higher-boiling material (distillation through 18-inch column).

Ethyl 10-keto-16-methyloctadecanoate, prepared by the general method described above for methyl 4-keto-7-methyloctoate, was distilled through an 18-inch Podbielniak type column, with no head and with the take-off just above the heating jacket. The keto ester, which was collected at 192–195° (2 mm.), weighed 11.5 g. (76.5% based on acid chloride, 53.7% based on bromide).

Anal. Calcd. for $C_{21}H_{40}O_3$: C, 74.07; H, 11.84. Found: C, 73.54; H, 12.30.

The fore-run from the keto ester consisted of 1.2 g. of material boiling at 71.5–73° (3 mm.) and 2.0 g. of material boiling almost entirely at 130° (2 mm.). The latter fraction was saponified and the product separated into neutral and acidic portions. After crystallization from water the acidic fraction weighed 0.44 g. and melted at 126–128°. After an additional crystallization from acetone–benzene it melted at 128–130.5° and gave no depression on mixing with pure sebacic acid. The liquid neutral fraction weighed 1.2 g. and was insoluble in concentrated sulfuric acid. The analysis corresponds to that of **3,14-dimethylhexadecane** (from coupling of the Grignard reagent).

Anal. Calcd. for $C_{18}H_{38}$: C, 84.95; H, 15.05. Found: C, 85.04; H, 15.20.

10-Keto-16-methyloctadecanoic acid was prepared by saponification of 0.68 g. of the ester according to the method described for the 17-methyl isomer.[2] The yield of material melting at 50.3–53.6° was 0.54 g. (86%). After three crystallizations from ligroin (b. p. 35–39°) this keto acid was obtained as fine feathery crystals melting at 52.7–54.1°.

Anal. Calcd. for $C_{19}H_{36}O_3$: C, 73.03; H, 11.62. Found: C, 73.06; H, 11.67.

Ethyl 16-methyloctadecanoate was prepared by Clemmensen reduction of the above-described keto ester in alcoholic solution.[6] From 10.7 g. of keto ester there was obtained, after distillation through the Podbielniak type column, 8.1 g. (78.6%) of reduced ester, b. p. 170–175° (1.5 mm.).

Anal. Calcd. for $C_{21}H_{42}O_2$: C, 77.24; H, 12.97. Found: C, 77.10; H, 13.11.

16-Methyloctadecanoic Acid.—From saponification of 8.0 g. of the ester there was obtained 7.3 g. (99%) of 16-methyloctadecanoic acid melting at 45.7–49.3°. After one crystallization from acetone and two from methanol there was obtained 5.22 g. of translucent blades melting at 49.9–50.6°, $n^{70}D$ 1.4342, $n^{65}D$ 1.4361, $n^{60}D$ 1.4379, $n^{55}D$ 1.4400.

Anal. Calcd. for $C_{19}H_{38}O_2$: C, 76.45; H, 12.83; mol. wt., 298.5. Found: C, 77.00; H, 12.73; mol. wt., 297.0.

When 16-methyloctadecanoic acid was prepared from 1-bromo-6-methyloctane obtained from *s*-butylcarbinol as starting material, the crude acid precipitated from the saponification mixture melted at 43–49°. After a 5.1-g. sample had been fractionally crystallized ten times there was obtained 0.25 g. of 17-methyloctadecanoic acid melting at 66.7–67.3°.

For preparation of the amide, the acid chloride from 1.54 g. of acid was dissolved in 15 cc. of dioxane and added with stirring to 25 cc. of cold concentrated ammonium hydroxide. The precipitated amide weighed 1.53 g. (99%) and melted at 89.4–91.8°. After three crystallizations from ligroin (b. p. 80–100°) there was obtained 1.23 g. of transparent blades melting at 92.5–93.0°.

Anal. Calcd. for $C_{19}H_{39}ON$: C, 76.71; H, 13.21. Found: C, 76.94; H, 13.52.

A 1.0-g. sample of this amide was saponified by refluxing for thirty-six hours with a mixture of 10 cc. of ethanol and 30 cc. of 10% aqueous sodium hydroxide, 20-cc. portions of 10% sodium hydroxide being added at twelve-hour intervals. On acidification there was obtained 0.99 g. of 16-methyloctadecanoic acid melting at 48.0–49.9°. After three crystallizations from acetone the constant m. p. of 49.9–50.6° was reached.

The **tribromoanilide** was prepared in 89% yield (m. p. 103.8–105.8°) from 0.51 g. of the acid, using the method previously described by one of us.[2] After three crystallizations from ligroin (b. p. 80–100°) the constant m. p. of 106.8–106.9° was reached.

C_{25} Acids

6-Methyltetracosanoic Acid.—Octadecyl bromide was prepared from commercial octadecyl alcohol with anhydrous hydrogen bromide.[20] On distillation through an 18-inch Vigreux type column there was obtained an 81% yield of product boiling at 177.5–179° (3 mm.). The Grignard reagent prepared from 8.56 g. of this bromide in 50 cc. of ether was added during fifty minutes to a solution of 3.45 g. of ethyl 6-ketoheptoate in 50 cc. of ether. During addition the mixture was stirred at 0°, and after addition was complete the mixture was stirred under reflux for one hour. After decomposition of the organometallic complex with ice and sulfuric acid the ether layer was separated and filtered to remove 0.6 g. of suspended hexatriacontane (m. p. after crystallization from ligroin, 75.2–76.1°). The aqueous phase was extracted twice with ether and the ether extracts were washed with water, 5 % sodium carbonate solution, water and saturated sodium chloride solution, then filtered through a layer of anhydrous sodium sulfate. The total ether solution was concentrated to about 25 cc. and allowed to stand overnight in the refrigerator, whereupon a small additional amount of hexatriacontane separated. After removal of the hexatriacontane and distillation of the remaining solvent, the residual hydroxy ester was heated for thirty minutes at 180–190° with a crystal of iodine. The mixture was then heated to 150° under 1 mm. pressure to remove about 3 cc. of low-boiling material. The residue was treated with Norit in ether, then hydrogenated over platinum oxide in 100 cc. of alcohol. Hydrogenation was slow and several 0.1-g. portions of catalyst were required. The reduced ester was distilled through an 18-inch Podbielniak type column. After a forerun of 2.1 g., **ethyl 6-methyltetracosanoate** was collected at 211–214° (*ca.* 0.5 mm.); yield, 2.4 g. (29.2%).

Anal. Calcd. for $C_{27}H_{54}O_2$: C, 78.76; H, 13.47. Found: C, 79.33; H, 13.29.

Saponification of 2.3 g. of the ester gave 1.92 g. (90%) of acid melting at 57.5–60.5°. After three crystallizations from ligroin (b. p. 72–80°), the constant m. p. of 55.8–56.6° was reached. Slightly impure samples usually melted higher than the pure substance.

Anal. Calcd. for $C_{25}H_{50}O_2$: C, 78.46; H, 13.17; mol. wt., 382.6. Found: C, 78.77; H, 13.35; mol. wt., 384.6.

In one run the unsaturated ester was saponified and the potassium salt of the acid was purified by washing with ether. The unsaturated acid was hydrogenated in acetic acid and the reduced acid was crystallized from acetic acid twice and from ligroin twice. The product obtained in this way melted at 55.2–56.4°. Crude samples of 6-methyltetracosanoic acid could not be purified by crystallization from acetone, methyl alcohol, acetic acid or petroleum ether (b. p. 30–40°).

The **amide**, prepared in 80% yield by the method described for 16-methyloctadecanoic acid, was crystallized four times from methanol and once from ligroin (b. p. 72–80°); m. p. 83.9–85.3°.

Anal. Calcd. for $C_{25}H_{51}ON$: C, 78.67; H, 13.47. Found: C, 78.56; H, 13.60.

The **tribromoanilide**, after crystallization from ligroin (b. p. 72–80°), acetone and ethanol, melted at 94.4–97.2°.

Anal. Calcd. for $C_{31}H_{52}ONBr_3$: C, 53.87; H, 7.58. Found: C, 54.00; H, 8.22.

6-Hydroxy-6-methyltetracosanoic Acid.—Ethyl 6-hydroxy-6-methyltetracosanoate was prepared from 17.1 g. of octadecyl bromide as described in the above section. The crude hydroxy ester was saponified with boiling alcoholic potassium hydroxide. After dilution of the alcoholic solution with hot water the soap was salted out with sodium chloride and, after filtration from the cooled solution, was washed well with saturated salt solution and ether. The crude hydroxy acid obtained by treating this soap with dilute hydrochloric acid weighed 5.19 g. (30.3%). After repeated crystallization from ligroin (b. p. 39–55°) this acid melted constantly at 46.0–47.3°.

Anal. Calcd. for $C_{25}H_{50}O_3$: C, 75.32; H, 12.64. Found: C, 75.46; H, 12.87.

10-Methyltetracosanoic Acid.—Myristyl bromide, prepared[20] from 100 g. of commercial myristyl alcohol (E. K. Co.), was distilled through an 18-inch Vigreux type column at 2 mm. pressure. There was obtained 4.4 g. of material boiling at 123–125°, 70.8 g. of myristyl bromide boiling at 135–137° and 24.8 g. of material boiling at 154–155°. Thus, the alcohol used apparently contained about 4% lauryl alcohol and 20% cetyl alcohol.

Starting with myristyl bromide and ethyl 10-ketohendecanoate, **ethyl 10-methyltetracosanoate** was prepared by the same general procedure described for the 6-methyl isomer; yield in a 0.15-mole run, 44.0%; b. p. 218–222° (*ca.* 0.5 mm.).

Anal. Calcd. for $C_{27}H_{54}O_2$: C, 78.76; H, 13.47. Found: C, 79.43; H, 13.25.

By saponification of the ester and crystallization of the crude acid from acetone an 89.5% yield of 10-methyltetracosanoic acid melting at 49.5–51.5° was obtained. After two additional crystallizations fine crystals were obtained which melted constantly at 50.5–51.5° (Schneider and Spielman,[6] 51.0–51.5°).

The **amide**, prepared in 96% yield, after crystallization from acetone, melted at 77.5–78.5° (literature,[6] 79–79.5°).

The **tribromoanilide**, prepared in 72% yield, crystallized from ethanol as fine white crystals, m. p. 84.2–84.8°.

Anal. Calcd. for $C_{31}H_{52}ONBr_3$: C, 53.87; H, 7.58. Found: C, 54.02; H, 8.18.

The authors wish to express their appreciation for a grant from the Natural Science Research Fund of Vanderbilt University.

Summary

16-Methyloctadecanoic acid has been synthesized from the intermediate ethyl 10-keto-16-methyloctadecanoate. This and four other keto esters were prepared in yields of 75–85% by the reaction between the appropriate ester acid chlorides and dialkylcadmium derivatives.

6-Methyltetracosanoic acid has been prepared from the corresponding 6-hydroxy acid. The ester of the hydroxy acid was prepared from octadecylmagnesium bromide and ethyl 6-ketoheptoate. Schneider and Spielman's synthesis of 10-methyltetracosanoic acid has been repeated and modified slightly.

The Synthesis of 3,4-Dicarboxy-2-furanvaleric Acid and Some of Its Derivatives

BY KLAUS HOFMANN[1]

Synthetic work on substances related to biotin, which is at present under way in this Laboratory called for the preparation of 3,4-dicarboxy-2-furanvaleric acid. Alder and Rickert[2] have described a procedure for the preparation of furan-3,4-dicarboxylic acid which we have successfully applied to the synthesis of 3,4-dicarboxy-2-furanvaleric acid. The starting material for the present investigation was 2-furanvaleric acid which was prepared by a modification of the method of Asano and Nakatomi.[3] Furylacrolein (I) and malonic acid were condensed to 4-(2-furyl)-1,3-butadiene-1,1-dicarboxylic acid (II). Attempts to decarboxylate this substance according to the procedure of the Japanese workers resulted in the formation of tarry products and in no instance was it possible to obtain 4-(2-furyl)-1,3-butadiene-1-carboxylic acid (III). The original procedure was therefore modified. The crude condensation product (II) was dissolved in methanol and was hydrogenated with palladium black as the catalyst until approximately 3 moles of hydrogen had been absorbed. Decarboxylation of the resulting product in pyridine solution at 130–140° resulted in the formation of 2-furanvaleric acid (IV) which was obtained in 50% yield as a white crystalline mass melting at 42–43°. The acid was further characterized by the preparation of its anilide which melted at 75–76°.

When equimolar amounts of this acid and diethyl-acetylene-dicarboxylate were heated on the steam-bath the diene addition compound (V) was obtained as a viscous oil. This oil when hydrogenated in the presence of palladium black, absorbed one mole of hydrogen and was transformed into the partially hydrogenated substance (VI). Heating of this product to 190–200° caused its decomposition into ethylene and 3,4-dicarbethoxy-2-furanvaleric acid (VII) which was obtained in 60–70% yield as a viscous oil boiling at 204–206° at 0.02 mm. Saponification of (VII) yielded 3,4-dicarboxy-2-furanvaleric acid (VIII) melting at 188–190°. The presence of the furan nucleus in this acid was demonstrated spectroscopically. The ultraviolet absorption spectrum of (VIII) was compared with the absorption curve of 3,4-dicarboxy-furan prepared according to Reichstein, *et al.*[4] As may be seen from Fig. 1 the two absorption curves are almost identical, demonstrating the furan nature of the tricarboxylic acid (VIII).

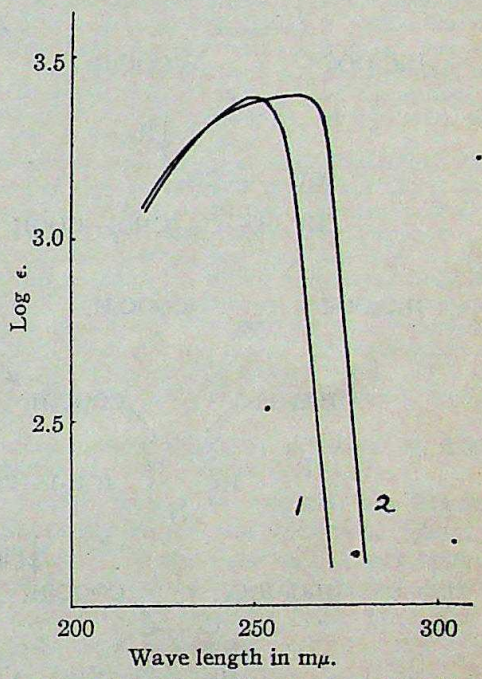

Fig. 1.—Ultraviolet absorption spectra of 3,4-dicarboxy-furan (curve 1) and 3,4-dicarboxy-2-furanvaleric acid (curve 2) in absolute alcohol.

The application of the Alder–Rickert synthesis made it possible to prepare derivatives of 3,4-dicarboxy-2-furanvaleric acid containing various substituents at the furan carboxyls as well as at the acid group at the end of the aliphatic side-chain. Thus treatment of the ester acid (VII) with thionyl chloride gave the acid chloride (X) which, when coupled with piperidine, formed the oily ester piperidide (XI). Treatment of this derivative with alcoholic potassium hydroxide removed the ester groups in positions 3 and 4 with the formation of 3,4-dicarboxy-2-furanvaleric acid piperidide (XII) melting at 133–134°. In contrast to the aliphatic carboxyl group, which is blocked by the piperidine residue, the ring carboxyl groups in compounds (XI) and (XII) are available for further transformations.

As may be seen in the experimental section, the triethyl ester (IX) of (VIII) has likewise been prepared.

It has been possible to hydrogenate some of the above compounds and thus to prepare the corresponding tetrahydrofuran derivatives. The results of these studies will be presented in a forthcoming publication from this Laboratory.

Experimental

All melting points are corrected.

4-(2-Furyl)-1,3-butadiene-1,1-dicarboxylic Acid (II).—325 grams of furyl-acrolein, prepared according to Burdick and Adkins,[5] and 600 g. of malonic acid were dissolved in 890 cc. of pyridine; 1 cc. of piperidine was then added and the solution was heated on the steam-bath for four hours in a stream of carbon dioxide. The resulting dark red solution was poured on cracked ice and acidified to congo red with concentrated hydrochloric acid. The reaction product began to crystallize and the crystallization was complete after the solution was kept in the refrigerator overnight. The crystalline material was then collected on a Büchner funnel, was washed with dilute hydrochloric acid and water and was dried at 100° *in vacuo*; 337 g. of the crude product was obtained in the form of orange needles. This material, which consists of a mixture of isomers, was used for the next step without further purification. A sample was recrystallized from dilute methanol. Red needles were obtained, which decomposed at 190–195° without melting.

Anal. Calcd. for $C_{10}H_8O_5$: C, 57.68; H, 3.87. Found: C, 57.80; H, 4.01.

(5) Burdick and Adkins, THIS JOURNAL, **56**, 441 (1934).

2-Furanvaleric Acid (IV).—Fifty grams of the above acid was dissolved in 400 cc. of methanol and was hydrogenated in the presence of palladium black at a pressure of 0.1 atmosphere until 13 liters of hydrogen had been consumed. The catalyst was then filtered off and the filtrate was evaporated to dryness *in vacuo*. The resulting sirup was dissolved in 100 cc. of pyridine and the solution was heated to 130–140° until the vigorous evolution of carbon dioxide had stopped. The cooled mixture was then dissolved in ether. The ether solution was washed with dilute hydrochloric acid and water, and was dried over sodium sulfate. The ether was removed on the steam-bath and the residue was distilled *in vacuo*. The fraction boiling at 110–130° at 0.02 mm., solidified on cooling and represents almost pure 2-furanvaleric acid. A sample which was recrystallized from petrol ether melted at 42–43°. The yield was 20 g. (50% of the theoretical yield).

Anal. Calcd. for $C_9H_{12}O_3$: C, 64.27; H, 7.18. Found: C, 64.02; H, 7.31.

Anilide of 2-Furanvaleric Acid.—3.3 grams of the above acid and 6 cc. of freshly distilled aniline were heated to 180° for twelve hours. The excess of aniline was removed *in vacuo*, the residue was taken up in ether and the ethereal solution was extracted with 3 *N* hydrochloric acid and water, and was dried over sodium sulfate. Sublimation

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

of the reaction product at 170° and 0.02 mm. yielded a white solid which was recrystallized from a mixture of ether and petrol ether; 3.7 g. of colorless needles melting at 75–76°, was obtained.

Anal. Calcd. for $C_{15}H_{17}O_2N$: C, 74.07; H, 7.04; N, 5.75. Found: C, 73.75; H, 6.83; N, 5.81.

3,4-Dicarbethoxy-2-furanvaleric Acid (VII).—54 grams of 2-furanvaleric acid (IV) and 62 g. of diethyl-acetylenedicarboxylate were heated on the steam-bath for twelve hours. The oily addition compound (V) was then dissolved in 300 cc. of ethyl acetate and was hydrogenated in the presence of palladium black until 1 mole of hydrogen had been absorbed. The catalyst was then removed by filtration and the ethyl acetate was evaporated. The residue which consists of the partially hydrogenated compound (VI) was then heated at 16 mm. pressure to 190–200° until the evolution of ethylene had stopped. The substance was then distilled and the fraction boiling at 205–210° at 0.02 mm. was collected; 68 g. (68% of the theoretical yield) of 3,4-dicarbethoxy-2-furanvaleric acid was obtained.

3,4-Dicarboxy-2-furanvaleric Acid (VIII).—21.6 grams of the above compound was dissolved in 80 cc. of 5 *N* potassium hydroxide and the solution was heated on the steam-bath for two hours; 80 cc. of water was then added and the solution was acidified to congo red with concentrated hydrochloric acid. The crystalline acid which separated out was collected, washed with water, and dried at 100° *in vacuo*; 16.8 g. (95% of the theoretical yield) of the crude acid melting at 180–182° was obtained. The material was purified by crystallization from a mixture of methanol and ethyl acetate. Needles melting at 188–190° were obtained.

Anal. Calcd. for $C_{11}H_{12}O_7$: C, 51.56; H, 4.72. Found: C, 51.45; H, 4.90.

3,4-Dicarbethoxy-2-furanvaleric Acid Ethyl Ester (IX).—13.5 grams of the above acid, 200 cc. of absolute ethanol and 20 cc. of concentrated sulfuric acid were refluxed for twelve hours. The solution was then concentrated *in vacuo* to one-third of its volume. The residue was diluted with ice-cold water and was extracted with ether. The ether solution was washed with 2 *N* sodium carbonate and water and was dried over sodium sulfate. The ether was removed on the steam-bath and the residue was distilled *in vacuo*; 12.5 g. (70% of the theoretical yield) of the ester boiling at 165–166° at 0.02 mm. was obtained: $n^{24}D$ 1.4741; d^{24} 1.124. The same ester was obtained in 90% yield when 3,4-dicarbethoxy-2-furanvaleric acid (VII) was esterified in the manner described above.

3,4-Dicarbethoxy-2-furanvaleryl Chloride (X).—11.8 grams of 3,4-dicarbethoxy-2-furanvaleric acid (VII) was mixed with 15 cc. of thionyl chloride and the mixture was heated on the steam-bath until the vigorous reaction was over. The excess of thionyl chloride was removed *in vacuo* and the residue was distilled; 9.4 g. (74% of the theoretical yield) of the acid chloride, boiling at 177–178° at 0.02 mm., was obtained.

3,4-Dicarbethoxy-2-furanvaleric Acid Piperidide (XI).—9.4 grams of the above acid chloride (X) was dissolved in 50 cc. of dry ether and this solution slowly added to a solution of 8 g. of freshly distilled piperidine in 50 cc. of ether. The mixture was kept at room temperature for thirty minutes, then washed with 3 *N* hydrochloric acid, 2 *N* sodium carbonate and water and dried over sodium sulfate. The ether was removed and the resulting oil was distilled *in vacuo*; 9.72 g. (90% of the theoretical yield) of the piperidide boiling at 210–211° at 0.02 mm. was obtained: $n^{24}D$ 1.5006; d^{24} 1.132.

3,4-Dicarboxy-2-furanvaleric Acid Piperidide (XII).—9.5 grams of the above ester piperidide (XI) was dissolved in 20 cc. of 5 *N* potassium hydroxide and 40 cc. of methanol and the mixture refluxed for two hours. The solution was then concentrated *in vacuo* and the residue was acidified to congo red with concentrated hydrochloric acid. The resulting oil crystallized on cooling and scratching with a glass rod. The material was collected, was washed with water and was dried. Crystallization of the material from dilute alcohol yielded 6.4 g. (79% of the theoretical yield) of whetstone shaped needles melting at 132–133°.

Anal. Calcd. for $C_{16}H_{21}O_6N$: C, 59.45; H, 6.55; N, 4.33. Found: C, 59.33; H, 6.72; N, 4.31.

The author wishes to express his thanks to Mrs. Florence Baker for technical assistance, and to Mr. William Saschek, Department of Biochemistry, College of Physicians and Surgeons, Columbia University, New York, for performing the micro-analyses.

Summary

1. 3,4-Dicarboxy-2-furanvaleric acid as well as some of its derivatives have been prepared.

2. A satisfactory procedure for the preparation of 2-furanvaleric acid has been described.

3. The ultraviolet absorption curves of 3,4-dicarboxy-2-furanvaleric acid as well as 3,4-dicarboxy-furan have been given.

Unsaturated Synthetic Glycerides. III. Unsaturated Symmetrical Mixed Diglycerides[1]

BY B. F. DAUBERT AND H. E. LONGENECKER

Of the several reliable methods for the synthesis of diglycerides, all involve the use of a glycerol derivative with two free hydroxyls and one temporarily blocked or potential hydroxyl group. Thus, in the Fisher[2] method 1-iodohydrin (Alival) is treated with an excess of an acid chloride, producing 1-iodo-2,3-diacylglycerol. During the subsequent replacement of the iodine by an hydroxyl group, acyl migration from the 2(beta) to the 1(alpha) position of glycerol is known to occur with the resulting production of a symmetrical diglyceride. Similarly, when the 2,3-diacyl derivatives of either the 1-trityl ether of glycerol or 1-carbobenzyloxyglycerol are hydrolyzed, acyl migration occurs to yield the more stable 1,3-diglycerides.[3,4,5,6] These three independent methods have been useful

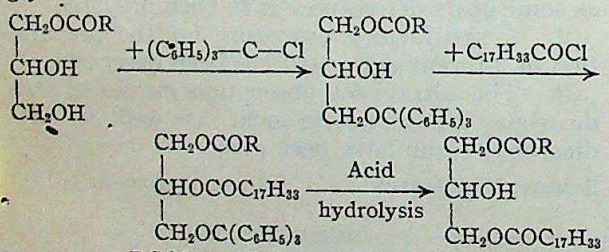
in preparing symmetrical (1,3-) diglycerides of a single fatty acid.

Verkade[6] observed that a 1-monoglyceride reacts with trityl chloride to form an easily separable 1-acyl-3-trityl glycerol with the 2-(beta) hydroxyl group unreacted. This fact makes possible the introduction of a second acyl radical differing from the one present in the original monoglyceride. Acid hydrolysis of the trityl group from the resulting 1,2-diacyl-3-tritylglycerol is again accompanied by a shift of the acyl group in the 2-(beta) position to that position formerly occupied by the trityl group. The resulting diglyceride is again symmetrical but may now contain two different acids in the 1 and 3 positions. Verkade[6] used this method to prepare several mixed symmetrical diglycerides containing two different saturated acids.

Malkin and associates[7] reported the preparation of symmetrical diglycerides containing saturated acids by the direct esterification of 1-monoglycerides (10 to 15% excess) with fatty acids in the presence of *p*-toluenesulfonic acid. This method could, likewise, be adapted to the preparation of symmetrical diglycerides containing two different fatty acids.

In the present investigation advantage was taken of acyl migration during removal, by acid hydrolysis, of the trityl group from a series of 1,2-diacyl-3-tritylglycerols to prepare symmetrical mixed diglycerides containing oleic acid and either lauric, myristic, palmitic, or stearic acid. The reactions starting with the 1-monoglycerides are as follows



$RCOO^-$ = Saturated acid radical
$C_{17}H_{33}COO^-$ = Oleyl radical

The identity and structure of the unsaturated diglycerides were verified by hydrogenation to the completely saturated symmetrical mixed diglycerides. It was necessary, however, for complete identification of the series, to prepare 1-lauryl-3-stearylglycerol by a method other than hydrogenation, since it had not previously been reported in the literature.

Experimental

1-Myristyl-3-tritylglyerol.—The method used for the preparation of this compound is essentially the same as that described by Verkade and van der Lee.[6]

Five grams of 1-monomyristin was dissolved in 10 ml. of quinoline and 5 g. of trityl (triphenylmethyl) chloride added to the solution. The mixture was refluxed on a steam-bath for two hours. On cooling the mixture to room temperature and allowing it to stand for several hours, a copious precipitate of quinoline hydrochloride separated. The semi-solid mass was dissolved in 200 ml. of ether and the solution washed successively with 0.5 *N* sulfuric acid, 5% potassium carbonate solution, and water. The solution, after drying over anhydrous sodium sulfate, was filtered and the ether distilled. The sirupy residue remaining was dissolved in 300 ml. of warm petroleum ether and the solution allowed to stand at room temperature for six hours. The small amount (0.1 g.) of unreacted monoglyceride which separated was filtered off and the petroleum ether removed from the filtrate by distillation under reduced pressure. The residue was then dissolved in 30 ml. of 95% ethyl alcohol and the solution cooled to −20°. After several crystallizations from 95% ethyl alcohol and petroleum ether the product melted at 56.0°: molecular weight, 540 ± 4 (theory, 544.74).

Anal. Calcd. for $C_{36}H_{48}O_4$: C, 79.37; H, 8.88. Found: C, 79.22, 79.19; H, 8.79, 8.82.

1-Lauryl-3-tritylglycerol.—This compound was prepared in a manner similar to that described for 1-myristyl-3-tritylglycerol; m.p. 47.0°; molecular weight, 510 ± 3 (theory, 516.69).

Anal. Calcd. for $C_{34}H_{44}O_4$: C, 79.03; H, 8.58. Found: C, 78.95, 78.99; H, 8.62, 8.65.

1-Stearyl-3-tritylglycerol, m. p. 66.0°, and **1-palmityl-3-tritylglycerol**, m. p. 62.0° (Verkade and van der Lee,[6] 67° and 62°, respectively), were prepared in an analogous manner.

1-Stearyl-2-oleyl-3-tritylglycerol.—Five grams of 1-stearyl-3-tritylglycerol was dissolved in 5 ml. of quinoline and to this solution there was added 2.5 g. of oleyl chloride dissolved in 10 ml. of dry chloroform. The mixture was shaken over a period of two hours and then allowed to stand two days at room temperature. The mixture was dissolved in 250 ml. of ether and 50 ml. of 0.5 *N* sulfuric acid, and then washed successively with small volumes of 0.5 *N* sulfuric acid, 10% potassium carbonate solution and distilled water. After drying the ether solution over anhydrous sodium sulfate, the ether was removed under reduced pressure. The liquid residue remaining was dissolved in warm petroleum ether. An equal volume of 95% alcohol was then added and the solution cooled to −20°. Repeated attempts to induce crystallization from alcohol, petroleum ether, and mixtures of these two solvents, were not successful. The liquid which separated during cooling was washed repeatedly with cold 95% alcohol. This procedure was necessary to obtain a product of satisfactory purity.

1-Palmityl-2-oleyl-3-tritylglycerol, 1-myristyl-2-oleyl-3-tritylglycerol and **1-lauryl-2-oleyl-3-tritylglycerol**, all liquids at room temperature, were prepared in a similar manner (Table I).

1-Myristyl-3-oleylglycerol.—Two grams of 1-myristyl-2-oleyl-3-tritylglycerol was dissolved in 15 to 20 ml. of petroleum ether and the solution cooled to about 5° in an ice-bath. Dry hydrogen chloride was passed into the solution for fifteen minutes. After allowing the mixture to stand at room temperature for two hours, it was dissolved in 150 ml. of ether and the ether solution washed three times with 30-ml. portions of 5% potassium carbonate solution, and water. After drying over anhydrous sodium sulfate the solution was filtered and the ether removed from the filtrate by distillation. The solid residue was dissolved in a 1:2 mixture of ether and alcohol. On cooling at 5° for four hours flaky white crystals separated. After several crystallizations from the same mixture of solvents, the vacuum-dried product melted at 41°.

Analytical constants for **1-myristyl-3-oleylglycerol** and also for **1-stearyl-3-oleylglycerol, 1-palmityl-3-oleylglycerol and 1-lauryl-3-oleylglycerol**, prepared in a similar manner, are tabulated in Table II.

1-Stearyl-2-lauryl-3-tritylglycerol.—This compound not having been reported previously was prepared by essentially the same procedure as for 1-stearyl-2-oleyl-3-tritylglycerol; m.p. 25.0°; molecular weight, 775 ± 4 (theory, 783.14).

(8) Hanson and Bowman, *Ind. Eng. Chem., Anal. Ed.*, 11, 440 (1939).

(9) Daubert, Spiegl and Longenecker, THIS JOURNAL, 65, 2144 (1943).

Summary

Physical and chemical data are reported for seven new tritylglycerol intermediates: 1-myristyl-3-tritylglycerol, 1-lauryl-3-tritylglycerol, 1-stearyl-2-oleyl-3-tritylglycerol, 1-palmityl-2-oleyl-3-tritylglycerol, 1-myristyl-2-oleyl-3-tritylglycerol, 1-lauryl-2-oleyl-3-tritylglycerol, and 1-stearyl-2-lauryl-3-tritylglycerol.

Physical and chemical data are also reported for four new unsaturated symmetrical mixed diglycerides: 1-stearyl-3-oleylglycerol, 1-palmityl-3-oleylglycerol, 1-myristyl-3-oleylglycerol, 1-lauryl-3-oleylglycerol, and a new saturated symmetrical mixed diglyceride, 1-stearyl-3-laurylglycerol.

The refractive index and melting point of the unsaturated symmetrical mixed diglycerides increases with increase in the length of the carbon chain of the saturated fatty acid. The change in refractive index with change in temperature agrees in value with that previously reported for other series of synthetic glycerides.

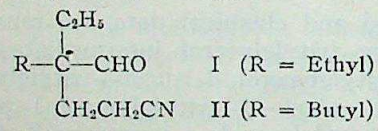
The Chemistry of Acrylonitrile. V. Cyanoethylation of Aldehydes

BY HERMAN ALEXANDER BRUSON AND THOMAS W. RIENER

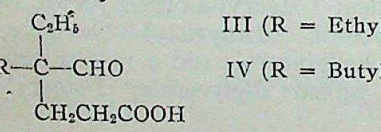
Acrylonitrile reacts with aldehydes in the presence of alkaline catalysts to yield condensation products which in general are more complex than those obtained by the action of acrylonitrile upon ketones.[1]

The direct cyanoethylation reaction so characteristic of ketones, is shown most clearly by those aldehydes which do not readily aldolize, oxidize, or resinify under the influence of the alkaline catalyst used. Typical of such amenable aldehydes are the dialkyl acetaldehydes, particularly those which are higher in the series than isobutyraldehyde. Of these, the commercially available diethylacetaldehyde and 2-ethylhexanal are eminently suitable. These aldehydes react smoothly with acrylonitrile in the presence of a little concentrated aqueous potassium hydroxide solution as a catalyst to form the corresponding cyanoethylation products (I) and (II) in good yields (75–80%).



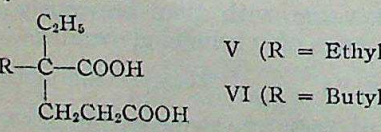
I (R = Ethyl)
II (R = Butyl)

From these aldehydo-nitriles, the corresponding aldehydo-acids (III) and (IV) were obtained by hydrolysis with aqueous sodium hydroxide solution; the tertiary aldehyde groups being hardly affected by the alkali.



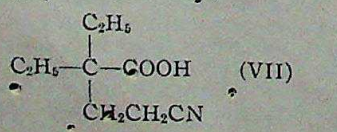
III (R = Ethyl)
IV (R = Butyl)

Upon oxidation with air, hydrogen peroxide, or potassium permanganate, the aldehydo-acids (III) and (IV) yielded the corresponding α,α-dialkylglutaric acids (V) and (VI), respectively, in crystalline form.



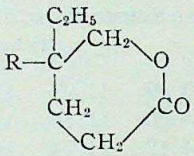
V (R = Ethyl)
VI (R = Butyl)

Although the aldehydo-nitriles (I) and (II) are not readily affected by dilute alkalies, they do rapidly autoxidize in the air to the corresponding cyano-acids. From (I), the cyano-acid (VII) separates in crystalline form upon exposure of a thin layer of the cyano-aldehyde to the air, whereas (II) remains oily.



(VII)

Upon catalytic hydrogenation of the sodium salts of the aldehydo-acids (III) and (IV) in water by means of nickel, the sodium salts of the respective δ-hydroxy acids are formed, which upon acidification yield the corresponding δ-lactones (VIII) and (IX).

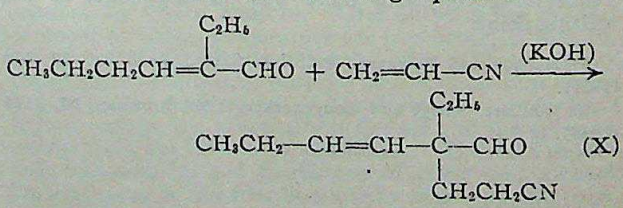


VIII (R = Ethyl)
IX (R = Butyl)

On the other hand, isobutyraldehyde and acetaldehyde are so strongly aldolized that they condense with acrylonitrile in the presence of potassium hydroxide to form a complex mixture of higher cyanoethylation products. The same holds true for propionaldehyde, *n*-butyraldehyde and heptaldehyde. Crotonaldehyde as well as acetaldol likewise form more complex nitrogeneous condensation products with acrylonitrile.

Since it appeared probable that dehydration products of the aldols involved in these reactions, also took part in the condensation with acrylonitrile, it was thought that α-ethyl-β-propylacrolein which is easily formed by the action of alkali on *n*-butyraldehyde through dehydration of the butyraldol[2] might yield a clue concerning the nature of some of the more complex cyanoethylation products encountered.

When equimolecular proportions of α-ethyl-β-propylacrolein and acrylonitrile were mixed in the presence of concentrated aqueous or methanolic potassium hydroxide solution as a catalyst, reaction occurred to form a 50% yield of a *mono*-cyanoethylation product *even though an α-hydrogen atom is lacking in the aldehyde used.* This *mono*-cyanoethylation product (X) is formed in accordance with the following equation



(X)

Under the influence of the alkali, the α-ethyl-β-propylacrolein apparently undergoes a hydrogen shift and the migrating hydrogen atom becomes stabilized by the powerful acceptor action of the acrylonitrile to yield compound (X). In this respect, the reaction is quite analogous to the behavior of other α,β-unsaturated compounds such as mesityl oxide, crotonamide and

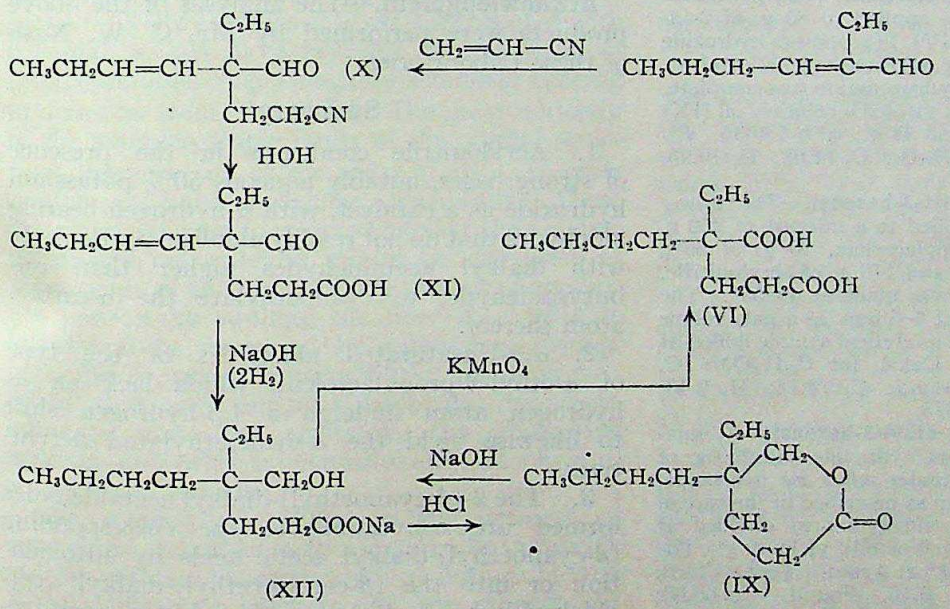
Digitized by Arya Samaj Foundation Chennai and eGangotri

crotononitrile toward acrylonitrile as described previously.[3]

That the cyanoethyl group is in fact *alpha* to the aldehydo group in (X) was shown by hydrolyzing (X) to the unsaturated aldehydo-acid (XI) by means of aqueous sodium hydroxide solution. The pure aldehydo-acid was isolated, converted to its sodium salt and the aqueous solution of the latter was subjected to catalytic hydrogenation in the presence of Raney nickel. The sodium salt of the saturated hydroxy acid formed (XII) was acidified to yield a liquid lactone (IX) which was found to be identical with γ-ethyl-γ-butyl-δ-valero-lactone obtained previously from 2-ethylhexanal through compounds II and IV. Furthermore a portion of this lactone was oxidized in alkaline solution by means of potassium permanganate to α-ethyl-α-butylglutaric acid identical with (VI) derived from 2-ethylhexanal.

The sequence of reactions described above is shown more clearly in the appended equations.



Experimental

(I) **2-(β-Cyanoethyl)-2-ethylbutyraldehyde.**—To a stirred solution of 700 g. of freshly distilled 2-ethylbutyraldehyde (7 moles) and 20 g. of aqueous 50% potassium hydroxide solution, there was added dropwise 408 g. of acrylonitrile (7.7 moles) during the course of two hours while maintaining the reaction temperature at 55–58° by occasional cooling. After all had been added, the mixture was stirred for an additional ninety minutes until the exothermal reaction had ceased, and finally heated for one hour at 55° to complete the reaction. The product was acidified to congo red with dilute hydrochloric acid, washed twice with water, dried under reduced pressure and the residual oil (1018 g.) distilled in vacuum while nitrogen was admitted through the capillary tube to prevent oxidation. The crude product distilled at 115 to 125° at 4–6 mm. as a colorless oil; yield 821 g. or 76.6%. Upon redistillation in nitrogen under vacuum the analytical sample boiled at 128° at 4 mm. *Anal.* Calcd. for $C_9H_{15}ON$: C, 70.53; H, 9.87; N, 9.14. Found: C, 69.98; H, 9.91; N, 9.24; $n^{25}D$ 1.4500; d^{25}_4 0.9528.

(II) **2-(β-Cyanoethyl)-2-ethylhexanal.**—The procedure above was applied to a mixture of 384 g. 2-ethylhexanal, 10 g. 50% potassium hydroxide solution and 175 g. of acrylonitrile. The product distilled at 130–138° at 4 mm. as a colorless oil; yield 432 g. or 79.5%. Upon redistillation in nitrogen the analytical sample boiled at 140–142° (5 mm.). *Anal.* Calcd. for $C_{11}H_{19}ON$: C, 72.87; H 10.57; N, 7.73. Found: C, 73.00; H, 10.61; N, 7.82; $n^{25}D$ 1.4515; d^{25}_4 0.9269.

(III) **2-(β-Carboxyethyl)-2-ethylbutyraldehyde.**—A mixture of 153 g. of compound (I), 50 g. of sodium hydroxide and 500 cc. of water was stirred and boiled under reflux for one and one-half hours until the oil had disappeared. The solution was cooled, acidified with hydrochloric acid, and the precipitated oil separated, washed with water and dried in vacuum. The residual oil (152 g.) was distilled *in vacuo* in a stream of nitrogen. The product (122 g.) came over at 145–150° (5 mm.) as a colorless oil; acid no. 335 (calcd., 326). The analytical sample obtained by redistillation in vacuum in an atmosphere of nitrogen, boiled at 142° (3 mm.). *Anal.* Calcd. for $C_9H_{16}O_3$: C, 62.74; H, 9.37. Found: C, 62.40; H, 9.46; $n^{25}D$ 1.4550; d^{25}_4 1.0338.

(IV) **2-(β-Carboxyethyl)-2-ethylhexanal.**—The procedure described above was applied to a mixture of 30 g. of compound (II), 10 g. of sodium hydroxide and 100 g. of water except that the boiling was continued for five hours. The crude yield of aldehydo-acid boiling at 160–165° (4 mm.) was 24.5 g. The analytical sample obtained by redistillation *in vacuo* was a colorless oil boiling at 157° (4 mm.). *Anal.* Calcd. for $C_{11}H_{20}O_3$: C, 65.94; H, 10.07. Found: C, 65.90; H, 10.12; $n^{25}D$ 1.4564; d^{25}_4 1.0325.

(V) **α,α-Diethylglutaric Acid.**—To a stirred solution of 41.6 g. of compound (III), 25 g. of potassium hydroxide and 250 g. of water, a suspension of 57 g. of potassium permanganate in 500 g. of warm water was added gradually during the course of fifteen minutes while maintaining the reaction temperature at 30–40° by occasional cooling. The mixture was stirred for three hours and allowed to stand eighteen hours. The product was filtered, the precipitate washed, and the combined washings and filtrate acidified with hydrochloric acid. The turbid solution obtained was evaporated to dryness *in vacuo* on a steam-bath and the crystalline residue extracted several times with acetone. The acetone extract upon evaporation of the acetone deposited 26 g. of colorless crystals which after recrystallization from nitromethane formed colorless needles, m. p. 84° (uncor.). *Anal.* Calcd. for $C_9H_{16}O_4$: C, 57.40; H, 8.57. Found: C, 57.20; H, 8.70.

(VI) **α-Ethyl-α-butylglutaric Acid.**—A suspension of 57 g. of potassium permanganate in 500 cc. of water was added gradually to a solution of 60 g. of compound (IV), 250 cc. of water and 25 g. of potassium hydroxide at 45–50°. The mixture was stirred thereafter at room temperature for eighteen hours, filtered, and the filtrate acidified with concentrated hydrochloric acid. The product precipitated as a viscous oil. It was taken up in toluene, washed once with water and dried to yield 53 g. of crude acid. This was dissolved in hot nitromethane from which it separated on cooling in colorless crystals; yield 39 g. After several recrystallizations from nitromethane the melting point remained constant at 81–82°. *Anal.* Calcd. for $C_{11}H_{20}O_4$: C, 61.07; H, 9.28. Found: C, 60.70; H, 9.25.

(3) Bruson and Riener, THIS JOURNAL, 65, 18 (1943).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

(VII) 2-(β-Cyanoethyl)-2-ethylbutyric Acid.—A small quantity of 2-(β-cyanoethyl)-2-ethylbutyraldehyde (I) was spread out on a watch glass and exposed to the air for about a week. The crystalline crust which formed was separated and recrystallized from diisobutylene or petroleum ether (90–100°). The product separated in colorless needles, m.p. 88° (uncor.). *Anal.* Calcd. for $C_9H_{15}O_2N$: C, 63.86; H, 8.94; N, 8.28. Found: C, 63.80; H, 8.88; N, 8.29.

(VIII) γ,γ-Diethyl-δ-valerolactone.—Eighty-six grams of 2-(β-carboxyethyl)-2-ethylbutyraldehyde (III) was made faintly alkaline with a solution of about 20 g. of sodium hydroxide in 115 g. of water. This solution was shaken in an autoclave with 10 g. of Raney nickel catalyst and hydrogen under an initial pressure of 100 atmospheres, for seven hours at 120–140°. At the end of this time the pressure had fallen to about 40 atmospheres. The mixture was filtered free from catalyst and the clear filtrate acidified with concentrated hydrochloric acid. The thick oil which separated was dissolved in toluene, washed with water and evaporated to dryness *in vacuo* on a steam-bath. The residual oil was distilled under reduced pressure. The lactone came over between 112 and 118° at 4–5 mm. as a colorless oil; yield 63 g. The analytical sample obtained by redistillation boiled at 101° (2.5 mm.); $n^{25}D$ 1.4634; d^{25}_4 1.0064. *Anal.* Calcd. for $C_9H_{16}O_2$: C, 69.17; H, 10.33. Found: C, 68.78; H, 10.40.

(IX) γ-Ethyl-γ-butyl-δ-valerolactone.—The procedure described in (VIII) above was applied to 80 g. of 2-(β-carboxyethyl)-2-ethylhexanal (IV), 16 g. sodium hydroxide and 100 g. of water, using 10 g. of Raney nickel catalyst. After three hours at 125° the hydrogenation was complete. The acidification of the product yielded a colorless oil (IX) boiling at 124° (3.5 mm.); yield 44 g.; $n^{25}D$ 1.4635; d^{25}_4 0.9747. *Anal.* Calcd. for $C_{11}H_{20}O_2$: C, 71.68; H, 10.95. Found: C, 71.30; H, 11.19.

(X) 2-(β-Cyanoethyl)-2-ethyl-3-hexenal.—The procedure described for (I) was applied to a mixture of 252 g. freshly distilled α-ethyl-β-propylacrolein, 10 g. of 50% potassium hydroxide solution, and 110 g. of acrylonitrile, except that the condensation was made at 45–55°. The product distilled at 126–135° at 4–5 mm. as a pale yellow oil; yield 175 g. or 49%. The analytical sample boiled at 138–140° at 6 mm. *Anal.* Calcd. for $C_{11}H_{17}ON$: C, 73.68; H, 9.57; N, 7.82. Found: C, 73.14; H, 9.43; N, 7.63; $n^{25}D$ 1.4640; d^{25}_4 0.9375.

(XI) 2-(β-Carboxyethyl)-2-ethyl-3-hexenal.—A mixture of 55 g. (X), 20 g. sodium hydroxide and 200 g. of water was stirred and boiled under reflux for five hours, cooled, acidified, and worked up as described in the case of compound (III). The crude aldehydo-acid distilled at 160–170° at 5 mm. as a pale yellow oil; yield 40 g. The analytical sample boiled at 154° at 4 mm. *Anal.* Calcd. for $C_{11}H_{18}O_3$: C, 66.62; H, 9.15. Found: C, 66.60; H, 9.35; $n^{25}D$ 1.4695; d^{25}_4 1.0112.

Hydrogenation of (XI).—Sixty-three grams of 2-(β-carboxyethyl)-2-ethyl-3-hexenal (XI) was made faintly alkaline with an aqueous 20% sodium hydroxide solution and shaken in an autoclave with 10 g. of Raney nickel catalyst for five hours at 130–135° with hydrogen at an initial pressure of 110 atmospheres. The filtered product (XII) was acidified with concentrated hydrochloric acid and the heavy oil taken up in toluene, washed, and evaporated to dryness *in vacuo* on a steam-bath. The residual oil was distilled under reduced pressure. The product (45 g.) came over at 121–123° at 3 mm. as a colorless oil. The redistilled analytical sample boiled at 120° (3 mm.) and possessed the following constants: $n^{25}D$ 1.4632; d^{25}_4 0.9736. *Anal.* Calcd. for $C_{11}H_{20}O_2$: C, 71.68; H, 10.95 Found: C, 71.24; H, 10.96. Its constants and analysis show it to be identical with γ-ethyl-γ-butyl-δ-valerolactone (IX).

Oxidation of γ-Ethyl-γ-butyl-δ-valerolactone.—Part of the above lactone (18.4 g.) obtained from the hydrogenation of the unsaturated aldehydo-acid (XI) was oxidized by dissolving it in a solution of 11.2 g. of potassium hydroxide and 200 g. of water. To this solution there was added while stirring, a suspension of 47.4 g. of potassium permanganate in 400 g. of water at 35–40°. The mixture was then heated for eight and one-half hours at 55–60°, filtered and the filtrate acidified with concentrated hydrochloric acid. The oil which separated solidified after several hours at 5°; yield 17 g. After recrystallization from nitromethane it formed colorless needles, m. p. 81° (uncor.). A mixed melting point with (VI) showed no depression. The product was therefore α-ethyl-α-butylglutaric acid.

Acknowledgment.—The analyses of the above products were performed by Mr. C. W. Nash of these Laboratories.

Summary

1. Acrylonitrile condenses in the presence of strong bases, notably aqueous 50% potassium hydroxide as a catalyst, with α-hydrogen-bearing aldehydes that do not readily aldolize, particularly with dialkyl acetaldehydes higher than isobutyraldehyde, to cyanoethylate the α-carbon atom thereof.

2. α,β-Unsaturated aldehydes of the type of α-ethyl-β-propylacrolein, which lack an α-hydrogen atom undergo a 1,3-hydrogen shift to likewise yield the α-cyanoethylated derivatives.

3. The 2-(β-cyanoethyl)-dialkyl acetaldehydes formed are convertible to the corresponding (β-cyanoethyl)-dialkyl acetic acids by autoxidation or into the (β-carboxyethyl)-dialkyl acetaldehydes by hydrolysis. The latter upon reduction yielded γ,γ-dialkyl-δ-valerolactones, and upon oxidation α,α-dialkyl glutaric acids.

A Study of the Amorphous Portion of Dry, Swollen Cellulose by an Improved Thallous Ethylate Method[1,2]

BY A. G. ASSAF, R. H. HAAS AND C. B. PURVES

Several recent reviews[3] summarize in detail the modern concept of the structure of fibrous cellulose. It is only necessary to remark here that the linear macromolecules are crystallized together along intermittent portions of their length to form elongated, dense crystallites, or micelles, that are of submicroscopic dimensions and produce a well-defined X-ray diffraction pattern. Other portions of the macromolecules have a more confused relationship in space to one another, give rise to a diffuse or "amorphous" X-ray background and form a less dense, highly porous system of great absorptive capacity. The coarsest flaws and discontinuities in the fiber are visible in the microscope and electron microscope.[4] X-Ray studies of fibers impregnated with colloidal metals have revealed the presence of intercommunicating, elongated channels ranging in diameter from 50–120 Å.[5] The great majority of the submicroscopic faults in the crystal structure, however, are of the order of 10 Å. in cross section, or have molecular dimensions. These ideas make it easy to understand that the amount of amorphous cellulose might be increased at the expense of the less perfectly organized crystallite portion by swelling the fiber in a suitable liquid and be decreased by subsequent drying, particularly under tension.[6a,6b,7] There is evidence that such changes have an important influence upon the elasticity, the absorptive capacity and other industrially valuable physical properties of the fiber.[6b]

One method of estimating the amount of amorphous cellulose is to measure the intensity of the diffuse "background" radiation in the X-ray diffraction pattern of the fiber.[6b] In other methods, the solid cellulose is submitted to a suitable chemical change and the percentage of the more accessible, amorphous portion is calculated from the extent of the initial, more rapid reaction. The rate plots of various heterogeneous reactions[8,9] have been interpreted in this way. These chemical procedures suffer from the disadvantage that the reagents either do, or possibly may, penetrate the cellulose crystallites and may also cause swelling during the estimation. Both eventualities would tend to make the results high by an undetermined amount. In an endeavor to avoid this difficulty, Harris and Purves studied the thallation produced in ramie fiber by thallous ethylate dissolved in ether or benzene, which are non-hydroxylic, non-swelling liquids.[10] Since thallous ethylate is a strong base like its sodium analog, cellulose hydroxyl groups that came into contact with the reagent were changed to thallium alcoholates

$$\text{Cellulose OH} + \text{TlOEt} \longrightarrow \text{Cellulose OTl} + \text{EtOH}$$

The reaction was considered to be restricted to the amorphous cellulose because the thallation of finely powdered sucrose crystals, or unswollen ramie fiber, was very small and because the X-ray diffraction pattern of thallium cellulosate had no signs of a regularly oriented thallium crystal lattice. The thallium cellulosate was heated with excess methyl iodide,[11] or dimethyl sulfate, in benzene and, after purification, the methoxyl content

$$\text{Cellulose OTl} + \text{MeI} \longrightarrow \text{Cellulose OMe} + \text{TlI}$$

of the resulting partly methylated cellulose was determined. Since the thallation and methylation of some fructosides proceeded almost quantitatively with sufficient excess of the reagents,[12] the methoxyl substitution of the partly methylated cellulose was accepted as proportional to the number of hydroxyl groups that had come into contact with the thallous ethylate reagent. The present article describes substantial improvements in the technique of the estimation, together with the behavior of dry, highly swollen cotton linters toward thallous ethylate dissolved in several organic liquids. A new definition of amorphous cellulose is suggested and the measurements show that its absolute amount varies greatly.

Experimental

The methods are described in detail. Although straightforward enough in principle, they can be used successfully only by avoiding many manipulative errors that are not so unimportant as they may seem.

Preparation of Cellulose Samples.—Thoroughly dewaxed, air-dried, high grade cotton linters,[13] 15 g., were immersed in 540 cc. of 10% caustic soda kept at 5°,[14] and after three hours the loose, swollen mass was diluted with 540 cc. of 2% caustic soda. Thirty minutes later the cotton was recovered by filtration and was washed thoroughly and in succession with water, with 1% acetic acid and with distilled water. Slight squeezing quickly removed most of the excess moisture before the wet mass was dispersed in a liter of 99+ % methanol. The methanol was removed and replaced by a fresh amount after fifteen minutes. A third immersion, this time in magnesium-dried methanol, was followed by two more, each of thirty minutes duration, in one-liter volumes of sodium-dried, thiophene-free benzene. The supernatant liquors were easily reclaimed and purified. Great care was taken to avoid letting the cellulose dry out even superficially, by keeping it completely covered by the methanol or benzene, and by quick manipulation during the transfers. Neglect of this precaution resulted in non-uniform preparations.

The swollen linters, now moist with benzene, were dried for several days in a desiccator containing solid paraffin wax. The desiccator was evacuated at intervals to 25 mm. pressure, but the use of a higher vacuum was avoided because a too rapid, irregular evaporation of the benzene produced a non-uniform product. This mishap was signalized by the appearance of white patches on the surface of the rather translucent mass. Although up to 15 g. of linters could be swollen and dried in a uniform way with available laboratory equipment, the degree of swelling could not be exactly duplicated in successive preparations. The dried, swollen linters were stored for ten days or more over concentrated sulfuric acid in a desiccator that was *not* evacuated and were then ready for thallation. Solid caustic potash *in vacuo* was a less efficient desiccating agent. The effect of this final drying on moisture-containing preparations is discussed in another article.[15]

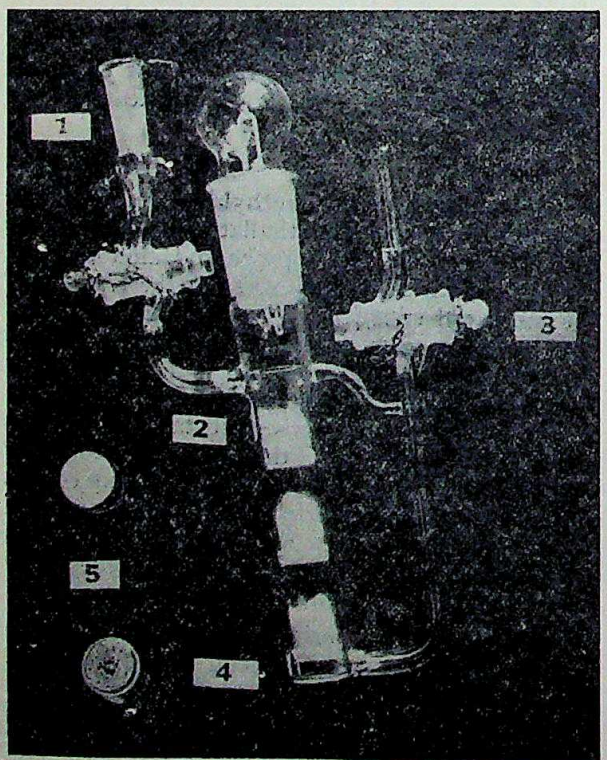

Fig. 1.—Apparatus used for thallation of cellulose.

Solvents.—The ready decomposition of thallous ethylate by moisture, by peroxides and other catalysts made it essential to purify all solvents carefully. Standard methods were used.[16]

Commercial 1,4-dioxane was freed from any acetals by refluxing with dilute hydrochloric acid in the presence of a stream of air. Thiophene was removed from benzene by bubbling the vapors, at 80°, through concentrated sulfuric acid. Other solvents were given suitable preliminary purifications when necessary. All hydrocarbons and ethers were dried with sodium before fractional distillation and were stored over sodium wire in brown glass bottles to avoid the formation of peroxides. These solvents were decanted from the sodium when required. All alcohols were dried either by adding small pieces of sodium or by refluxing with clean magnesium ribbon, and were recovered by distillation just before use. Methyl iodide was redistilled from phosphorus pentoxide.

Preparation of Thallous Ethylate Solutions.—Thin slices of clean, silvery thallium metal, 2 g., contained in a 125 cc. glass-stoppered, thick-walled Erlenmeyer flask, were covered with 50 cc. of absolute ethanol, and a stream of dry oxygen gas was played over the surface of the liquid for one or two minutes.[17] The flask was then stoppered, shielded from light and shaken mechanically. Solution of the metal was complete within two hours if the oxygen atmosphere was renewed at fifteen minute intervals. It was inadvisable to use thallium pellets in the preparation unless their surface was quite free from the insoluble brown crust formed by prolonged exposure to the air. The use of a trace of iodine to hasten the solution of the metal[10] was abandoned because iodine also catalyzed the decomposition of the thallous ethylate.

A small piece of porous porcelain was added to the solution to promote uniform boiling during the removal of ethanol in the vacuum of a water pump. The latter part of the distillation was from a warm water-bath but an excessive use of the pump was avoided lest moisture reach the ethylate when the vapor pressure of the residual alcohol became low. When the flask was shielded from light and the technique of distillation was satisfactory, the residual thallous ethylate formed about 1 cc. of a heavy, pale yellow oil. The oil was kept at room temperature for ten minutes in a high vacuum to remove any traces of ethanol and was dissolved in 50 cc. of the pure, anhydrous solvent to be used. Glass-stoppered graduates of 100-cc. capacity were convenient receptacles for these solutions.

The normality of the thallous ethylate was determined by pipeting 5 cc.[18] into a mixture of 20 cc. of methanol and 10 cc. of 0.1 *N* hydrochloric acid, the excess of which was then titrated with standard caustic soda. Dilution of the thallous ethylate solution to 0.1 *N* was made with the appropriate volume of the pure solvent. These solutions did not change their normality during several weeks if kept near 0° in the dark, but exposure to light caused a rather rapid formation of a spongy, brown decomposition product. Thallous ethylate oil was also fairly stable when properly stored.

Apparatus.—The all-glass Pyrex apparatus (Fig. 1) was designed for triplicate cellulose samples and was made from 20-mm. tubing about five inches long. The top carried a no. 20 female joint and could be closed with a well-fitting, lightly greased, ground stopper. Liquids introduced through the no. 7 female joint (1) from a 30-cc. separatory funnel passed through a stopcock and a sintered glass filter (2) before entering the tube a short distance below the stopper. Solutions were withdrawn through the stopcock (3) which was attached to the side of

the tube by a solid glass support and to the flat bottom (4) by capillary tubing. Both stopcocks were of the 2-mm. slant-bore type.

The cellulose samples were contained in three glass cups, one inch in height, that fitted rather closely, one above the other, into the 20-mm. tube. These cups, shown separately at (5), had sintered glass bottoms for finely divided samples and perforated bottoms for fibrous ones. An annular segment of glass rod raised the lowest cup from the bottom of (4) so that liquid passed without obstruction into the capillary exit tube.

Procedure for Thallation and Methylation.—The cotton samples, 0.1 to 0.3 g., were transferred from a desiccator into the tared cups and were quickly weighed on a magnetically damped balance prior to insertion into the apparatus (Fig. 1). The stopper was replaced promptly to prevent access of moisture and the apparatus was at once evacuated with an oil pump attached to (3). A low result was obtained when this evacuation was neglected. Stopcock (3) was then closed and (1) was opened to permit 0.1 *N* thallous ethylate solution to be sucked into the apparatus from the separatory funnel. About 20 cc. of solution was sufficient to fill all three cups and immerse them completely. After standing in the dark at room temperature for one hour, the partly exhausted solution was sucked out through stopcock (3), with a minimum use of a water pump, and the thallation was repeated with fresh solution drawn in through (1). Samples thallated in ethers or hydrocarbons were colored yellow and, the deeper the color, the greater the thallation. When the thallous ethylate was dissolved in an alcohol, no color developed, although thallation occurred. The thallous ethylate solution was withdrawn at the end of the second hour in the dark and residual amounts were washed from the samples by filling the apparatus with pure, dry benzene. Four or five benzene extractions, the first of fifteen and the others each of five minutes duration, were sufficient. The wet samples were then prepared for methylation by filling the apparatus with benzene containing a large excess, 2 cc., of methyl iodide. The no. 20 ground-glass stopper (Fig. 1) was replaced with a glass-jointed reflux condenser whose upper end was equipped with a calcium chloride tube, stopcocks (1) and (3) were closed and the entire apparatus was immersed up to the level of the upper sample cup in a water-bath kept at 80°. No exclusion of light was necessary during the methylation, which was complete within three and one-half hours. Since thallous iodide was a by-product of the reaction, the methylation was attended by a color change in the samples from yellow or white to orange, the final depth of which was a rough measure of the amorphous cellulose. An experienced operator could complete the thallation and methylation of twenty-one cellulose samples, contained in seven sets of equipment, during one long working day. The condenser was then exchanged for the glass stopper, the excess methyl iodide–benzene mixture in the cell was sucked out by the water pump and pure benzene was sucked in. The first two benzene extractions, each of fifteen minutes' duration, were followed by six more each lasting for five to ten minutes. Thoroughness was essential in this extraction lest traces of residual methyl iodide invalidate the final methoxyl estimation. The apparatus was then connected to a vacuum pump but in the beginning stopcock (3) was kept open only momentarily in order to avoid scattering of the samples by a too sudden evaporation of the residual benzene. After a final drying in high vacuum at 80° for two hours, the whole of each sample, with its occluded thallous iodide, was analyzed at leisure for its methoxyl content. Clark's procedure[19] was followed except that 5 g. rather than 2 g. of phenol was added to the hydriodic acid to promote more regular ebullition, and the sample was dissolved in the reagent by a preliminary heating for a few minutes in a boiling water-bath.[20] The methoxyl content was expressed as a percentage of the original, *unsubstituted* cellulose, and multiplication by the factor 100/57.4 gave the percentage of the cellulose hydroxyl groups that had been methylated.[21] This value was assumed to be equal to the percentage of the cellulose wetted by the solvent for the thallous ethylate.

[a] Based on weight of original cellulose sample. [b] Mean methoxyl percentage × 100/57.4 = percentage of cellulose hydroxyl groups methylated. [c] Extraction of last traces of methyl iodide as described in experimental portion.

Reproducibility of the Estimation.—Table I contains a representative portion of the data, which included more than two hundred and fifty individual estimations. Cups 1, 2 and 3 refer to triplicate analyses carried out simultaneously in the top, middle and bottom cups of a single piece of apparatus. If the observed methoxyl content decreased markedly and steadily from the top to the bottom cup, as in the case quoted for thallous ethylate in isoamyl ether, incomplete thallation was at once suspected and the analyses were repeated. The other serious cause of divergence between triplicates was failure to extract the last traces of methyl iodide from the methylated samples prior to the methoxyl estimation. Most of the present data were obtained before this fact was fully appreciated and the divergence from the averages quoted below was sometimes as much as ± 10%. When the method of extraction already described was rigidly followed, the agreement between triplicates was usually better than ± 5%. The third analysis on samples known to be uniform was sometimes omitted when the first two gave the same result. Wide fluctuations that persisted in a second series of analyses were characteristic of samples that were not uniform and were usually connected with poor technique during the drying of the swollen cellulose.

Estimation of Cellulose Hydroxyl Groups by Means of Methylmagnesium Iodide.—Use was made of a modified Zerewitinoff apparatus that had been extensively tested during the determination of active hydrogen in insulating and other oils.[22,23] A thoroughly dried specimen of highly swollen linters, 0.117 g., was brought into contact with excess of an approximately 0.4 *M* solution of methylmagnesium iodide in isoamyl ether[24] and 4.96 cc. of methane (cor. to N.T.P.) was collected. This amount corresponded to the active hydrogen in 10.2% of the hydroxyl groups in the sample. A preliminary result of 5.7% was rejected as erroneous. Parallel estimations by the thallation-methylation method, giving 6.8, 6.5 and 6.5% methoxyl with thallous ethylate dissolved in the same

(21) Trimethyl cellulose has a methoxyl content of (3 × 31 × 100)/162, or 57.4% on this basis, and the figure for lower methylated derivatives is directly proportional to their substitution.

solvent, indicated that 11.5% of the hydroxyl groups had been methylated. The latter figure was 20% with thallous ethylate in diethyl ether. Although the Zerewitinoff method checked the thallous ethylate technique, the utility of the former for present purposes was limited by its sensitivity to traces of moisture in the sample and by the necessity of employing a solvent with a low vapor pressure.

Results and Discussion

In Fig. 2, the percentage of methoxyl introduced into three different samples of uniformly swollen, dried linters by the thallation-methylation technique is plotted against the molecular volume of the liquid in which the thallous ethylate was dissolved. Each point is the average of duplicate or triplicate estimations that agreed with the mean to within ±10% and all thallations of each cellulose sample were made simultaneously in order to avoid the effects of possible change in the specimen.[15] These precautions were taken throughout the work. The points for ethyl, *n*-propyl (Fig. 2, plot II), *n*-butyl and *n*-amyl ethers fall on three straight lines whose slope and position are characteristic of the cellulose sample. Although the decrease in the degree of methylation with increasing molecular volume could have been predicted from the work of others,[25,26,27] the closely linear nature of the relationship suggests that the cross-section of the capillaries in the amorphous portion of the linters diminishes in a regular way as a crystalline region is approached. Plot IV, obtained with the same cellulose and at the same time as the other plot II, demonstrates that the extent of thallation with the normal hydrocarbons is entirely independent of their molecular volume. Attempts were made to reconcile the data in the two series by plotting the per cent. of methylation against some other physical property, such as the viscosities or the molecular weights, of the liquids in question. These attempts revealed no regular relationship and the results with normal hydrocarbons require amplification. Their curious behavior may be connected with the fact that they differ from ethers in having no dipole moment and no residual affinity for hydroxyl groups. Since branched chain and cyclic molecules are more limited in shape configurations than their normal analogs, it is to be expected that they would have greater difficulty in entering the finest capillaries and would permeate the amorphous portion of cellulose less efficiently. Figure 3 shows that the methoxyl contents produced with thallous ethylate in isoamyl ether, 1,4-dioxane and decalin were lower than those obtained with *n*-amyl ether, diethyl ether and *n*-decane, respectively, although each pair had approximately the same molecular volume. The figure for dioxane is interpolated from similar experiments.

The data summarized in Fig. 4 are strictly comparable with the exception of those for methanol, which were obtained with an 0.056 *N*, instead of the usual 0.1 *N*, thallous ethylate solution.[28] Individual estimations are recorded because those for the ethers were unusually discordant. Although the results with the normal alcohols from ethyl to heptyl are regular and reproducible, the molecular volume plot is not linear and lies below that of the ethers. Since

alcohols swell cellulose somewhat, they should penetrate the amorphous portion more readily than ethers of comparable molecular volume and lead to more, rather than less, thallation and methylation. This discrepancy strongly suggests that thallation in alcohols was incomplete, probably because the large number of hydroxyl groups they contain competed effectively with those in the cellulose for the thallium. There is also a possibility that molecular association rendered the effective volumes of the alcohols three to seven times larger than those calculated.[29]

The thallous ethylate molecule has a calculated molecular volume of about 69 (density about

(29) Fox and Martin, *Trans. Faraday Soc.*, **36**, 897 (1940), express the opinion that up to four benzyl alcohol molecules may form hydrogen bonds with each other. The resulting, unstable, cyclic structure may have the hydrocarbon groups on the outside.

3.6,[17] mol. wt. 249) and any part it played in the above experiments was a matter of importance. A consideration of Figs. 2 to 4 strongly suggests that the ethylate functioned merely as a delineator of the penetration of the liquid in which it was dissolved, because otherwise the dependence of the methylation data upon the molecular volume of the solvent would be incomprehensible. This conclusion was supported by parallel experiments with solutions of methyl magnesium iodide and thallous ethylate in isoamyl ether. The methane liberated in the first case corresponded to 10.2% of the cellulose hydroxyl groups and 11.5% reacted in the control experiment. The approximate equality of these figures shows that the extent of the reaction was independent, or nearly so, of the nature of the reactive solute. When this view is accepted, the extrapolation of the normal ether plots to zero methylation (Figs. 2 to 4) theoretically gives the maximum molecular volume a liquid may have if it can enter the fiber at all. These limiting volumes range from 360 upward and are large enough to accommodate molecules as bulky as those of many dyestuffs. Such molecules, however, would come into contact with the visible external surface and would enter the coarsest channels of the submicroscopic capillary system.[5] Since the wetting of these minute portions of the fiber would be independent of the molecular volume of the liquid, the above extrapolation must become asymptotic to the abscissa at a small methoxyl percentage.

Extrapolation of the normal ether plots in the other direction gives the theoretical methylation, or thallation, produced by thallous ethylate dissolved in a liquid of zero molecular volume. This observation suggests that the amorphous portion of cellulose can be defined as the percentage accessible to a liquid of zero molecular volume and with no tendency to swell the cellulose or penetrate its crystallites.[30] If this definition has any validity, the result should be independent of the particular homologous series of liquids in which the thallous ethylate is dissolved. Figure 4 shows that this inference is probably true for the normal ethers and alcohols (omitting methanol) and that the methylation at zero molecular volume lay between 14.5 and 16.5%. The amorphous cellulose in this sample was therefore 15.5 × 100/57.4 or 27%, with an absolute error of the order of ±2%. Since the extrapolation was a large one, an attempt was made to determine the data for dimethyl ether (mol. vol. 40) which falls at an intermediate point on the plot. The estimation was tried at atmospheric pressure and −30° but was not completed because the thallous ethylate crystallized rapidly from solution at this low temperature. Another attempt with water (mol. vol. 18) was more successful and led to a new and reasonable interpretation of the cellulose-moisture adsorption isotherm.[15] The above definition of amorphous cellulose has at least the merit of practicality, although the anomalous behavior of the normal hydrocarbons (Fig. 2) makes it advisable at present to use only ethers or alcohols in the estimation.

Table II, column 3, summarizes the results of the present research and includes other relevant data. The infrared absorption study[31] showed that all, or nearly all, of the hydroxyl groups in dry, unswollen ramie are hydrogen bonded and presumably are present in the molecular lattice of the crystalline portion. Neither the infrared study, nor statements based upon the X-ray method,[6b,7,32,33] are considered to be necessarily in conflict with the very small percentages of amorphous cellulose revealed in unswollen samples by the thallous ethylate technique, or by methylation with an ethereal solution of diazomethane.[34] If these percentages are accepted as approximately correct, it follows that suitable swelling and drying procedures increase the amorphous fraction fifty or even an hundredfold and therefore increase the accessibility of fibrous cellulose to non-swelling reagents by a factor of similar magnitude. Another article[15] discusses this matter in greater detail. It also follows from column 3 that estimations of the amorphous fraction by acetylation[8] or by oxidation with ferric chloride in aqueous hydrochloric acid[9] involve a surprisingly large degree of swelling, and record the amounts present in swollen products rather than those in the initial samples. This characteristic, of course, may enhance the utility of such methods as control estimations for celluloses destined for industrial processes in which swelling plays a prominent role.

If it be assumed from X-ray data that a single glucose residue has an area of 52×10^{-16} sq. cm.,[35] a continuous, unimolecular film of cellulose weighing 1 g. covers $52 \times 10^{-16} \times 6.02 \times 10^{+23}/162$ or $1.87 \times 10^{+7}$ sq. cm. The colloidal surfaces (Table II, column 4) corresponding to the amorphous fractions found by the thallous ethylate method range up to 520×10^{4} sq. cm. per gram and their extent approximates those developed by good grades of carbon black.[36] The order of magnitude of these surfaces is also in agreement with the general value of 300×10^{4} sq. cm. per gram derived for swollen celluloses

from the areas covered by various adsorbed films.[37] The latter investigations, however, assign a cross-sectional area to the adsorbed molecule, rather than to the cellulose itself, and assume the adsorbed film to be monomolecular and continuous. A close comparison of these data with the results of the present work is therefore hardly possible. As might be expected, the microscopically visible surface of about 2×10^3 sq. cm. per gram assigned to unswollen fibers[37] is considerably smaller than the 5×10^4 sq. cm. per gram available to an ether of zero molecular volume (Table II).

Summary

1. Cotton linters, highly swollen in caustic soda and dried through methanol and benzene, were immersed in a large excess of 0.1 *N* thallous ethylate solution. The thallium cellulosate so formed was methylated with excess methyl iodide in benzene. The methoxyl content of the product was accepted as proportional to the percentage of the cellulose wetted by the particular liquid in which the thallous ethylate was dissolved.

2. The extent of the methylation did not depend upon the molecular volume of normal hydrocarbon solvents for the thallous ethylate, but the relationship was inverse and linear for the normal ethers from diethyl to di-*n*-amyl. Branched chain or cyclic ethers and hydrocarbons penetrated the cellulose less efficiently than their normal analogs and thallations in alcohols, although reproducible, were thought to be incomplete.

3. "Amorphous" cellulose was defined to be the percentage wetted by an ether of zero molecular volume and was estimated by extrapolating the linear methylation-molecular volume plots of three or more straight chain ethers. An extrapolation of the similar plot for the normal alcohols from ethyl to hexyl tended to confirm the result, which was probably accurate to ±10%.

4. The amorphous fractions of swollen linter samples were as high as 27 ± 2% but the amount present in unswollen fibers was of the order of 0.25 to 0.5%. The corresponding colloidal surfaces, ranging from 520×10^4 to 5 or 10×10^4 sq. cm. per gram, were not inconsistent with published estimates based upon other experimental methods.

A New Interpretation of the Cellulose–Water Adsorption Isotherm and Data Concerning the Effect of Swelling and Drying on the Colloidal Surface of Cellulose[1,2]

BY A. G. ASSAF, R. H. HAAS AND C. B. PURVES

The great affinity of dry cellulose for water is today attributed to the hydrogen bonding capacity[3] of the alcoholic groups because progressive masking of the latter by esterification progressively reduces the amount of moisture absorbed from standard, humid surroundings.[4,5,6a] Although immersion in heavy water replaces the hydrogen in all alcoholic groups throughout the mass of cellulose by deuterium,[7] X-ray[8] and optical data[9] strongly suggest that the water molecule as a whole fails to penetrate the crystallites and that the absorption is a function of the amorphous portion. It is well known[10] that cellulose acquires an equilibrium moisture content when kept for a sufficiently long time in a humid atmosphere and that the adsorption isotherm is of the sigmoid type illustrated in Fig. 1, plots I and II. Flexed curves are also obtained by plotting the absorbed moisture, or the relative humidity, against other physical properties such as the rigidity,[11a] the electrical conductivity,[6,12] capacitance and power factor.[13] Moreover, similar relationships exist between the amount absorbed and the specific heat[14] and apparent specific volume[15] of the absorbed water, the heats of wetting by water, aqueous alkali and methanol,[12,16] the selective absorption of water, or of solute, from various solutions[17] and the absorption of gases[18,19] and alcohols.[5b,20,21] All the results are consistent with the view that the first avid adsorption of moisture (to region B, Fig. 1) is caused by the strong hydrogen bonding of single molecules to each of all the alcoholic groups accessible to water in the amorphous portion of the cellulose. The intermediate, nearly linear portions of plots I and II (region B to region D) correspond either to the formation of multilayers that are held with diminishing tenacity[3] or to the filling up of the finer capillaries.[19,22] There is agreement to the effect that the steep, final portion of the adsorption isotherm (from region D) at high humidities owes its shape to the swelling of the cellulose and to the condensation of "free" or "unbound" water in the coarser capillaries.[23] On this interpretation, the moisture content at B provides a measure of the amount of cellulose, or of the extent of its col-

loidal surface, that is accessible to water, and similar information can be obtained by studying the adsorption of other vapors.[19] These views have the great merits of being intrinsically reasonable, of correlating a very large mass of information and of being not inconsistent with the work of Emmett and his collaborators on the adsorption of gases by inorganic catalysts.[24] Nevertheless, the validity of applying this interpretation to adsorption by cellulose does not appear to be supported by direct, experimental proof. The present research originated in an attempt to remedy this deficiency. As explained in the preceding article,[25] the fraction of the cellulose alcoholic groups wetted by a normal ether can be determined by using a thallous ethylate solution and by subsequently methylating the thallium cellulosate produced. The relationship between the percentage wetted and the molecular volume of the normal ether is linear and extrapolation to molecular volumes of 18 and 35[26] gives the percentages theoretically available for adsorption of vapors of water and nitrogen molecules, respectively. The weights of adsorbed layers were calculated from these amounts by assuming that each available alcoholic group bonded one molecule and the data were compared with those corresponding to the B and D points on the adsorption isotherms of the same cellulose samples. Although alteration in the colloidal surface of the samples during the adsorption of nitrogen and ethers could be assumed to be negligible, many quantitative results confirmed the fact that the sorption of water produced changes of great magnitude in unswollen cellulose. This effect was minimized, but not eliminated, in the comparative experiments by employing samples that were already highly swollen.

Experimental

Cellulose Samples.—The high grade cotton linters[27] were dewaxed, swollen in caustic soda and dried through methanol and benzene with all the precautions previously described.[25] Sample I contained 1.47% of moisture when examined, but samples II and III were thoroughly dried over concentrated sulfuric acid at room temperature and atmospheric pressure.

Estimation of Accessible Cellulose.—The thallations of approximately 0.3-g. samples of celluloses I, II and III were carried out with excess thallous ethylate dissolved in normal ethers exactly as already described, and the methylation of the thallium cellulosates was completed in the same way.[25] The methoxyl contents in duplicate or triplicate estimations of cellulose I were 11.5, 10.0 and 9.7% in diethyl, 8.1, 8.1% in dibutyl and 5.5, 7.4 and 6.7% in diamyl ether. Cellulose III gave values of 10.7, 12.6, 10.9; 9.7, 9.3, 9.5; and 7.5, 7.5, 7.5% methoxyl, respectively, with thallous ethylate dissolved in the same three ethers. The average methylation corresponding to each ether is plotted in Fig. 2 against the molecular volume of the ether and extrapolation to volumes of 18 and 35, respectively, gave the methylation theoretically corresponding to the penetration of the celluloses by water vapor and nitrogen gas. Ethyl ether values of 10.7, 11.6 and 11.1% methoxyl were the only ones available for cellulose II, but the line drawn through this point is approximately correct, since the slopes of the plots for highly swollen celluloses do not vary greatly. The difference between samples II and III, although obvious in Fig. 2, was in fact well within the experimental error. As previously explained,[25] multiplication of the methoxyl percentage by the factor 100/57.4 gave the percentage of cellulose, or of cellulose alcoholic groups, accessible to the penetrant (Fig. 2, Tables I and II). The product of the latter percentages and the factor 1.87×10^7 expressed the data as accessible colloidal surface in sq. cm. per g. of cellulose.

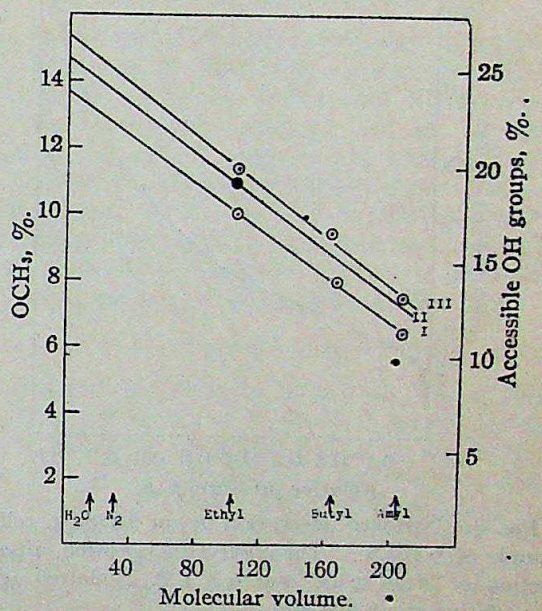

Fig. 2.—Superficial thallation–methylation of celluloses I, II and III, with thallous ethylate in normal ethers. Molecular volume of ether plotted against %OCH_3 and % accessible hydroxyl groups in the celluloses.

Sorption of Water Vapor at 20 and 25°.—The lower portions of twelve small desiccators, kept in a room whose temperature was constant at 20, or 25°, to within 1°, were filled with aqueous sulfuric acid of various definitely known concentrations. Published tables[28] gave the relative humidity within each desiccator at either temperature.

The cellulose sample, 1.5 to 1.7 g., held in an open weighing bottle, was kept in the desiccator containing concentrated sulfuric acid until the weight became constant, when the sample was assumed to be quite dry. It was then transferred to desiccators of increasing humidity, and daily weighings, quickly made on a magnetically damped balance, determined the moisture absorbed. The sample remained in each desiccator until weighings made on successive days did not differ by more than 1 mg. Three days at the lower humidities and five to seven days at the higher ones were required for equilibrium to be established within this weight limit. The best straight line was drawn through the observed points in the linear, intermediate portion of each adsorption isotherm (Figs. 1 and 4) and the moisture contents at the humidities where the plots commenced to diverge perceptibly from the extrapolation of this line were observed (Table I).[24] At ordinary temperatures, these humidities were 7 to 10% for the B, and 45 to 50% for the D point.

The desorption isotherms were obtained by transferring the cellulose samples through the desiccators in reverse order, but the data are omitted from Fig. 1. Sample I had 26.7% moisture at 100% relative humidity, when desorption was commenced, and the corresponding figure for sample II was 40.4% at 20°. The desorption of III and of II at 25° was from equilibrium at 56% relative humidity, or from just beyond the D point, when the moisture contents were 7.35 and 10.7%, respectively (Figs. 1 and 4). After desorption had been completed by standing over concentrated sulfuric acid, the standard estimation with thallous ethylate in ethyl ether gave methoxyl contents of 0.2, 0.2, 1.4 and 2.5% (latter in ethanol) for samples I, II at 20°, II at 25° and III, respectively. A value of 0.5% methoxyl (ethyl ether) was obtained when 2.06% moisture still remained in cellulose I.

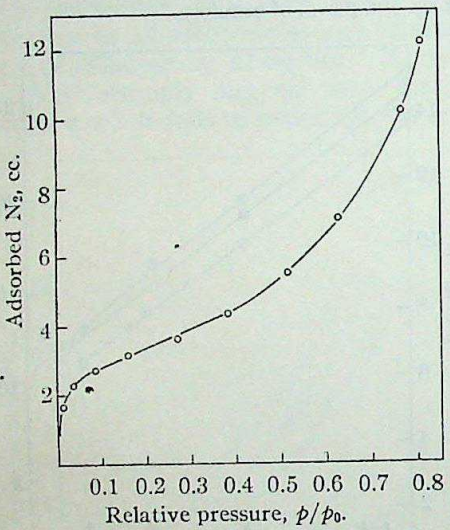

Fig. 3.—Nitrogen adsorption by an 0.3284 g. cellulose sample at −195.8°. The observed adsorption, after correction for "dead space" and to N.T.P., is plotted against the relative vapor pressure.

Adsorption of Nitrogen at −195.8°.—The isotherms for celluloses I and II were determined by the method of Brunauer, Emmett and Teller[29,30] with 0.2-g. samples. Helium was used to estimate the "dead space" in the apparatus and the data for the adsorption of nitrogen were corrected accordingly. The preliminary evacuation was at 80°. If v is the volume adsorbed at pressure p, and p_0 is the saturation pressure at the same temperature, v_m, the volume adsorbed at the first inflection of the isotherm (the B point) is given by the relationship

$$\frac{p}{v(p_0 - p)} = \frac{1}{v_m C} + \frac{C - 1}{v_m C}\frac{p}{p_0}$$

where C is a constant.

Samples I and II had v_m values of 2.34 cc. and 2.83 cc., corrected to N.T.P. These results correspond to adsorptions of 11.6 cc. and 14.0 cc. per gram of cellulose, or to unimolecular layer surfaces of 53.0×10^4 sq. cm./g. and 64.6×10^4 sq. cm./g., respectively, if 17 sq. Å. is assumed for the area covered by a nitrogen molecule in the liquid condition. A complete isotherm for a different sample is reproduced (Fig. 3) to show that the shape is sigmoid and that the above method of calculating area was probably legitimate when applied to cellulose. The area computed for this sample was 34.8×10^4 sq. cm./g.

(30) We wish to thank Dr. W. R. Smith and Mr. F. S. Thornhill, of the Godfrey Cabot Laboratories, Boston, Massachusetts, for their great kindness in determining all of the nitrogen isotherms and in calculating the results.

Results and Discussion

Suggested Interpretation of the Cellulose-Moisture Adsorption Isotherm.—When swelling is neglected, the percentages of the cellulose samples I, II and III theoretically accessible to water vapor can be read from Fig. 2 and are recorded in Table I, column 2, as percentages of accessible alcoholic groups. If each of the latter is assumed to become hydrogen bonded to one water molecule, the calculated moisture content of the entire mass of cellulose is one-third of this percentage because fully hydrated cellulose, $C_6H_{10}O_5 \cdot 3H_2O$, has 33.3% water (column 3). The B and D points of inflection in the moisture adsorption–relative humidity plots at 20 or 25° (Figs. 1 and 4), are given in columns 5 and 6 of Table I. Comparison between columns 3 and 5 shows at once that the water adsorption calculated from the thallous ethylate-methylation data is far higher than that at the B point. Since the accuracy of the calculated values is thought to be well within ±15% and lines

drawn through the isotherms to produce a similar variation are obviously misplaced, the total experimental error of perhaps ±30% is quite insufficient to reconcile the two sets of values. The same remark is true of the effect of any swelling during moisture adsorption because the observed B point would have already been increased, rather than decreased, by this contingency. On the other hand, the agreement between columns 3 and 6 of Table I is good, especially since the exact position of the D point cannot be read from the plots with accuracy and is probably sensitive to swelling. The conclusion reached is that a complete coverage of the accessible cellulose hydroxyl groups by water corresponds to the second region of inflection in the adsorption isotherms for ordinary temperatures, and not to the first, as has hitherto been supposed.

If this conclusion is entertained, it becomes desirable to find a new interpretation for the B point. Each glucose residue in cellulose contains three hydroxyl groups that differ markedly in chemical reactivity. Those in the primary or sixth positions of the glucose units are known to react more rapidly in esterification and de-esterification,[31,32] etherification[33] and possibly nitration[34] than those in the two secondary alcoholic positions. Those in some sugar derivatives behave similarly.[35] Simple primary alcohols are considered to be more highly associated in benzene solution than their secondary isomers,[36,37,38,39] and their boiling points at atmospheric pressure are about 20° higher.[40] All these observations make it plausible to argue that primary alcohols form intermolecular hydrogen bonds, and, presumably, hydrogen bonds with water molecules, that are stronger than those pertaining to secondary alcohols. The initial strong adsorption of water by cellulose (up to the B region, Fig. 1) accordingly may be attributed for the most part to the primary alcoholic groups, and is identifiable with the powerful "*a*" absorption assumed by Peirce.[11b] The intermediate portion of the isotherm represents the weaker adsorption of the secondary alcoholic groups but is progressively distorted from the region of the D point onward by enlargement of surface through swelling and by the filling up of the capillaries. Since there is on the average one primary for every two secondary alcoholic groups accessible in the cellulose, the above interpretation requires that the moisture content at the B point should be approximately one-third of that at the D point. This deduction is supported by the most probable ratios observed both in our own experiments and in those of others[10] (Table I, column 7), although it is true that graphical manipulation of the data in Figs. 1 and 4 may give values ranging from 0.25 to 0.4.

Another deduction from the new interpretation is that the shape of the adsorption isotherm must be determined by the three equilibria

$$R_2OH + H_2O \rightleftharpoons R_2OH\cdot H_2O$$
$$R_3OH + H_2O \rightleftharpoons R_3OH\cdot H_2O$$
$$R_6OH + H_2O \rightleftharpoons R_6OH\cdot H_2O$$

when both swelling and the slight affinity of water for acetal oxygens and hydrocarbon chains are neglected. R_2OH, R_3OH and R_6OH represent the equimolar amounts, m, of alcoholic groups in the second, third and sixth positions of the glucose residues accessible to moisture in the cellulose. If x_2, x_3 and x_6 moles are the equilibrium amounts of moisture adsorbed by the three kinds of alcoholic group at the vapor pressure p, the law of mass action states that

$$x_2/p(m - x_2) = \text{a constant } K_2, \text{ or } x_2 = K_2mp/(1 + K_2p)$$

with similar equations for x_3 and x_6. Since these equations are identical in form to those devised by Langmuir for unimolecular layer adsorption, cellulose may be regarded as a surface containing equal amounts of three kinds of elementary space, each adsorbing with different intensity.[41] The constant K_6 is so large that the primary alcoholic groups are extensively hydrated at a relative humidity of 7 to 10% (Fig. 1), but K_2 and K_3 are such that the hydration of the secondary alcoholic groups is very much less in the same conditions. It follows that the selective hydration of R_6OH is responsible for the 15.7 kcal. of heat evolved when one mole of water vapor at ordinary temperature is adsorbed by a very large mass of perfectly dry cellulose.[3,42] Since the latent heat of condensation of water vapor is 10.5 kcal., the difference of 5.2 kcal. may be attributed to the heat of formation of the $R_6OH\cdot H_2O$ hydrogen bond. This value is approximately half-way between those of 4.5 and 6.0 kcal. reported for the hydrogen bond strength in ice and aliphatic alcohols, respectively.[43,44] It is to be expected that the $R_2OH\cdot H_2O$ and $R_3OH\cdot H_2O$ bonds have a heat of formation smaller than 5.2 kcal. and this supposition, plus the utilization of energy to cleave pre-existing cellulose–cellulose hydrogen bonds during swelling, would explain

the sharp decrease in the heat evolved by the adsorption of additional amounts of water.[3] The thermal effects connected with the adsorption of the lower alcohols[20] would be subject to similar considerations.

It is well known that moist cellulose rapidly becomes bone dry when heated in air to slightly more than 100°.[11b] This is, therefore, the temperature range in which even the most powerfully adsorbed moisture, $R_6OH \cdot H_2O$, is expelled and in which the corresponding hydrogen bond, like that in liquid water, becomes quite unstable. The hydrogen bonds holding the cellulose crystallites together resist far higher temperatures because their strength is additive in this case. Since the bond system in an associated liquid secondary alcohol disintegrates at a temperature about 20° lower than that in the primary isomer,[40] it is reasonable to suppose that the complexes $R_2OH \cdot H_2O$ and $R_3OH \cdot H_2O$ in moist cellulose have only a transient existence at 80° or more. In other words, the moisture-adsorption isotherms at such elevated temperatures should be a function of the primary alcoholic groups alone. Urquhart and Williams[10] determined isotherms at 80° and above, one of which is reproduced in Fig. 1; plot IV. An inflection corresponding to the B point at lower temperatures is scarcely perceptible and the plot remains practically linear until distorted upward by swelling. The linearity at lower humidities is consistent with Langmuir's adsorption isotherm for surfaces containing only one kind of elementary space. It follows that plots of similar shape may be expected at *all* temperatures with high molecular materials that swell but possess only one kind of hydroxyl or other adsorbing group. If some other physical properties of cellulose, such as elasticity or rigidity, happen to be connected with hydrogen bonding between secondary alcoholic groups in the amorphous regions, such properties may alter more or less abruptly about 80°.

These general principles may eventually throw fresh light upon the mechanism of some gelations. Heymann and his collaborators, for example, provided evidence that the gelation of aqueous solutions of methylcellulose (substitution 1.59) in the temperature range 40 to 50° is accompanied by a decrease in the solvation of the macromolecules.[45] Most of this decrease might be caused by the preferential, partial desolvation of the unsubstituted, secondary alcoholic groups, rather than to the decomposition of hydrated ether complexes, as was suggested. The pasting of starch in water kept at 65 to 85°[46] may be connected with the breakdown of hydrogen bonds uniting secondary alcoholic groups in the granule and with their inability to remain extensively solvated in this temperature range. When the paste cools, its rigidity increases[47] because these groups recover their ability to hydrogen bond with each other, with the primary alcoholic groups, and with water to form a random system in dynamic equilibrium.

The Cellulose Nitrogen Adsorption Isotherm.—The percentages of the celluloses I and II theoretically accessible to nitrogen (Fig. 2) are given in Table II, column 2, together with the adsorption calculated on the basis of three nitrogen molecules for each accessible glucose residue (column 4). Column 5 shows that the gas actually adsorbed at the B point, as found by Brunauer, Emmett and Teller's method[29] was *one-seventh to one-eighth of the calculated amount*, and the surfaces calculated by the thallous ethylate and the nitrogen methods were in practically the same ratio (columns 3 and 6). This coincidence originated in the fact that the former method of calculating surface assumed an area of 52 sq. Å. for a glucose residue, which in the second method would be almost completely covered by three nitrogen molecules forming a continuous film with a total area of 3 × 17 sq. Å., or 51 sq. Å. It therefore happened that the assumed adsorption at three discrete points in each glucose residue very nearly corresponded to a continuous film that was "unimolecular" in the accepted sense of the word.[29] Although the measurements are not extensive, they are in accord with Babbitt's[3] conclusion that it is necessary to assume *six or seven* superimposed, unimolecular water layers, calculated by Emmett, Brunauer and Teller's method, in order to account for the observed moisture content of cotton and spruce wood in the region of the 20° isotherms just above the D point. The agreement suggests that nitrogen as well as water molecules are adsorbed by the exposed alcoholic groups of the cellulose and in this event the first three of the "unimolecular" layers might represent adsorption on the three different

kinds of alcoholic group present.[48] This assumption would render the areas calculated by Emmett, Brunauer and Teller's method about one half, instead of about one sixth, as large as those derived from the thallous ethylate technique. Further work is required to overcome the discrepancy. In the meantime, the suggestion that the D point, rather than the B point, of sigmoid adsorption isotherms corresponds to the complete monolayer must be restricted to the adsorption of water vapor by cellulose.

Changes in Accessible Surface Caused by Solvent-Exchange Drying and by Sorption of Water.—Samples of the highly swollen, dry cellulose II were permitted to absorb known equilibrium amounts of water before being submitted to the thallous ethylate–methylation determination. The solvents chosen for the ethylate were diethyl ether, in which water dissolves sparingly, 1,4-dioxane, which is miscible with water, and absolute ethanol, which competes effectively with cellulose for traces of moisture.[49] The usual large excess of thallous ethylate was increased to offset the decomposition of a portion by the water. Experiments 1 and 2, 5 and 6 (Table III) show that a moisture content of 9% made about three-quarters of the original surface inaccessible not only to ether, but also to dioxane. The preliminary removal of water by standard solvent-exchange drying procedures was also unsatisfactory (expts. 3 and 4) but comparison with experiments 7, 8 and 9, in which even a slight, final drying *in vacuo* was scrupulously avoided, showed that the latter step was the major cause of difficulty. The results support Kistler's conclusion that the formation of aerogels by the direct evaporation of liquids below their critical temperature must involve a collapse of surface.[50]

Figure 4 records an attempt to follow the surface changes exhibited by cellulose III during a moisture sorption cycle from zero to 47% relative humidity at 25°. The method employed thallous ethylate in absolute alcohol and involved no drying. Points 1, 2 and 3, determined during adsorption, are reliable and show that the adsorption of as little as 2.3% of moisture increases the accessible cellulose by at least one fifth, even although the original sample was highly swollen. Points 4 and 5, determined during adsorption, and point 6, after desorption was commenced, merely reveal the inadequacies of the experimental method at higher humidities because the surface was certainly not contracting during the adsorption of additional amounts of water. Point 7, determined when desorption was complete, is accurate, and comparison with point 1 shows that two-thirds of the original surface became inaccessible to ethanol during the complete sorption cycle. The experimental portion contains data showing that the obliteration of surface may amount to 98% as a result of desorption from 100%, instead of 47%, relative humidity.

(48) This idea is analogous to the opinion expressed by Brunauer and Emmett, THIS JOURNAL, **62**, 1732 (1940), concerning certain synthetic iron catalysts, the heterogeneity of whose surfaces was probably due to different developed crystal faces. See also the review by Emmett, "Twelfth Report of the National Research Council Committee on Catalysis," John Wiley and Sons, New York, N. Y., 1940, pp. 53–67.

whose initial moisture content of 1.47% was not sufficient to render the thallation method with ethers inaccurate. When stored in the dark and *in vacuo* over solid caustic potash, the moisture content diminished during ninety-nine days to 0.43%, while the accompanying change in the amount of cellulose accessible to an ether of zero molecular volume (amorphous cellulose[25]) was from 24% to 10%. Although experimental inaccuracies make the intermediate plots doubtful, the slopes of the initial and final plots are such as to render the percentage decrease in accessible cellulose almost independent of the molecular volume of the ether. The drying process, therefore, seems to obliterate the larger and smaller capillaries of molecular dimensions to almost the same extent. The magnitude of the effect suggests that the removal of a water molecule from the more confined spaces may make possible the formation of a hydrogen bond between two glucose residues on opposite sides of the fissure, and that the corresponding macromolecules, held together in this way at one point, then crystallize imperfectly but extensively against each other.[15,51] In this event, the mechanism may be compared to the action of the domestic "slide fastener" as it unites two serrated edges. The removal of adsorbed liquid appears to be essential for the contraction in surface because the thoroughly dry cellulose II retained its original, superficial methylation of 11.2% unchanged during storage for three months over concentrated sulfuric acid.

Interpretation of the "Mercerization Ratio" of Cellulose.—Data in this and the preceding article[25] show that the accessibility of cellulose to thallous ethylate dissolved in normal ethers may be increased perhaps a hundredfold by appropriate swelling and drying. The value of the "mercerization," "activation" or "reactivity" ratio[23] is therefore of the order of 100 in this case and ratios of similar magnitude probably describe the behavior of cellulose toward other non-swelling reagents. For example, oxidations with chromic anhydride dissolved in glacial acetic acid fall in this category.[52]

Since the amount of unswollen cotton accessible to thallous ethylate in ether is about 0.5%, an adsorption of one water molecule by each available alcoholic group would correspond to a moisture content of the order of 0.2% if swelling did not occur. The value of 6% observed at the D point (Table II) indicates that swelling does in fact multiply the original, minute surface some thirty times. When aqueous solutions of oxidants, mineral acids or dyestuffs[23] are used to measure reactivity, the results for *unswollen* cellulose are probably too large by a factor of similar size. After the specimen has been highly swollen in caustic soda, the water-wet product is usually directly dried before its reactivity is measured. The drying processes used obliterate by far the greater part of the original, swollen surface, which is then regenerated to a considerable extent during the final measurement. It follows that the reactivity ratios of approximately 1.5 obtained by these methods record only the net effect of swelling and contracting changes of much greater magnitude.

This article has profited greatly from constructive suggestions made by Professors P. H Emmett and G. Scatchard, although responsibility for the opinions expressed remains entirely with the authors.

Summary

1. Three highly swollen samples of cotton linters were immersed in solutions of thallous ethylate in normal ethers of different molecular volume. Methylation of the resulting thallium cellulosates gave products whose methoxyl contents were accepted as proportional to the penetration of the ether into the celluloses. Extrapolation of the linear methylation-molecular volume plots to volumes of 18 and 35 gave the respective percentages of cellulose theoretically accessible to water vapor and nitrogen gas.

2. The moisture adsorption isotherms, at 20 or 25°, of the same swollen samples were determined. The moisture content at the second region of inflection in the sigmoid shaped plots, occurring at a relative humidity of about 50%, was approximately that predicted from (1) by assuming the adsorption of one water molecule by each accessible alcoholic group. This region in the isotherm was considered to be approximately equivalent to a unimolecular water layer completely covering the accessible surface of the cellulose.

3. The moisture content at the first region of inflection in the isotherm, occurring at a relative humidity of about 10%, was approximately one-third of the value at the second inflection. This fact, together with other considerations cited, suggested that the avid adsorption of water up to the first inflection was mainly a function of the strong hydrogen bonding capacity of the accessible, primary alcoholic groups. The flat, intermediate portion of the isotherm represented the water less strongly hydrogen-bonded to the secondary alcoholic groups, but its shape was influenced at the higher humidities by the effects of swelling and by capillary condensation. Some physical-chemical implications of these ideas were discussed, particularly the inference that the moisture sorption characteristics of cellulose and starch at 80° or more must be those of the primary alcoholic groups exclusively.

4. Up to 98% of the surface of moist, swollen cellulose was obliterated by direct drying, but up to 75% was preserved during solvent-exchange with ethanol. The absorption of 6% to 9% of

water increased the colloidal surface of highly swollen cellulose by at least 20%, but the increase for unswollen samples was perhaps thirty-fold. These data threw fresh light upon the significance of the "mercerization" or "reactivity" ratio of cellulose, which is usually given as about 1.5.

5. The surfaces of two of the swollen cellulose samples were estimated by a standard method involving the determination of the nitrogen adsorption isotherm at −195.8° but the correlation of this method with the thallous ethylate technique requires further study.

Diacetone Xylitol (2,3,4,5-Di-isopropylidene-D,L-xylitol)

BY RAYMOND M. HANN, A. T. NESS AND C. S. HUDSON

Tipson and Cretcher[1] have recently prepared a crystalline diacetone xylitol by condensing the components under suitable conditions. The substance contains one free hydroxyl group and they prepared its crystalline monotosyl derivative and subjected this substance to the action of a solution of sodium iodide in acetone at 100° for two hours, conditions which have been recommended by Oldham and Rutherford[2] for use in their method of distinguishing primary and secondary hydroxyl groups in the case of the aldohexosides, where it appears to be a general rule that a tosyl group is replaced by iodine only when it is attached at the primary hydroxyl of carbon atom 6. Tipson and Cretcher found that tosyl diacetone xylitol reacts with sodium iodide, as is shown by their isolation of sodium tosylate in nearly quantitative yield; it is not mentioned whether the isolation of the expected iodo diacetone xylitol was attempted. They found on the other hand, that all four tosyl groups of tetratosyl-erythritol are removable as sodium tosylate by the acetone solution of sodium iodide under the same conditions and that the erythritol moiety undergoes extensive change to volatile products, a component of which appears to be butadiene, as shown by a test for conjugated double bonds. They concluded therefore that "Oldham and Rutherford's rule apparently does not apply to tosyl esters of the sugar alcohols." Drawing this conclusion, the position of the free hydroxyl group in diacetone xylitol was left undecided.

We have used the Oldham–Freudenberg technique for the preparation of iodo derivatives of the sugar alcohols on numerous occasions. In all but two cases, the tosyl groups of the substances which we studied were attached only to primary hydroxyl groups; these tosyl groups were replaceable by iodine in conformity with the Oldham–Rutherford rule. However, in these cases the general question of the applicability of the Oldham–Rutherford rule did not arise, because we determined the position of the iodine atom in the iodo derivative by an independent and conclusive method, namely, the replacement of the iodine by hydrogen to yield a desoxy compound, the structure of which was then determined through oxidation by per-iodic acid or lead tetraacetate and the estimation of the resulting acetaldehyde. In one of the excepted cases,[3] the 1,4-ditosyl derivative of 2,3,5,6-di-isopropylidene-D,L-galactitol has been shown to give a nearly quantitative yield of a mono-iodo monotosyl derivative, a result which agrees with the Oldham–Rutherford rule in an appropriate test case. In the second excepted case,[4] it has been shown that the substance which has the structure 1,6-ditosyl-2,3,4,5-dimethylene-D-mannitol (as proved conclusively by per-iodic acid oxidation of an appropriate derivative and the estimation of acetaldehyde) reacts with sodium iodide according to the Oldham–Rutherford directions to give the expected 1,6-di-iodo-2,3,4,5-dimethylene-D-mannitol in 98% yield. A second substance which is also a di-tosyl-dimethylene-D-mannitol, was found to be entirely unreactive toward sodium iodide even under more drastic conditions; it seems highly improbable that this second closely similar substance can have either of its tosyl groups at a primary position. We assumed from their lack of reactivity, as contrasted with the proved reactivity of the 1,6-tosyl groups in the isomer, that they are attached to secondary hydroxyl groups; our interpretation of this case is that it follows the Oldham–Rutherford rule.

In the course of studies on methylene acetals of sugar alcohols we have obtained a dimethylene-L-xylitol (m. p. 215–217° (cor.), $[\alpha]^{20}D$ −25.3° in water) and a crystalline desoxy-dimethylene-D,L-xylitol (m. p. 155–156°), which will be described further in later publications; it became important in the study of these substances that the desoxy-xylitol which would be expected to be obtainable from Tipson and Cretcher's diacetone xylitol, be prepared. Our results confirm their work in the preparation of the diacetone xylitol and its tosyl derivative. The replacement of the tosyl group by iodine was accomplished

by a modification of the Oldham–Freudenberg technique which has been suggested by Murray and Purves,[5] namely, the use of acetonylacetone in place of acetone as the solvent of the sodium iodide. On allowing the reaction to proceed at 60° for nineteen hours the tosyl-di-isopropylidene-xylitol was converted in a yield of 88% to a crystalline iodo-di-isopropylidene-xylitol. This iodo derivative was transformed in alkaline solution by hydrogen and Raney nickel to a desoxy-di-isopropylidene-xylitol, which is a colorless, mobile and somewhat volatile liquid which could be purified by distillation (b. p. 88–90° at 6–7 mm.); its analysis for carbon and hydrogen gave correct percentages. Mild acid hydrolysis removed its acetone groups and there resulted a desoxy-xylitol, which is a colorless viscid odorless sirup, of correct carbon and hydrogen analysis. The oxidation of the desoxy-di-isopropylidene-xylitol by per-iodic acid showed that a reaction was complete in five hours at room temperature, with the consumption of 3.06 molecular equivalents of oxidant; evidently the substance is easily hydrolyzed in the acid solution to acetone and desoxy-xylitol and the latter is then oxidized according to the following equation, which represents the only course that is compatible with the consumption of three moles of the oxidant

$$CH_3(CHOH)_3CH_2OH + 3HIO_4 = CH_3CHO + 2HCOOH + HCHO + 3HIO_3 + H_2O$$

The equation limits the desoxy group to a terminal position. This inference was confirmed by the oxidation of the desoxy-xylitol with sodium periodate; each mole consumed 2.88 moles of oxidant and generated 1.96 moles of acid, 3.00 and 2.00 moles, respectively, being the theoretical values. Finally, desoxy-xylitol was oxidized by per-iodic acid and the resulting acetaldehyde was determined by the procedure of Nicolet and Shinn[6] for the estimation of acetaldehyde in the presence of formaldehyde. Each mole of desoxy-xylitol produced 0.91 mole of acetaldehyde. These quantitative results, and especially the acetaldehyde measurement, prove conclusively that the desoxy-xylitol has the terminal CH_3 in its structure, from which it follows that the free hydroxyl group of diacetone xylitol is a primary one. The acetone groups must be attached to the remaining four carbon atoms; the arrangement of these groups is left undecided. Owing to the *meso* configuration of xylitol, the desoxy-xylitol must consist of equal amounts of two enantiomorphs and the substance is to be named 1-desoxy-D,L-xylitol. This relationship would not hold for a terminal desoxy-D-arabitol because 1-desoxy- and 5-desoxy-D-arabitol are different substances. The tosyl derivative is 1-tosyl-2,3,4,5-di-isopropylidene-D,L-xylitol, the iodo derivative is 1-iodo-2,3,4,5-di-isopropylidene-D,L-xylitol and the product from its reduction is 1-desoxy-2,3,4,5-di-isopropylidene-D,L-xylitol. The question of whether any of the crystalline members of this series of racemic mixtures is a true racemate has not been investigated.

It is apparent from the foregoing that the Oldham–Rutherford rule should not be regarded as inapplicable to sugar alcohols in general. We believe that its apparent failure to hold in the case of tetratosyl-erythritol, where Tipson and Cretcher find that all four tosyl radicals are removed by sodium iodide in acetone, only discloses a special structural influence that has not been noticed in previous applications of the rule. In tetratosyl-erythritol, the tosyl groups that are on secondary hydroxyl positions are contiguous to tosyl groups on primary ones. Except for tritosyl-glycerol[7] and tetratosyl-erythritol, we are not aware that there has been any previous test of a 1,2-ditosyl derivative in considering the applicability of the Oldham–Rutherford rule. However, some evidence on the subject can be supplied at present.[8] Upon heating the known 5,6-ditosyl-1,2,3,4-dibenzylidene-D-sorbitol[9] with sodium iodide and acetone at 100° for four hours, there were formed two molecular equivalents of sodium tosylate and a crystalline compound (m. p. 187–188°; $[\alpha]^{20}D$ +19.0° in chloroform) which decolorizes bromine in carbon tetrachloride and shows a correct analysis for 1,2,3,4-dibenzylidene-D-sorbitoleen; the latter substance was reduced by hydrogen and Raney nickel to what is presumably 1,2,3,4-dibenzylidene-5,6-di-desoxy-D-sorbitol (m. p. 184–185°; $[\alpha]^{20}D$ +39.4° in chloroform. Calculated for $C_{20}H_{22}O_4$: C, 73.60; H, 6.79. Found: C, 73.84; H, 6.78). It appears, therefore, that contiguous tosyl groups, one of which is attached at a primary hydroxyl position and the other at a secondary, are both removed by treatment with sodium iodide in acetone with the ultimate production of a double bond. The behavior which Tipson and Cretcher have described falls in this category. The behavior of tritosyl-glycerol may be analogous. This method of forming a double bond in a 1,2-position opens many possibilities, particularly in the study of sugar alcohols. According to the idea which underlies the Oldham–Rutherford rule, a 1-iodo-2-tosyl derivative is to be expected as the first step in the ultimate formation of a double bond.

We express our appreciation to Dr. B. H. Nicolet and Mr. L. A. Shinn, of the Bureau of Dairy Industry, U. S. Department of Agriculture, for assistance in the acetaldehyde determinations.

Experimental

2,3,4,5-Di-isopropylidene-D,L-xylitol.—Xylitol and acetone were condensed by the method which Levene and Tipson[10] used for the condensation of uridine and acetone. A mixture of 10.0 g. of crystalline xylitol,[11] 200 cc. of acetone, 20.0 g. of anhydrous copper sulfate and 0.2 cc. of concentrated sulfuric acid was agitated on a shaking machine for forty-eight hours at 25°; the copper sulfate was separated by filtration and the filtrate was shaken with 10 g. of powdery calcium hydroxide for one hour to neutralize the acid; the solids were removed by filtration and the solvent by distillation *in vacuo* at 50°. The sirupy residue, weighing 14.8 g. (97%) seems to be essentially 2,3,4,5-di-isopropylidene-D,L-xylitol. It is sufficiently pure for the preparation of derivatives, but if the crystalline substance be desired, seed crystals of it may be obtained by dissolving the sirupy product in hexane and cooling the solution in dry-ice. If seed crystals are available, the crystallization of the substance from hexane solution progresses satisfactorily at ice-box temperatures. The crystalline diacetone xylitol melted at 33–34° in agreement with the melting point of 34–34.5° reported by Tipson and Cretcher.

1-Acetyl-2,3,4,5-di-isopropylidene-D,L-xylitol.—A solution of 6.9 g. of 2,3,4,5-di-isopropylidene-D,L-xylitol in a mixture of 50 cc. of pyridine and 50 cc. of acetic anhydride was kept at 25° for eighteen hours and then poured into 500 cc. of ice-water. The acetic acid was neutralized with potassium carbonate and the solution was extracted with five 50-cc. portions of chloroform. The chloroform extracts were combined, washed successively with ice-cold 2% hydrochloric acid, 2% sodium bicarbonate solution and water, and dried over anhydrous sodium sulfate. The chloroform was removed by concentration *in vacuo* and the thin sirup which remained was brought to crystallization by dissolving it in a small amount of alcohol and cooling the solution in dry-ice. The acetyl derivative was recrystallized from 10 parts of 50% alcohol and it formed prisms which melted at 45–46°. The substance is soluble in acetone, chloroform, ether, methyl alcohol and hot water and relatively insoluble in cold water. The yield was nearly quantitative.

Anal. Calcd. for $C_{13}H_{22}O_6$: C, 56.92; H, 8.08; CH_3CO, 15.7. Found: C, 56.90; H, 8.10; CH_3CO, 15.5.

1-Benzoyl-2,3,4,5-di-isopropylidene-D,L-xylitol.—This compound was obtained in quantitative yield (10.0 g.) by the benzoylation of 2,3,4,5-di-isopropylidene-D,L-xylitol (6.9 g.) in pyridine solution with benzoyl chloride. It was recrystallized from 5 parts of alcohol and obtained in the form of stout needles which melted at 61–62°. The substance is soluble in warm methyl and ethyl alcohols, acetone and chloroform, relatively insoluble in cold alcohol, and insoluble in water.

Anal. Calcd. for $C_{18}H_{24}O_6$: C, 64.27; H, 7.19; C_6H_5CO, 31.2. Found: C, 64.47; H, 7.31; C_6H_5CO, 31.0.

1-Tosyl-2,3,4,5-di-isopropylidene-D,L-xylitol.—A solution of 14.3 g. of 2,3,4,5-di-isopropylidene-D,L-xylitol in 71.5 cc. of pyridine was cooled in ice and 14.3 g. of *p*-toluenesulfonyl chloride was added. After standing for forty-eight hours at 25° the reaction mixture was poured into 500 cc. of ice water and the precipitated tosyl derivative (21.6 g.; 91%) was separated by filtration and recrystallized from 3 parts of alcohol. The once recrystallized compound melted at 77–78° and further recrystallization did not alter this melting point; Tipson and Cretcher record 70–71°. The substance is relatively unstable which may account for the difference in melting point; it decomposed spontaneously on standing a few days at room temperature. It is readily soluble in acetone, methyl and ethyl alcohols, chloroform and ethyl acetate and insoluble in water.

Anal. Calcd. for $C_{18}H_{26}O_7S$: C, 55.94; H, 6.78; S, 8.30. Found: C, 55.82; H, 6.81; S, 8.26.

1-Iodo-2,3,4,5-di-isopropylidene-D,L-xylitol.—A solution of 15.5 g. of recrystallized 1-tosyl-2,3,4,5-di-isopropylidene-D,L-xylitol and 15.0 g. (2.5 molecular equivalents) of sodium iodide in 60 cc. of acetonylacetone,[5] was heated at 60° for nineteen hours; the cooled reaction mixture was poured into 1 liter of ice water and after standing at 5° overnight the precipitated 1-iodo-2,3,4,5-di-isopropylidene-D,L-xylitol (12.1 g.; m. p. 55–57°; 88%) was separated by filtration and recrystallized by solution in 2 parts of alcohol and the addition of 1 part of water; it was obtained in the form of thin rectangular plates which melted at 57–59°. The substance is soluble in acetone, chloroform, methyl and ethyl alcohols and dioxane and insoluble in water.

Anal. Calcd. for $C_{11}H_{19}O_4I$: C, 38.61; H, 5.60; I, 37.09. Found: C, 38.66; H, 5.72; I, 37.19.

1-Desoxy-2,3,4,5-di-isopropylidene-D,L-xylitol.—The suspension of 2.0 g. of Raney nickel in 25 cc. of absolute methyl alcohol was saturated with hydrogen at a temperature of 27° and a pressure of 5 cm. of mercury and then 2.5 g. of 1-iodo-2,3,4,5-di-isopropylidene-D,L-xylitol and 4.5 cc. of 1.8 *N* barium methylate[12] (0.55 molecular equivalent) were added and the reaction mixture was agitated in a glass bottle under a slight positive pressure of hydrogen. In thirty minutes the calculated amount of hydrogen (181 cc. at 27° and 756 mm.) was taken up and no further absorption occurred in an additional thirty minutes. The catalyst was separated by filtration and the filtrate was concentrated *in vacuo* to a thick slurry; this residue was extracted with ether and the extract, upon evaporation of the solvent, yielded a colorless liquid. The product is volatile and care must be exercised in the last stages of the evaporation to prevent loss. A sample of 4.3 g. of this sirup was distilled *in vacuo* and a 3.1 g. fraction boiling at 83–89° at 7 to 8 mm. was collected; this fraction was redistilled *in vacuo* and the major portion (2.8 g.), which distilled at 88–90° at 6 to 7 mm., was analyzed and found to agree in composition with desoxy-di-isopropylidene-xylitol. The clear mobile liquid, which had a mild and slightly pungent but rather agreeable odor, showed a refractive index $n^{21}D$ of 1.4308.

Anal. Calcd. for $C_{11}H_{20}O_4$: C, 61.08; H, 9.32. Found: C, 61.15; H, 9.32.

Per-iodic Acid Oxidation of 1-Desoxy-2,3,4,5-di-isopropylidene-D,L-xylitol.—To a solution of 0.2236 g. of 1-desoxy-2,3,4,5-di-isopropylidene-D,L-xylitol in 25 cc. of water at 25° was added 5 cc. of 0.675 *M* per-iodic acid (3.26 molecular equivalents) and the volume was adjusted to 50 cc. with water. Analysis of 5-cc. subsamples at the expiration of one, two and one-half, five and twenty-two hours showed that 2.48, 3.00, 3.06 and 3.18 molecular equivalents of oxidant had been consumed. This experimental result indicated that the diacetal was readily hydrolyzed by the per-iodic acid under the experimental conditions, and that the resulting 1-desoxy-xylitol was then oxidized in accordance with the expected reaction course, the equation for which has been given.

1-Desoxy-D,L-xylitol.—A solution of 1.6 g. of 1-desoxy-2,3,4,5-di-isopropylidene-D,L-xylitol in 25 cc. of 20% aqueous acetic acid was refluxed for four hours and the solvent then removed by concentration *in vacuo*. The sirupy reaction product was dried by the successive addition and evaporation *in vacuo* of two 25-cc. portions of absolute alcohol. The final product was a viscid odorless sirup showing $n^{21}D$ 1.4706. The yield was 0.8 g. (quantitative).

Anal. Calcd. for $C_6H_{12}O_4$: C, 44.11; H, 8.88. Found: C, 44.12; H, 8.66.

Sodium Periodate Oxidation of 1-Desoxy-D,L-xylitol.—To an ice-cold solution of 0.1255 g. of 1-desoxy-D,L-xylitol in 35 cc. of water 8.54 cc. of 0.432 *M* sodium periodate (4.00 molecular equivalents) was added and the solution was allowed to warm to 25°; the volume was then adjusted to 50 cc. with water. Analysis of 5-cc. aliquots at the expiration of one, six and twenty-four hours indicated that 2.85, 2.88 and 2.88 molecular equivalents of oxidant had

been consumed. At the expiration of twenty-four hours the titration of a 10-cc. subsample required 3.60 cc. of 0.1 *N* sodium hydroxide (using methyl red as indicator), equivalent to 1.96 molecular equivalents of formic acid. As previously mentioned, the oxidation of 1-desoxy-xylitol should consume three molecular equivalents of sodium periodate and produce two molecular equivalents of formic acid.

Determination of the Acetaldehyde Produced in the Oxidation of 1-Desoxy-D,L-xylitol by Per-iodic Acid.—A 5-cc. aliquot (0.0737 millimole) of a solution of 0.1003 g. of 1-desoxy-D,L-xylitol in 50 cc. of water was oxidized by per-iodic acid and the acetaldehyde produced was determined by the procedures described by Nicolet and Shinn.[6] The consumption of 0.02 *N* iodine (6.68 cc.) corresponded to 0.0668 millimole of acetaldehyde, equivalent to 0.91 mole of acetaldehyde per mole of 1-desoxy-xylitol. As previously indicated, the expected production of acetaldehyde was one molecular equivalent.

Summary

Proof of the structure of the diacetone xylitol of Tipson and Cretcher is presented. Its tosyl derivative reacts with sodium iodide in acetonylacetone solution to form a crystalline iododiacetonexylitol, which is reduced by hydrogen and Raney nickel to a liquid desoxydiacetonexylitol. The latter substance, upon mild acid hydrolysis, yields a sirupy desoxyxylitol, which must be a 1-desoxy derivative because it is oxidized by per-iodic acid or sodium periodate with the consumption of three moles of oxidant and the production of one mole of acetaldehyde. Owing to the meso configuration of xylitol the substances are racemic mixtures. Their structures may now be described by the following names: 2,3,4,5-di-isopropylidene-D,L-xylitol, 1-tosyl - 2,3,4,5 - di - isopropylidene - D,L - xylitol, 1 - iodo - 2,3,4,5 - di - isopropylidene - D,L - xylitol, 1 - desoxy - 2,3,4,5 - di - isopropylidene - D,L - xylitol, 1-desoxy-D,L-xylitol. The arrangement of the acetal linkages among the 2,3,4,5-positions remains undecided.

The applicability of the Oldham–Rutherford rule to sugar alcohols is discussed.

The Formation of Anhydro Derivatives by the Action of Alkali upon Some Mononitrate-acetates of Glucose and Methylglucoside

BY E. K. GLADDING[1] AND C. B. PURVES

The recognition that the organic esters of sulfonic acids not only are cleaved by alkaline reagents in the sense $R_1R_2R_3C—O\vdots SO_2R$, but also in the sense $R_1R_2R_3C\vdots O—SO_2R$, explains the frequency with which the course of the reaction resembles the hydrolysis of the corresponding alkyl chloride, $R_1R_2R_3C\vdots Cl$.[2] Walden inversions often occur in both cases[3,4] and today are attributed to the formation of a charged, asymmetric carbonium ion, $R_1R_2R_3C^+$, whose rearrangement to an electrically neutral molecule is associated with the expulsion of a proton. The final molecule may contain a double bond, an anhydro ring, or be combined with a negative group, such as alkoxyl, derived from the environment. These ideas have been very successfully used to explain the chemical behavior of sugar sulfonates in alkaline media[5,6,7] and there is evidence that *p*-toluenesulfonic esters of cellulose react in a similar way.[8]

The mechanism underlying the reaction between alkali and the esters of nitric acid has not been studied extensively and most of the published work is restricted to the identification of the products.[9] Guncotton, for example, suffers rapid oxidative degradation when immersed in aqueous caustic soda, and carbon dioxide and sodium nitrite are formed.[9] Degradation in presence of diphenylamine and traces of copper salts produces oxidized and nitrated derivatives of the base.[10,11] Degradation is marked in ammonia at 65°[12] and we have found that such a weak base as pure, dry pyridine causes a vigorous decomposition of dissolved, stabilized guncotton at steam-bath temperature. Nitrogen dioxide is evolved in this decomposition as a volatile pyridine addition complex that readily crystallizes when cooled. Nef,[13] however, has emphasized that simple, aliphatic nitrates, sulfates

and halides are analogous in their behavior toward alcoholic caustic potash, although in the case of the nitrates the formation of unsaturates is suppressed and an oxidation–reduction process often produces potassium nitrite and the corresponding aldehyde or ketone. This process is stated to proceed quantitatively with benzyl nitrate, glycol dinitrate and glycerol trinitrate, but to be completely suppressed with methyl nitrate, which gives large yields of methyl ether. Ethyl and higher nitrates produce ethers mixed with decomposition products derived from carbonyl compounds exposed to excess alkali. A straightforward hydrolysis to the aliphatic alcohol occurs to an extent which, although small, increases with the stability of the nitrate toward alkali. It is also known that the *beta* forms of tetraacetyl glucosyl nitrate (Structure I)[14,15] and chloride (Ia)[15,16] resemble each other in their ready isomerization to the *alpha* configurations and that the latter produce tetraacetyl-β-methylglucoside (Ic) when warmed with methanol and barium carbonate.[17] This reaction apparently involves a Walden inversion. Tetraacetyl glucosyl methylsulfonate (Ib) also gives (Ic) when dissolved in methanol.[18] Another instance of the resemblance between halides, sulfonates and perhaps nitrates is known when these groups are present in the sixth position of methylglucoside (Structures IIa, IIb and II). Aqueous or alcoholic caustic soda produces high yields of 3,6-anhydromethylglucoside (III) from the two former[5,6,7] and the rotatory change undergone by the 6-nitrate (II) suggests that the reaction follows a similar course.[19]

The foregoing illustrations tend to show that the action of alcoholic caustic soda on a carbohydrate nitrate may remove the elements of nitric acid and produce anhydro or alkoxyl derivatives, either with or without Walden inversions. Unsaturated products may possibly be encountered. An ordinary hydrolysis, leading to sodium nitrate and the parent carbohydrate, may also take place and the third possibility is that the nitrate group may be reduced to nitrite and the carbohydrate oxidized to carbonyl derivatives. The latter, of course, would quickly undergo further change in the excess alkali. The present article assesses the practical importance of these possibilities for four simple cases (Structures I, II, V and VI) and demonstrates that the analogy in principle between the behavior of corresponding halogen, *p*-toluenesulfonyl and nitrate derivatives toward alkali is probably of wide application in the carbohydrate field.

Experimental

Materials.—2,3,4,6-Tetraacetyl-α-D-glucopyranosyl nitrate (α-acetonitroglucose, I) was prepared by nitrating 10 g. of dry, commercial *beta*, not *alpha*, glucose pentacetate dissolved in 100 cc. of chloroform with an equal volume of ice-cold, chloroform-soluble nitric acid.[17,20] The observed m. p., 148–49° (cor.), and specific rotation in chloroform, 148°,[21] were each one degree less than the recorded values.

Crude, crystalline D-glucosan<1,5>β<1,6> prepared from starch was methylated[22] and the resulting, crystallized trimethyl derivative on nitration gave crystalline 2,3,4-trimethyl-α-glucosyl-1,6-dinitrate. The latter, when boiled with methanol and barium carbonate, gave 2,3,4-trimethyl-β-methyl-D-glucopyranoside-6-nitrate (V) in an over-all yield of 50%. The product, m. p. 52–54°, had a specific levorotation, observed at 25° in chloroform, of −7° (*c*, 4.35) and analyzed correctly. Oldham[19] found the levorotation to be −5.2° but otherwise the physical constants and yields he recorded were checked throughout the synthesis.

The preparation and properties of 2,3,4-triacetyl-α-methyl-D-glucopyranoside-6-nitrate (II) and 3,4,6-triacetyl-β-methyl-D-glucopyranoside-2-nitrate (VI) have been described elsewhere.[23]

Methods.—A solution made by diluting 30 cc. of 4 *N* aqueous caustic soda to 100 cc. with methanol was used in determining the alkali-lability of the nitrate groups (Fig. 1). Samples weighing 0.10 to 0.14 g. were shaken at room temperature with 5-cc. aliquots of the alkali until solution was complete. Duplicate solutions were titrated at different times with 0.1 *N* hydrochloric acid. Miller's method of estimating nitrite[24] was used because it is valid in presence of a large excess of nitrate. A stock solution contained 30 cc. of water, 50 cc. of concentrated hydrochloric acid and 20 cc. of dimethylaniline that was free from the monomethyl derivative. This solution did not deteriorate noticeably when stored in the dark. A small aliquot, 0.25 to 1.0 cc., of the nitrite solution was made acid to litmus with hydrochloric acid and was diluted to 10 cc. with water. The addition of 0.5 cc. of the stock solution produced intensely yellow *p*-nitrosodimethylaniline and the transmission of light by the solution became constant within two hours. A photoelectric colorimeter, a blue filter and 1-cm. glass cells were used to estimate the transmission, and distilled water in an identical cell was the standard taken for 100% transmission.

The standard nitrite solution contained 0.5050 g. of the C. P. sodium salt in 500 cc. of water, or 14.6×10^{-6} mole of nitrite in 1 cc. Dilutions were made to bracket the concentration of nitrite in the unknown. Although Beer's law did not apply exactly, a plot of log % transmission against nitrite-concentration was linear up to about 2×10^{-6} mole per cc.

Action of Alkali on α-Acetonitroglucose (I) (A).—A suspension of 5.04 g. (0.017 mole) of the acetonitroglucose in 100 cc. of methanol was mixed at room temperature with 50 cc. of absolute 1.75 *N* sodium methylate (0.088 mole). Solution was complete within five minutes and the molecular rotation of the slightly yellow liquid acquired a final constant value of −6,500 within ten minutes. The solution was acidified with glacial acetic acid after one hour and was evaporated to dryness under diminished pressure. The product obtained by acetylating the residue with pyridine, 30 cc., and acetic anhydride, 15 cc., contained constituents, 3.56 g., that were extracted from the aqueous acetylation liquors by chloroform. These constituents partly crystallized when seeded with tetraacetyl-β-methylglucopyranoside and recrystallizations from 6-cc. volumes of methanol left 1.3 g. (28%) of this substance as hexagonal plates or stout prisms with the correct elementary analysis. The m. p., 102.5–104.5° (cor.), and the specific levorotation of −18.0° in chloroform agreed with the accepted constants.[25]

A duplicate experiment gave 3.49 g. of crude, acetylated material which on this occasion crystallized completely, rather than partly, to a hard mass, m. p. 83–90°. Four recrystallizations from methanol and ethanol alternately left the main fraction still melting over the broad range of 85 to 102° and with a specific levorotation of −28.6° in methanol. A brief microscopic examination, kindly carried out by Dr. T. R. P. Gibb, showed all the crystals to be biaxial and probably monoclinic with large optic angles. The optic sign was usually positive but was negative for a few rod-like crystals. The mother liquors yielded prismatic needles, m. p. 80–90°, with a rotation of −34° in methanol.

Since the first experiment proved that at least 1.3 g. of tetraacetyl-β-methylglucoside was present, and since this substance had a specific levorotation of −21.8° in methanol,[25] the remaining constituent, or constituents, of the mixture had a levorotation of at least −40°. Triacetyl-glucosan occurs as needles and has a levorotation of −45.5° in methanol.[26] *Anal.* Calcd. for tetraacetyl-methylglucoside: acetyl, 47.5; OCH_3, 8.56. Calcd. for triacetylglucosan; acetyl, 44.8; OCH_3, 0.0. Found for main fraction prior to powdering and mixing: acetyl, 46.8; OCH_3, 3.1, 8.1.

(B) A solution of 10 g. (0.034 mole) of acetonitroglucose in 50 cc. of peroxide-free 1,4-dioxane was cooled in a water-bath and stirred while 100 cc. of 1.75 *N* aqueous caustic soda was added slowly. The mixture at first became cloudy but subsequently clarified to give a slightly yellow solution whose color quickly darkened. After standing for twenty-four hours, a 1-cc. sample of the very dark brown liquid contained 8.1×10^{-6} mole of nitrite, corresponding to 4.5% of the original nitrate groups.

The remainder was acidified with acetic acid and was evaporated under reduced pressure to a dark gum. Methylation[22] of this gum gave a chloroform-soluble product that distilled completely at 112–114° (5 mm.) and crystallized completely when nucleated with 2,3,4-trimethylglucosan <1,5>β<1,6>; yield, 1.8 g. or 33%. Two recrystallizations from ether left the long needles with m. p. 56–58° and a specific levorotation of −61.8° in water. Trimethylglucosan, which is difficult to purify, has m. p. 62–65° and a rotation of −63.5°.[27a] A mixed m. p. with an authentic sample was not depressed and the elementary analyses were satisfactory.

Action of Alkali on Triacetyl-α-methylglucoside-6-nitrate (II).—(A) The sample, 6.08 g. or 0.0167 mole, was wetted with 38 cc. of ethanol and the total volume was made up to 60 cc. with aqueous, 4 *N* caustic soda (about 0.08 mole). After solution was complete (thirty minutes), the liquid was kept at 75–80° for seventy minutes or until its molecular rotation had decreased to 9,180°. A quantitative conversion to the 3,6-anhydro derivative required M_D 9,850°. One cc. of the liquid contained 5.2×10^{-6} mole of nitrite, corresponding to 1.9% of the original nitrate.

The remaining 53 cc. was acidified with acetic acid and evaporated under reduced pressure to dryness. Five 25-cc. volumes of boiling acetone extracted the product, which was recovered and dissolved in 20 cc. of hot ethyl acetate. This solution was dried with a little anhydrous sodium sulfate and after filtration was evaporated. The residual, straw colored sirup crystallized solidly when nucleated with 3,6-anhydro-α-methylglucopyranoside (III); yield, 2.0 g. or 77%. After two recrystallizations from ethyl acetate, the m. p. of the product, 105.5–107.5°, and the specific rotation of 56.5° in water agreed with the constants of the 3,6-anhydro derivative.[28] The elementary analysis also checked.

A duplicate experiment was carried out in which the mixture of triacetyl methylglucoside-6-nitrate and alkali was kept at room temperature for two days. Since the molecular rotation decreased to 13,300 in these conditions, instead of to the proper value of 9,850, the reaction was completed by heating at 70° for thirty minutes. An 88% yield of crystalline anhydro-methylglucoside was isolated and 2% of the nitrate groups were reduced to nitrite.

(B) A suspension of 5.03 g. (0.0138 mole) of the triacetyl methylglucoside-6-nitrate in 100 cc. of absolute methanol was mixed at room temperature with 50 cc. of freshly pre-

pared, 1.3 *N* sodium methylate in methanol. Solution was complete within five minutes but the molecular rotation decreased to the nearly correct value of 9,890 only after forty-eight days. The crude, crystalline product amounted to 1.72 g., or 77%, and an easy purification left it with physical constants in agreement with those already given for 3,6-anhydro-α-methylglucopyranoside.

Action of Alkali on 2,3,4-Trimethyl-β-methylglucoside-6-nitrate (V).—A 5.06 g. (0.018 mole) sample of the 6-nitrate was heated at 60° with 4.0 g. (0.10 mole) of caustic soda dissolved in 150 cc. of 50% aqueous methanol. The container was an Erlenmeyer flask with a wired-in rubber stopper. Solution of the 6-nitrate was complete within two hours but the liquid was too discolored to be observed on the polarimeter. The consumption of alkali, followed by titrating 5-cc. aliquots with standard acid, amounted to 1.17, 1.38 and 1.46 moles per nitrate group after six, twenty and twenty-four hours, respectively, of heating at 60°. These measurements were corrected by means of blank experiments containing none of the methylglucoside nitrate. Aliquots of 0.25 and 0.35 cc., withdrawn at the latter time, contained 11.5×10^{-6} and 17×10^{-6} mole of nitrite, corresponding to 19 and 20% of the original nitrate.

The remaining 59 cc. of the original solution was extracted while still alkaline with two 50-cc. volumes of chloroform. These extracts, after being combined, dried and evaporated, yielded 2.0 g. of a colorless sirup that quickly crystallized. After recrystallizations from 50 and 30 cc. volumes of warm ligroin, the long white needles melted at 92.5–93.5° and had specific levorotations at 25° of −20.8° in methanol and −21.2° in chloroform. A m. p. of 93–94°, rotations of −22.9°[27] to −25.1° in methanol,[29] and of −20.6° in chloroform,[30] have been observed for 2,3,4-trimethyl-β-methylglucopyranoside. An 0.130-g. sample of this substance would liberate 12.3 cc. of methane, corrected to N. T. P., in a Zerewitinoff estimation of active hydrogen. The value found was 12.7 cc.

The aqueous residue from the chloroform extractions was acidified with hydrochloric acid and then re-extracted with chloroform. A dark sirup, 0.5 g. recovered from the extract crystallized spontaneously and nearly completely. Recrystallization from ligroin gave long needles that were non-acidic, contained no double bonds and melted at 87–93°. Since this product was identified as slightly impure 2,3,4-trimethyl-β-methylglucopyranoside, the total crude yield of the latter was raised to 2.5 g. or to 75%.

Action of Alkali on 3,4,6-Triacetyl-β-methylglucoside-2-nitrate (VI).—A solution of 6.06 g. of the 2-nitrate in 18 cc. of peroxide-free dioxane was shaken at room temperature with 60 cc. of 1.67 *N* aqueous sodium hydroxide and precipitated material redissolved within two hours. Table I gives the subsequent change in the observed and the molecular rotation of the solution, whose volume was 77 cc.

TABLE I

ROTATORY CHANGE OF THE METHYLGLUCOSIDE-2-NITRATE IN ALKALI

Hours	α^a	$[M]_D$	Hours	α^a	$[M]_D$
2.5	−3.25°	−15,000°	5.5	−3.86°	−17,900°
3.5	3.50	16,200	8.7	4.02	18,600
4.0	3.63	16,800	10.4	4.17	19,300
4.5	3.73	17,300	23	4.58	21,200[b]

[a] Observed in a 1-dm. tube. [b] Corresponds to a specific levorotation of −120° if anhydromethylhexoside (mol. wt. 176) was the sole product.

After twenty-three hours, 3-cc. samples contained 14.7×10^{-6} mole of nitrite, equivalent to 2.3% of the original nitrate groups.

The remainder of the solution, 72 cc., was examined by the methods already described for the isolation of 3,6-anhydromethylglucoside. A clear, colorless sirup resulted in a yield of 2.30 g. or 84%, and with a specific levorotation of −101° in water at 26°. A negative test for nitrate groups was obtained with ferrous sulfate and concentrated sulfuric acid. In a test for the presence of unsubstituted, adjacent hydroxyl groups, an 0.0545-g. sample reduced 0.7 cc. of 0.1 *N* sodium periodate at *p*H 4.1 in two hours, or in circumstances where 1 mole of methylglucopyranoside reduced the correct amount of 2 mole.[31] The estimation showed that the amount of any methylhexopyranoside present in the sirup did not exceed 5 or 6%. An 0.3-g. sample of the sirup, when acetylated with acetic anhydride and pyridine, gave 0.29 g. of an uncrystallized acetate with a levorotation of −68.8° in chloroform. This acetate required 7.85 cc. of *N* sodium hydroxide per gram in an acetyl estimation. Calcd. for the diacetate of an anhydromethylhexoside, 7.73 cc.; for the tetraacetate of a methylhexoside, 11.5 cc.

The remainder of the unacetylated sirup, 1.9 g., partly crystallized. Cautious dilution of the mass with 10 cc. of ethyl acetate–ethyl ether led to the separation of 0.18 g. of long, feathery needles melting at 127–136° and with a specific levorotation of −111° in water. An 0.0493-g. sample reduced 0.765 cc. of 0.1 *N* sodium periodate or 0.07 mole per mole of crystals, calculated as anhydromethylhexoside. Evaporation of the mother liquors from the crystals gave a residual sirup with a specific levorotation of −106° in water. When a 2.58% solution in 0.01 *N* hydrochloric acid was heated on the steam-bath,[32,33] the rotations observed in a 1-dm. tube were −2.72 (calcd), −1.26, −0.85 and −0.65° after zero, thirty, one hundred and twenty and two hundred minutes, respectively. The solution had developed reducing properties and quickly deposited a yellow precipitate when treated at room temperature with 3 cc. of acetic acid and 2.5 cc. of phenylhydrazine. This precipitate was too small in amount for a detailed examination. The development of reducing power, however, showed that methylglycosidic groups in the sirup had been hydrolyzed.

Anal. Calcd. for an anhydromethylhexoside, $C_7H_{12}O_5$: C, 47.7; H, 6.8, OCH_3, 17.6. Calcd. for a methylhexoside, $C_7H_{14}O_6$: C, 43.3; H, 7.2; OCH_3, 16.0. Found for the crystals: C, 46.4, 45.9, 46.0; H, 6.9, 7.1, 6.9. Found for the residual sirup: C, 46.0, 45.7, 45.4; H, 7.1, 7.3[34]; OCH_3, 16.4. Neither the crystals nor the sirup were obtained in a pure condition. Although the sirup was volatile at 150–165° (3 mm.), an attempt to purify it by vacuum distillation failed owing to rapid decomposition.

Discussion

The quick neutralization of five moles of alkali by tetraacetyl-α-glucosyl nitrate (Structure I, Fig. 1) confirms the fact that the nitrate group in the reducing position of glucose is at least as labile as the four acetyl groups. The yellow gum obtained by dissolving the nitrate in absolute sodium methylate was acetylated prior to examination and the chloroform-soluble portion amounted to 75%. On one occasion, when the crude, acetylated product crystallized spontaneously but incompletely, there was no difficulty in isolating a 28% yield of crystalline tetraacetyl-β-methylglucoside (Ic) and in characterizing it definitely. Crystallization of the crude product was complete on a subsequent occasion and an attempt to isolate the glucoside by fractional recrystallization was unsuccessful. The physical properties of the fractions suggested that the

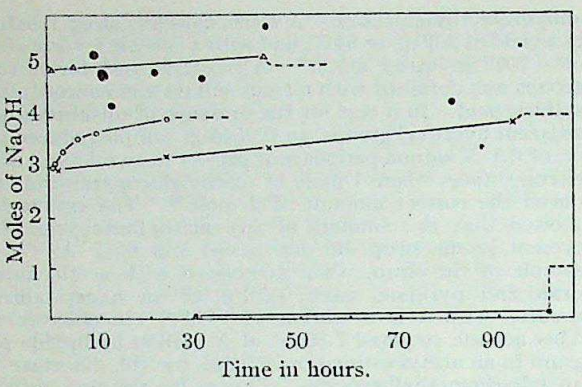

Fig. 1.—Rates of de-acylation by 1.2 *N* aqueous methanolic sodium hydroxide at 25°: 2,3,4,6-tetraacetyl-α-glucosyl-1-nitrate, Δ; 3,4,6-triacetyl-β-methylglucoside-2-nitrate, ○; 2,3,4-triacetyl-α-methylglucoside-6-nitrate, ×, .and 2,3,4-trimethyl-β-methylglucoside-6-nitrate, ●; broken lines show theoretical consumptions of alkali.

original was a mixture of almost equal amounts of tetraacetyl-β-methylglucoside and the more levorotatory triacetylglucosan <1,5>β<1,6>. This interpretation was confirmed when the formation of methylglucoside was suppressed by replacing the absolute sodium methylate with caustic soda dissolved in aqueous dioxane, glucosan (IV) being isolated in 33% yield as the crystalline, trimethyl derivative. The formation of glucosan in these reactions completes the analogy between the behavior of tetraacetyl glucosyl-α-nitrate and the corresponding α-bromide (Ia), which is known to give glucosan when treated in succession with trimethylamine and aqueous barium hydroxide.[35] The analogy, indeed, suggests that the trimethylamine step in the latter preparation may be unnecessary. It is plausible to assume that alkali forms the same carbonium ion from both the α-nitrate and the α-bromide and that a Walden inversion occurs as this ion combines with solvent methanol to give β-methylglucoside, or with the primary alcoholic group of the glucose residue to give glucosan. The explanation, however, fails to account for the formation of glucosan in similar conditions from beta, but not from alpha, phenylglucoside[36] and must at present be accepted with great reserve.

About one quarter of the tetraacetylglucosyl nitrate used in the experiments with absolute sodium methylate produced a yellow gum that was not examined in detail. A much darker colored gum comprised two-thirds of the product obtained with caustic soda in aqueous dioxane. Since only 4.5% of the nitrate groups was reduced to sodium nitrite in the latter experiment, the oxidation of carbohydrate during denitration was likewise insignificant and the gum did not originate in the action of excess alkali upon oxidized glucose residues. This action was probably exerted upon glucose, or upon a reducing intermediate at the glucose level of oxidation, that was formed during denitration. It is apparent that such substances did not reduce sodium nitrate to nitrite in the experimental conditions.

The nitrate group in 2,3,4-triacetyl-α-methylglucoside-6-nitrate (II) neutralized one mole of alkali more slowly than the three acetyl groups (Fig. 1) and only 2% was identified as sodium nitrite in the resulting, nearly colorless solution. Both aqueous alcoholic caustic soda and absolute sodium methylate caused the molecular rotation of the 6-nitrate to decrease to a value corresponding to a practically quantitative formation of 3,6-anhydro-α-methylglucopyranoside (III)[19] and in both cases 77–88% yields of this substance were isolated in a crystalline condition. The preparation of the anhydroglucoside from the 6-nitrate, therefore, proceeds at least as smoothly as those employing the 6-bromo (IIa),[37] the 6-*p*-toluenesulfonyl (IIb)[28] or the 6-sulfonyl[38] derivative.

The nitrate group in 3,4,6-triacetyl-β-methylglucoside-2-nitrate (VI) was removed by alkali somewhat more rapidly than that in the isomeric 6-nitrate (Fig. 1), and only 2.3% was reduced to sodium nitrite. Sodium hydroxide dissolved in aqueous dioxane gave an 84% yield of a clear, colorless, non-reducing, nitrate-free sirup about one-tenth of which eventually crystallized as needles, m. p. 127–136°. Analytical data and physical properties showed that both the crystals and the residual sirup were impure anhydromethylhexosides. An estimation for unsubstituted, adjacent hydroxyl groups by the periodate method showed that, if methylhexoside was present, its amount did not exceed 6% in either fraction. This denitration, therefore, followed a path fundamentally similar to that observed for the deacylation of 2-*p*-toluenesulfonyl-β-methylglucoside (VIa) to a sirup consisting mainly of 2,3-anhydro-β-methyl mannoside (VII).[39,40] The latter sirup, however, had a levorotation of −25° in water, whereas the rotations of the crystals and the residual sirup isolated from the 2-nitrate were −111 and −106°, respectively. Perhaps the discrepancy is connected with the use of sodium methylate in chloroform at 0° as the alkali in one case and sodium hydroxide in aqueous dioxane at 25° in the other. The first reagent produced an anhydro sirup with a specific levorotation of −80 to −90° from triacetyl-3-*p*-toluenesulfonyl-β-methylglucoside[41] in circumstances where a boiling solution of sodium hydroxide in aqueous acetone yielded a product with the large levorotation of −328°.[42] Ohle and Wilcke[42] are of the opinion that 2,3-anhydro derivatives may

sometimes rearrange to other anhydro structures, such as the 3,6, either with or without Walden inversions. Although an examination of the mixture from the methylglucoside-2-nitrate along these lines was outside the scope of the present work, it was observed that at least a portion resembled 3,6-anhydromethylhexosides to the extent that the glucosidic group was very readily removed by acid hydrolysis.[28]

The three denitrations already discussed tend to show that the preferred alkaline cleavage of carbohydrate nitrate groups takes place in the sense $R_1R_2CH\vdots O—NO_2$ and leads to the quick expulsion of the elements of nitric acid in a substantially unreduced condition. The dependence of this method of elimination upon a facile production of methylglucoside or anhydro structures is illustrated in Fig. 1, by the relatively great stability displayed toward alkali by 2,3,4-trimethyl-β-methylglucoside-6-nitrate (V), in which the methyl ether groups block anhydro formation. More drastic conditions promoted a straightforward hydrolysis to crystalline 2,3,4-trimethyl methylglucoside (Va), which was isolated in 75% yield. The alkaline hydrolyses of the "blocked" *p*-toluenesulfonyl radicals in such substances as 2-tosyl-3,4,6-trimethyl-β-methylglucoside[39], 2-methyl-3,4-isopropylidine-6-tosyl-α-methylgalactoside[43] and 2,5-dimethyl-3-tosyl-β-methylxylofuranoside[44] proceed with difficulty but often in high yield along exactly the same lines. No Walden inversions were observed[45] and the hydrolyses were therefore attributed to scission in the sense $R_1R_2CH—O\vdots SO_2C_7H_7$. It is probably legitimate to assume the similar mechanism, $R_1CH_2—O\vdots NO_2$, for the scission of the "blocked" nitrate group in the present case.

The most interesting aspect of this denitration was the reduction of no less than 20% of the organic nitrate to sodium nitrite and the decomposition of up to 25% of the methylated carbohydrate to a discolored tar that slowly neutralized some of the excess alkali. These occurrences showed unequivocally that the direct hydrolysis of "blocked" nitrate groups was slow enough to render the still slower side-reaction, $R_1CH_2—O—NO_2 \rightarrow R_1CHO + HNO_2$, of considerable importance. When it is remembered that a proton is readily expelled from the methylene group in benzyl alcohol and that the oxidative cleavage is quantitative with benzyl nitrate,[13] it appears possible that the mechanism involves the loss of a methylene proton from the scission fragment $R_1CH_2—O—$ and rearrangement to $R_1CH=O$. This mechanism resembles that advanced to explain the formation of *p*-toluenesulfinic acid when certain N-benzyl sulfonamides are heated in strong alkali,[46] although no search seems to have been made for sulfinic acids among the hydrolysis products of "blocked" sulfonyl residues in carbohydrates. The alkaline hydrolysis of 6-bromo-2,3,4-trimethyl-β-methylglucoside (Vb) is reported to yield unsaturated substances[27b]; presumably by the loss of halogen from the sixth carbon atom and of a proton from the adjacent, rather than from the same, position.

The authors wish to thank Professor R. C. Hockett for valuable advice and for several samples of seed crystals.

Summary

1. When 2,3,4-triacetyl-α-methylglucopyranoside-6-nitrate was denitrated by aqueous or alcoholic caustic soda, the product consisted almost entirely of 3,6-anhydro-α-methylglucopyranoside. An 84% yield of a semi-crystalline mixture of crude anhydro methylhexosides was recovered after submitting 3,4,6-triacetyl-β-methylglucopyranoside-2-nitrate to a similar denitration. The constitution of the mixture was not examined in detail.

2. 2,3,4,6-Tetraacetyl-α-glucosyl nitrate and absolute sodium methylate produced a 75% yield of β-methylglucopyranoside mixed with a second substance, which was supposed to be glucosan $<1,5>\beta<1,6>$. The latter was isolated in 33% yield when aqueous alcoholic sodium hydroxide was substituted for the absolute sodium methylate.

3. Aqueous alcoholic sodium hydroxide slowly hydrolyzed 2,3,4-trimethyl-β-methylglucopyranoside-6-nitrate to the 2,3,4-trimethylglucoside in 75% yield. The remainder was recovered as a discolored gum and 20% of the nitrate groups was reduced to sodium nitrite. Only 2 to 4.5% of nitrite resulted in (1) and (2) where an easy formation of methylglucoside or of anhydro derivatives was possible.

4. The very close analogy between the behavior toward alkali of these nitrates and the corresponding *p*-toluenesulfonyl, sulfonyl and halide derivatives was emphasized.

The Preparation of Unsymmetrical Secondary Aliphatic Amines[1]

BY KENNETH N. CAMPBELL, ARMIGER H. SOMMERS AND BARBARA K. CAMPBELL

Until recently unsymmetrical secondary aliphatic amines have been difficult to prepare in quantity. One of the most promising methods of preparing these amines would appear to be by reduction of aliphatic aldimines. A survey of the literature has shown that this approach has been investigated before, with varying degrees of success. Although several workers have reported the preparation of various aliphatic aldimines,[2,3,4] there appears to be no good general description of the method of preparation. Reduction of aliphatic aldimines by sodium and alcohol has been reported to yield the secondary amines[2,4,5] but the yields are not always good; possibly considerable cleavage or polymerization of the aldimine occurs during the reduction. Skita and his co-workers[6,7] investigated the low-pressure catalytic hydrogenation of aldimines, using platinum as catalyst and acetic acid as solvent. They obtained secondary amines, but the carbon content was greater than would be expected. Winans and Adkins[8] and Henze and Humphreys[9] have shown that aldehyde-amine condensation products can be hydrogenated to secondary amines of the same carbon content at high pressures in the presence of nickel catalysts; these workers did not isolate the intermediate aldimines, and while their method gives good yields of amines, there is also need for a procedure which does not involve the use of high-pressure hydrogenation equipment.[10] We therefore undertook a study of the preparation and isolation of aliphatic aldimines, and of their catalytic hydrogenation at low pressures and temperatures.

We have found that aldimines can be obtained in a pure state and good yield from aliphatic aldehydes and amines only by observing certain precautions rather strictly. The method of Emerson, Hess and Uhle[11] could not be extended satisfactorily. The method finally adopted is a modification of the one described by Chancel[12] for propylidene propylamine; the reaction is best carried out by adding the aldehyde to the amine, without a solvent, at 0°. When the order of addition is reversed, the yields are much lower. After the addition is complete, solid potassium hydroxide is added to remove the water formed in the reaction. This step is essential; when other drying agents such as potassium carbonate or magnesium sulfate were tried, practically no aldimine was obtained on distillation, and attempts to hydrogenate the undistilled material were unsuccessful. The aldimine should be distilled from fresh potassium hydroxide. The aldimines obtained in this work were water-white when freshly distilled; they are unstable, and polymerize on standing, and should be used within a few hours after distillation.

The aldimines can be hydrogenated to secondary amines of the same carbon content at room temperature and pressures of 2–3 atmospheres with certain restrictions. The best solvent appears to be absolute ethyl alcohol. Palladium-charcoal catalyst can be used, but the hydrogenation is more rapid, and the yields of amine seem better when pre-reduced platinum oxide is used. With Raney nickel the calculated amount of hydrogen is taken up rather rapidly, but side reactions appear to predominate, and but little of the desired secondary amine is formed. The hydrogenations are best carried out in the presence of a small amount of the original primary amine in order to minimize cleavage of the aldimine.

Experimental

Preparation of Aldimines.—The aldehydes and amines were obtained from Eastman Kodak Co., and were used without further purification. Since the procedure for the condensation was the same in all cases, only a typical example is described.

A 250-ml. 3-neck conical bottom flask, fitted with reflux condenser, mercury-seal stirrer and dropping funnel, was packed in an ice-bath. It was charged with 23.6 g. (0.4 mole) of *n*-propylamine, and 28.8 g. (0.4 mole) of butyraldehyde was added gradually over a period of two hours. The reaction mixture was stirred for an additional fifteen minutes; potassium hydroxide flakes were then added, and the mixture was allowed to stand until separation into two layers appeared complete; this required about ten minutes. The organic layer was then removed, and was allowed to stand over crushed potassium hydroxide in the refrigerator overnight. The dried material was decanted into a 100-ml. conical-bottom Claisen flask, a few pellets of potassium hydroxide were added, and the material was distilled. There was a small preliminary fraction; the temperature then rose rapidly to 120°, and the bulk of the material came over at 120–124°. When the treatment with potassium hydroxide was omitted, and when another drying was substituted, the boiling point of the product rose gradually and continuously, and there was no plateau.

The data on the aldimines prepared are summarized in Table I. The indices of refraction and densities were determined on the freshly-distilled samples.

[a] This is the over-all yield from the primary amine. [b] From the fractionation data this appeared to be the pure material. Nitrogen analysis (Dumas) gave N; 16.3%; calculated, N, 16.1%. [c] From the fractionation data this appeared to be the purer material. Nitrogen analysis gave N, 13.6%; calculated, N, 13.8%.

Hydrogenation of Aldimines.—Preliminary runs were carried out with a microhydrogenation machine, using 0.01-mole samples of butylidenebutylamine in absolute alcohol. With 50 mg. of platinum oxide, "pre-reduced," 0.01 mole of hydrogen was absorbed in thirty minutes; with 0.1 g. of 10% palladized charcoal, the time required was seventy-five minutes, and with Raney nickel, sixty minutes. On the basis of these results "pre-reduced" platinum was chosen as catalyst, and the following procedure is typical.

A suspension of 0.20 g. of platinum oxide[13] in 50 ml. of absolute alcohol was shaken with hydrogen at 25 lb./sq. in. for ten minutes, or until no more hydrogen was absorbed. The hydrogen pressure was then released, and 31.6 g. of freshly distilled butylidenepropylamine (0.28 mole), 50 ml. of absolute alcohol and 3 ml. of propylamine were added to the catalyst mixture. The mixture was shaken with hydrogen at an initial pressure of 51 lb./sq. in. until no more hydrogen was absorbed; this required forty minutes, and 0.26 mole of hydrogen was taken up. The catalyst was removed, and the alcoholic solution was distilled through a small Whitmore–Fenske column at atmospheric pressure and a 5:1 reflux ratio until the alcohol was removed. The residue was distilled through the same column under reduced pressure. The yield of product boiling at 92–93° (209 mm.) was 20.8 g., 65% of the theoretical amount.

In the case of ethylpropylamine the amine and the alcohol boil too close together to permit of separation by distillation. In this case, therefore, the alcoholic solution of the reduction product was acidified with hydrochloric acid and evaporated to dryness. The free base was liberated from the hydrochloride by aqueous alkali, taken up in ether and the ether solution distilled through the column.

Two attempts were made to use Raney nickel as catalyst; in both cases the correct amount of hydrogen was taken up, but distillation of the reduction product yielded little or no secondary amine.

The unsymmetrical secondary amines prepared in this work have been reported in the literature, but in many cases the data recorded are very meager. For this reason we determined the physical constants and prepared the

hydrochlorides and α-naphthylthioureas. The hydrochlorides were analyzed for chlorine. The data are summarized in Tables II and III. In several cases the secondary amine was prepared from both possible combinations of aldehyde and amine, and the two products shown to be identical by comparison of physical constants and derivatives.

Summary

1. A procedure has been described for the preparation of aldimines from aliphatic aldehydes and amines.

2. The catalytic hydrogenation at low temperatures and pressures of the aldimines has been studied, and several unsymmetrical, secondary aliphatic amines have been prepared, their physical constants determined and certain derivatives made.

NOTRE DAME, INDIANA RECEIVED SEPTEMBER 25, 1943

[CONTRIBUTION FROM THE NORTHERN REGIONAL RESEARCH LABORATORY[1a]]

Linear Superpolyesters from Dilinoleic Acid

BY JOHN C. COWAN AND DONALD H. WHEELER[1b]

Linear superpolymers prepared from saturated dibasic acids with other difunctional molecules have been described by Carothers.[1c] However, the preparation of linear superpolymers from dibasic acid containing non-benzoid unsaturation has not been described despite reported preparation of such α-polyesters[2] and α-polyamides.[2a]

Vorländer[3] reported the preparation of a resinous polyethylene maleate and crystalline polyethylene fumarate. Carothers[4] prepared the same polyesters, reporting that the maleate polymer was crystalline, and the fumarate resinous. In addition, Carothers reported that both polyethylene maleate and fumarate were heat-convertible to insoluble three-dimensional polymers.

Bradley[5] and Vincent[6] showed that these polyesters were oxygen-convertible and confirmed Carothers' observation on their heat-convertibility. Vincent reported that one polyester, the triethylene glycol citraconate, was very difficult to heat-convert. This observation indicated that under controlled conditions certain types of unsaturated dibasic acids might give linear superpolyesters. It was believed that the kind of unsaturation present in the acid, as well as the possible effect of steric hindrance, were important.

Dibasic acids which contain unsaturation not conjugated with the carboxyl groups, or contain unsaturation which does not easily shift to conjugation, have not been readily available until recently. By suitable polymerization,[7] and fractional distillation[8] under reduced pressures, the esters of linoleic acid of semi-drying oils can be converted to esters of dilinoleic acid.[8a] Although the structure of dilinoleic acid is not known with certainty, the following data indicate its properties[8,9]

Unsaturation	Two double bonds
Molecular weight	560
Neutral equivalent	280
Conjugation	Negligible[10]
Conjugation after alkali treatment[11]	Negligible[12]

Bradley[8] described the preparation of the polyester of triethylene glycol dilinoleate. He obtained a viscous liquid which had an acid value of 13.1. This description indicates that the polymer was an α-polyester, having a molecular weight of approximately 4,300. No description of an attempt to prepare superpolyesters was reported. As a part of the program of the Oil and Protein Division of the Northern Regional Research Laboratory on the polymerization phenomena of semi-drying oils, an investigation of the polyesters of dilinoleic acid was undertaken.

By use of methods developed by Carothers[13] and Flory[14] superpolyesters were prepared from dilinoleic acid with ethylene, decamethylene, and hydrogenated dilinoleyl glycols.[14a] All superpolyesters were soluble in chloroform and, in

general, exhibited solubilities similar to those reported by Carothers for saturated superpolyesters. The dilinoleate superpolyesters were non-crystalline plastic solids which on continued exposure to oxygen converted to insoluble three-dimensional polymers. Also, by long heating at temperatures as high as 290–300°, conversion to insoluble three-dimensional polymers was effected. However, some doubt remains as to whether this conversion was actually caused by the high temperature or by traces of oxygen which might have come in contact with the polyesters.

Despite indications from end-group determinations; and from the general properties of the polyesters, it was believed that additional proof of the linear nature and high molecular weight of these polyesters was necessary. This proof was established by use of the relationship of the logarithm of viscosity of the molten polyesters to the square root of molecular weight from end-group determination. Flory[14] showed that this relationship is linear for polyesters from saturated dibasic acids, and he obtained molecular weights in excess of 10,000. Polyesters from dilinoleic acid with decamethylene and hydrogenated dilinoleyl glycols were readily converted to superpolyesters having molecular weights of 10,000 with little deviation from the linear viscosity relationship. However, at higher molecular weights of the order of 20,000–30,000, close correlation was not obtained. At a molecular weight of 20,000, a small deficiency or excess of either reactant makes an enormous variation in the molecular weight obtained by end-group titration (see experimental part). Therefore, failure to obtain exact correlation at high molecular weights is not surprising. Such a failure is probably due to the loss or decomposition of either reactant or to impurities present in the reactants.

Superpolyesters from ethylene glycol were obtained by means of glycolysis. In all cases where dilinoleic acid was used with a theoretical or a slight excess over the theoretical amount of ethylene glycol, deviations from the viscosity relationship occurred at molecular weights above 5,000–6,000. It was believed that the difficultly controllable loss of ethylene glycol and its decomposition[15] at temperatures used for polyesterification were responsible for the failure of dilinoleic acid and ethylene glycol to give superpolyesters when molar or approximately molar quantities of the glycol were used. However, when an excess of glycol was used with the dilinoleic acid, and a glycolysis catalyst added, a superpolyester was obtained. Viscosity determinations indicate that superpolyesters having molecular weights as high as 24,000 were obtained by this method.

(15) Gallaugher and Hibbert, THIS JOURNAL, 59, 2514 (1937); 59, 2521 (1937).

Direct comparison of preparations of polyesters from dilinoleic acid and hydrogenated dilinoleic acid showed that the unsaturation did not contribute to the viscosity of the final products. This behavior was maintained when an inert atmosphere was kept over the reaction mixture and oxygen excluded from the reaction. This work shows that essentially linear superpolymers can be obtained containing nonconjugated unsaturation, and therefore this type of unsaturation is not functional under proper preparative conditions.

Bradley[5] studied the properties of triethylene glycol maleate and triethylene glycol succinate. He obtained relative viscosities and molecular weights by end-group titration of the polyesters at various stages of reaction up to molecular weights of approximately 3,000. Application of Flory's relationship to Bradley's data indicates that under special conditions, *i. e.*, under an atmosphere of pure nitrogen, linear α-polyesters having molecular weights of 2,500 were obtained with triethylene maleate. This work indicates that superpolyesters from maleic and citraconic anhydride and other unsaturated dibasic acids or anhydrides might be obtained by suitable methods. However, conditions required for the preparation of superpolyesters may cause heat conversion too readily to make possible preparation of such superpolyesters. Investigation of the use of unsaturated dibasic acids other than dilinoleic acid for the preparation of superpolyesters is planned, to determine whether essentially linear superpolymers can be obtained which contain conjugated aliphatic unsaturation. This work will determine if conjugated aliphatic unsaturation is functional under preparative conditions necessary for formation of superpolyesters.

Experimental

Dilinoleic Acid.—The acids used in this investigation were prepared from corn or soybean oil. The method used was essentially that described by Bradley[8] for the preparation of methyl dilinoleate from dehydrated castor oil. Corn or soybean oil was converted by methanolysis to methyl esters. The distilled methyl esters were polymerized at 300° with 0.3% anthraquinone catalyst for sixteen to twenty-four hours. Unpolymerized esters were removed by distillation under reduced pressure of 1–5 mm., and the residual methyl dilinoleate carefully fractionated in a short path pot still (a modified alembic flask)[16] at 2 to 50 microns, or in a cyclic molecular still.

Middle cuts of the main methyl dilinoleate fraction were taken as pure dilinoleate for the preparation described. The presence of about 5% linolenic acid in soybean oil resulted in a dimeric product of slightly higher refractive index and iodine value, but otherwise it was very similar to the methyl dilinoleate from corn and dehydrated castor oil.

Methyl dilinoleate from corn oil had the following analysis: Calcd. for $C_{38}H_{68}O_4$: C, 77.20; H, 11.64. Found: C, 77.46; H, 11.68.

The acid was prepared from the ester by usual methods; neutral equivalent varied slightly with each preparation.

Hydrogenated Dilinoleic Acid.—To 3 liters of anhydrous ethanol was added 346 g. of methyl dilinoleate and approximately 20 g. of Raney nickel catalyst[17] suspended in anhy-

drous ethanol. The material was hydrogenated in a high pressure bomb at 100° and 1,400 pounds for two and one-half hours. Two additional treatments with fresh catalyst were carried out at 150° and 1,000 pounds for three hours each. The final product had an iodine value of 15.6, $n^{30}D$ 1.4705, and d^{30}_4 0.9306. It is possible that some alcoholysis occurred, giving a mixed ester. On saponification and neutralization the hydrogenated dilinoleic acid was obtained: neutral equivalent, calculated, 282.4; found, 299, 286.9, on two different preparations.

Hydrogenated Dilinoleyl Glycol.—Methyl dilinoleate from corn oil was hydrogenated, using Adkins catalyst, copper chromium oxide.[5,18]

Anal. Calcd. for $C_{36}H_{66}(OH)_2$: sapon. no., 0.0; OH no., 209.5; I no., 0. Found: sapon. no., 6.8; OH no., 204.1; I no., 11.3.

Original Preparations of Polyesters.—The first preparations of the polyesters from dilinoleic acid were made from the acid and ethylene glycol without catalyst. Several preparations were made with a variation in the amount of reactants used, and all of the polyesters prepared exhibited properties somewhat similar to superpolyesters. However, later work showed that these esters were probably ω-polyesters, although some preparations such as the following may have higher molecular weights.

A mixture of 328 g. of dilinoleic acid (neutral equivalent 288) and 45 g. of ethylene glycol was heated under carbon dioxide ebullition in a Claisen flask for seventy-two hours and for one hundred and forty-six hours in a pot still (Corning 3480). Table I shows the temperatures used and neutral equivalent of the polyester.

TABLE I

PREPARATION OF ETHYLENE GLYCOL DILINOLEIC ACID POLYESTER

Sample	Time, hours	Temp., °C.	Neutral equivalent
1	24	125	817
2	72	150	2200
3	120	240	3620

6	194	250	4900

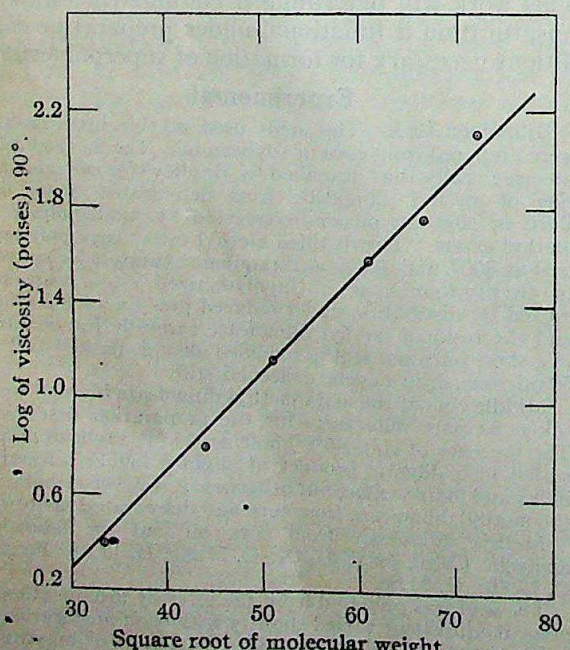

Fig. 1.—Viscosity–molecular weight relationship, polyester from dilinoleic acid with ethylene glycol.

(18) Folkers and Adkins, THIS JOURNAL, 54, 1146 (1932).

The polyester at the end of one hundred and ninety-four hours dissolved slowly but completely in chloroform. After twenty-four more hours heating at 300 to 320°, the polyester converted to a gel and only a portion of it was soluble in chloroform. The method used to remove samples from the reaction chamber permitted air to enter. Although the increased temperature appeared to be responsible for this gelation, oxygen conversion cannot be ruled out. A film of the soluble polyester having a neutral equivalent of 4,900 was exposed to the atmosphere. After sixty days, the film was only partly soluble in chloroform.

Despite repeated attempts with catalysts to obtain superpolyesters using molar or slightly greater quantities of ethylene glycol, no polyester was obtained which could be classified with certainty as a true superpolyester. Therefore, a study based on Flory's work[14] was undertaken.

Preparation of Superpolyesters and Viscosity Studies.—The esterifications were carried out in a vapor-jacketed vessel fitted with an inlet tube for introducing inert gas (purified nitrogen or carbon dioxide) below the surface of the reaction mixture, and an exit tube sealed with a bubbler to prevent back-diffusion of oxygen. Viscosities were usually measured by the rolling ball method, using 6 mm. i. d. tubes and an 1/8 inch steel ball. The relative kinematic viscosities thus obtained were converted to approximate values in poises by standardizing the viscosimeter with an oil of known viscosity. In several cases, viscosities were measured at reaction temperature with pipets or tubes in the reaction vessel, following the methods described by Flory.[14]

Molecular weights were determined by titrating samples in chloroform with alcoholic sodium hydroxide, using phenolphthalein or brom thymol blue indicator.

1. Ethylene Dilinoleate.—An ethylene glycol polyester of approximately 6,000 molecular weight was obtained as follows. A mixture of 50.8 g. (0.1810 equivalent) of dilinoleic acid (neutral equivalent, 286.4) and 5.82 g. (0.1877 equivalent) of ethylene glycol was heated for twenty-four hours at 100°, and then at 155–160° for another twenty-four hours, and then the temperature was raised to 195° for one hundred and fifty hours. Samples taken during the run showed the following neutral equivalents and viscosities.

Sample	Total hours	Molecular weight (neutral equivalent)	30° poises	90° poises
1	30	1142	70.8	2.47
2	42	1960	195	6.15
3	50	2630	514	14.8
4	65	3920	1295	37.7
5	77	4480	2120	56.6
6	140	5190	4650	125.5
7	over 200	5690	12140	....

The relationship of the log of viscosity at 90° to the square root of the equivalent weight is shown in Fig. 1. The values at 30° showed the same degree of agreement with a straight line relationship up to molecular weights of 5,000. Repeated attempts failed to obtain polyesters of much higher molecular weight which correlated with viscosity. Apparently ethylene glycol was lost or decomposed so that the reaction could not proceed above a molecular weight of 5,000 when equivalent amounts of reactants were used.

The experience with the polyesters just described led to the use of excesses of ethylene glycol with the addition of a small amount of alcoholysis catalyst. A mixture of 33.8 g. of dilinoleic acid (0.1205 equivalent), 4.86 of ethylene glycol (0.1567 equivalent, 30.5 % excess), and 15 mg. of *p*-toluenesulfonic acid was heated with purified nitrogen passing through the mixture. The reaction was run at 195° with the viscometer pipet in the reaction vessel, and was followed by viscosity values only since acid end-group determinations would be meaningless with such a large excess of glycol. After eighteen days, the viscosity had reached a

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized By Arya Samaj Foundation Chennai and eGangotri

value of 4,600 poises at 195°, which corresponds to a molecular weight of approximately 24,000. This value is arrived at by extrapolating to 195° from the viscosities at 30 and 90°, as described in the previous run, making use of the fact that the log of viscosity is a linear function of the reciprocal of absolute temperature (*cf.* Flory, *loc. cit.*). The calculated values for log of viscosity at 195° plotted against the square root of molecular weight showed good agreement with linear relationship. Extension of this curve indicates that a viscosity of 4,600 poises at 195° corresponds to a molecular weight of 24,000. This superpolyester was a soft elastic material which was soluble in chloroform at room temperature.

2. **Polyester of Ethylene Glycol with Hydrogenated Dilinoleic Acid.**—A mixture of 25.48 g. (0.0852 equivalent) of dilinoleic acid (equivalent weight found, 299) and 2.67 g. (0.086 equivalent) of ethylene glycol was heated at 195° under purified nitrogen with the results shown in Fig. 2. The linear relationship was again retained to a molecular weight of approximately 5,000.

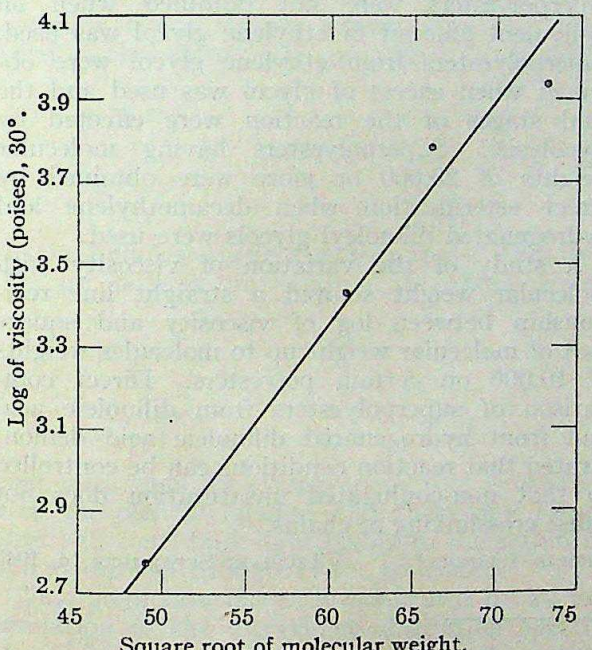

Fig. 2.—Viscosity–molecular weight relationship, polyester from hydrogenated dilinoleic acid with ethylene glycol.

3. **Decamethylene Dilinoleate.**—One method which served to minimize loss of reactants was to use a high molecular weight glycol such as decamethylene glycol with the dilinoleic acid. Although an observable loss of decamethylene glycol occurred, it was much less than when ethylene glycol was used.[18a] A mixture of 31.27 g. (0.115 equivalent) of dilinoleic acid and 9.72 g. of decamethylene glycol (0.116 equivalent) reacted at 195°, and the data obtained on viscosity and molecular weights are shown in Fig. 3. The values up to molecular weights of 10,000 are in excellent agreement with the linear relationship expected. The last two values deviate from an extension of the line for the first four. According to relationships developed by Flory, the deviation of the last two points would correspond to a deficiency of about 0.7% of glycol. Such a deficiency would not appreciably affect the previous points, and is in accord with the qualitative observation of some loss of glycol. The last sample was chloroform soluble, and represents a superpolyester of molecular weight of at least 20,000 or about 28,000, according to viscosity by extrapolation of the first four points.

4. **Polyester from Decamethylene Glycol and Hydrogenated Dilinoleic Acid.**—A mixture of 36.99 g. (0.1289 equivalent) of hydrogenated dimer acid (neutral equivalent found, 286.9) and 11.230 (0.1289 equivalent) of decamethylene glycol was heated at 195° with the results (see Fig. 4) similar to those of the decamethylene dilinoleate run. The deviation of the points beyond the fourth (10,400 molecular weight) corresponds to a loss of 0.8 to 0.9% of glycol. The final sample, with molecular weight of 15,500 by titration, or about 22,000 by vicosity, was also soluble in chloroform.

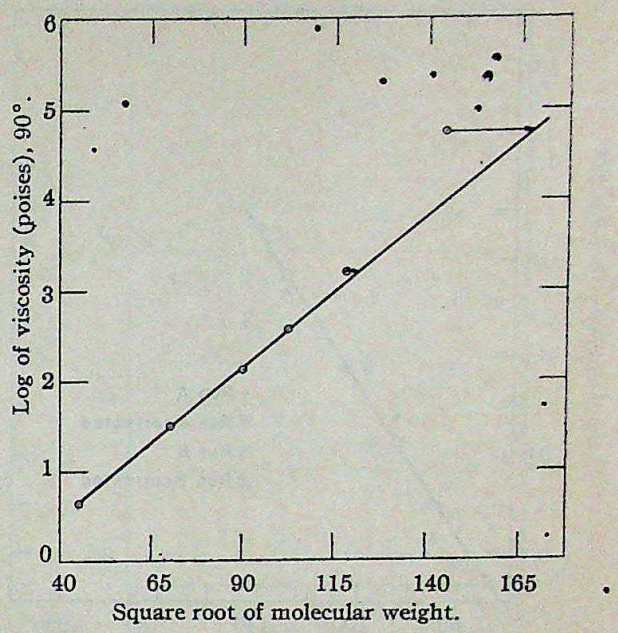

Fig. 3.—Viscosity–molecular weight relationship, polyester from dilinoleic acid with decamethylene glycol.

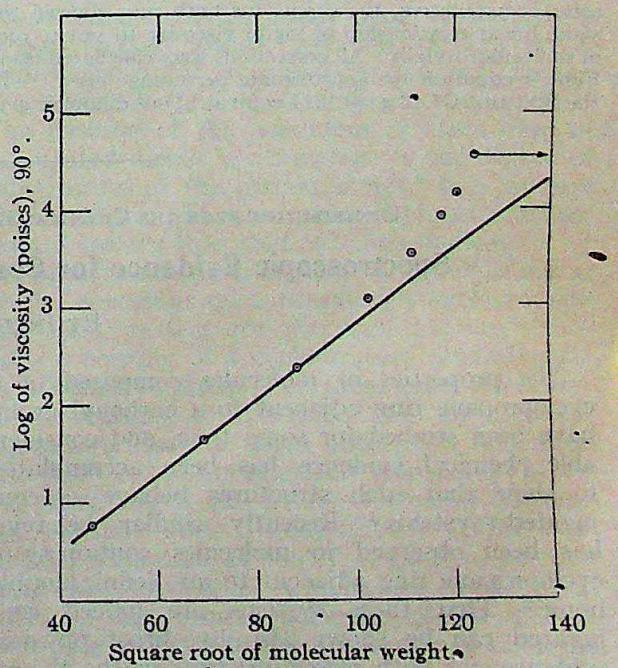

Fig. 4.—Viscosity–molecular weight relationship, polyester from hydrogenated dilinoleic acid with decamethylene glycol.

5. **Polyester from Dilinoleic Acid with Hydrogenated Dilinoleyl Glycol.**—In the first run, an excess of acid was used due to an error in calculations. In the second run, equivalent amounts of glycol and acid were used, assuming

(18a) Flory[14] reports a similar experience with decamethylene glycol.

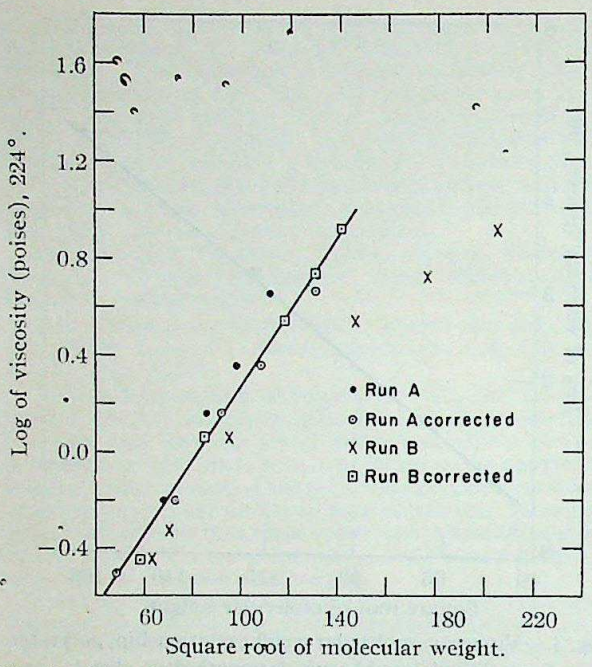

Fig. 5.—Viscosity–molecular weight relationship, polyester from dilinoleic acid with dilinoleyl glycol.

that the ester present in the glycol would be reactive by glycolysis and should be allowed for in calculating the required amount of acid to be used. The viscosity–molecular weight relationships of samples taken during this run indicated that an excess of glycol was present, and since no catalyst was present, it would appear that the ester had not reacted. When the results of both runs were corrected for the excess of acid or glycol present, assuming that the ester is unreactive, the points for both runs showed the same linear relationship of log of viscosity to square root of molecular weight. All corrections were calculated using Flory's equation for approximate percentage error.[14] In the first run, 34.42 g. (0.1214 equivalent) of dilinoleic acid (from soybean oil; neutral equivalent, 283.8) and 32.76 g. (0.1193 equivalent, based on OH no.) of hydrogenated dilinoleyl glycol reacted at 224°. In the second run, 31.14 g. (0.1098 equivalent) of dilinoleic acid and 31.09 g. (0.1131 equivalent) of the same glycol reacted at 224°. The results for viscosity molecular weight relationship are identified as Run A and Run B, respectively, in Fig. 5. The corrected values lie on the same straight line, and again indicate linear superpolyesters of molecular weights up to 20,000. Final samples from both runs were soluble in chloroform.

Summary

Superpolyesters were prepared from an unsaturated dibasic acid, dilinoleic acid, with ethylene, decamethylene and hydrogenated dilinoleyl glycols.

Loss and decomposition of ethylene glycol at reaction temperatures occurred and therefore superpolyesters were not obtained when an equivalent amount of ethylene glycol was used. Superpolyesters from ethylene glycol were obtained when excess of glycol was used and the final stages of the reaction were effected by glycolysis. Superpolyesters having molecular weights of 20,000 or more were obtained by direct esterification when decamethylene and hydrogenated dilinoleyl glycols were used.

A study of the variation of viscosity with molecular weight showed a straight line relationship between log of viscosity and square root of molecular weight up to molecular weights of 10,000 on certain polyesters. Direct comparison of superpolyesters from dilinoleic acid and from hydrogenated dilinoleic acid demonstrated that reaction conditions can be controlled so that non-conjugated unsaturation does not cause crosslinking of chains.

Spectroscopic Evidence for Conjugation in Cyclopropane Systems

BY IRVING M. KLOTZ

The properties of molecules composed of a cyclopropane ring adjacent to a carbonyl group have been studied for some time, and considerable chemical evidence has been accumulated to show that such structures behave as conjugated systems.[1] Recently similar behavior has been observed in molecules containing a cyclopropane ring adjacent to an olefinic double bond.[2] That these systems are indeed conjugated can be shown also by direct physical evidence, for with recent progress in the theory of absorption spectra[3] it is now possible to interpret ultraviolet spectra in terms of molecular structure.

The intense absorption bands of single ethylenic linkages lie in the region near 1800 Å., and if the carbon atoms are highly substituted, strong absorption may extend somewhat beyond 2000 Å.[4] However, when two double bonds are conjugated to each other a pronounced shift in the absorption toward the red end of the spectrum is observed. Wave-mechanical considerations[3] have shown that high intensity ultraviolet absorption spectra are due to transitions from a neutral ground state of the molecule to an ionic excited state. Conjugation permits the existence of a number of ionic structures which contribute appreciably to the resonance in

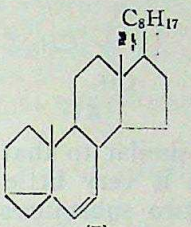
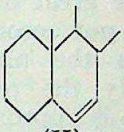
the excited state, but not to that in the ground state, and hence lower the energy of the former relative to that of the latter.

Since it is now recognized that conjugation may also occur between a saturated group and a double bond (hyperconjugation[3]) it would be expected that a compound such as Δ^6-*i*-cholestadiene (I) should have an ultraviolet absorption

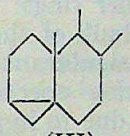


(I)

spectrum much farther toward the red than either 6-cholestene (II) or *i*-cholestene (III).

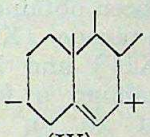


(II)

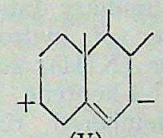


(III)

For in *i*-cholestadiene the structures (IV) and (V) are possible in addition to those which



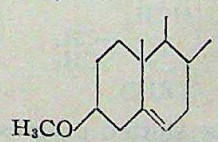
(IV)



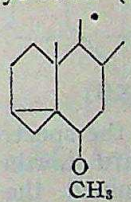
(V)

exist even when the cyclopropane ring is isolated from the olefinic linkage, and these new structures will contribute appreciably to the stabilization of the excited state of the molecule.

This prediction has been confirmed by an examination of the ultraviolet absorption spectra of Δ^6-*i*-cholestadiene (I), cholesteryl methyl ether (VI) and *i*-cholesteryl methyl ether (VII).



(VI)



(VII)

The two methyl ethers show no significant absorption, when examined in thickness and concentration comparable with Δ^6-*i*-cholestadiene (I), as low as 2230Å., the limit of our present instrument. These latter compounds correspond to structures (II) and (III) except for slight, non-influential differences in the position of the double bond and in the presence of a methoxy group. The *i*-cholestadiene, on the other hand, shows appreciable absorption below 2500Å. and gives strong indications of a peak near 2100Å. The spectrum of the compound has been plotted in Fig. 1 in conjunction with some mono- and di-

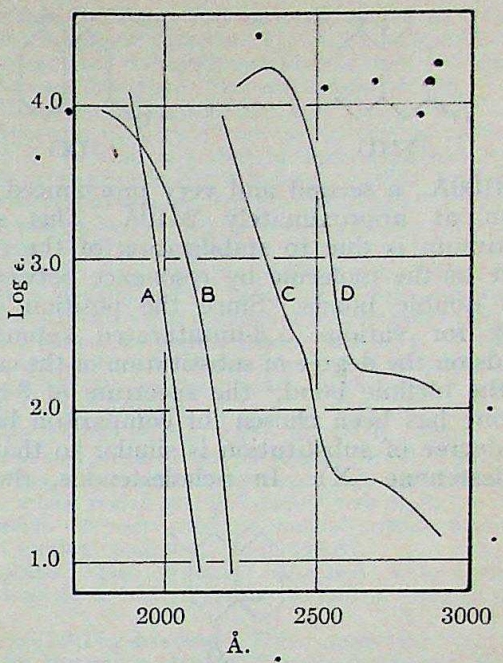


Fig. 1.—Absorption spectra of diallyl, A, trimethylethylene, B, Δ^6-*i*-cholestadiene (I), C, and cholestadiene, D. A and B from G. Scheibe and R. Pummerer, *Ber.*, **60**, 2163 (1927), and D from E. L. Skau and W. Bergmann, *J. Org. Chem.*, **3**, 166 (1938).

olefins for comparison. The unconjugated diolefin absorbs far to the left of *i*-cholestadiene, as is predicted by quantum mechanics.[3] Cyclopropane absorbs at even shorter wave lengths. Cholestadiene, on the other hand, absorbs in a region farther toward the red than even *i*-cholestadiene, for hyperconjugation is a second order effect compared to ordinary conjugation.[5] The position of the maximum of absorption of conjugated dienes is a function of the degree of substitution of the carbon atoms,[6] but for any cholestadiene, the absorption is much farther toward the red than that of *i*-cholestadiene.

The considerations leading to an explanation of the spectrum of a conjugated cyclopropane ring–olefin system are also applicable to structures consisting of a cyclopropane ring adjacent to a carbonyl group. In these cases, however, it is necessary to recognize that all carbonyl compounds show a small absorption maximum near 3000Å., but are relatively transparent below this wave length unless some degree of conjugation exists. Thus 3-cholestanone (VIII) exhibits a maximum at 2860Å. (Fig. 2), a position quite close to that for acetone despite the great bulk of the former molecule. Below 2860Å. there is a decrease in the absorption of cholestanone down to about 2600Å. and a slight rise thereafter. In contrast, 3-cholestenone (IX) which has a conjugated olefinic and carbonyl group, shows, in addition to the carbonyl peak

(5) R. S. Mulliken, C. A. Rieke and W. G. Brown, THIS JOURNAL **63**, 41 (1941).

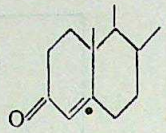
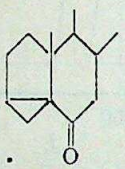
(VIII)



(IX)

at 3100Å., a second and very pronounced maximum at approximately 2410Å. This second maximum is due to stabilization of the excited state of the molecule by resonance between the two double bonds. Since the position of the peak for various α,β-unsaturated ketones depends on the degree of substitution of the carbons in the olefinic bond,[7] the spectrum of 3-cholestenone has been chosen for comparison because its degree of substitution is similar to that of *i*-cholestenone (X). In *i*-cholestenone, the con-



(X)

jugation of cyclopropane ring and carbonyl group introduces a number of ionic structures, in addition to those possible when the groups are isolated, which stabilize the excited state sufficiently to produce the spectrum shown in Fig. 2.

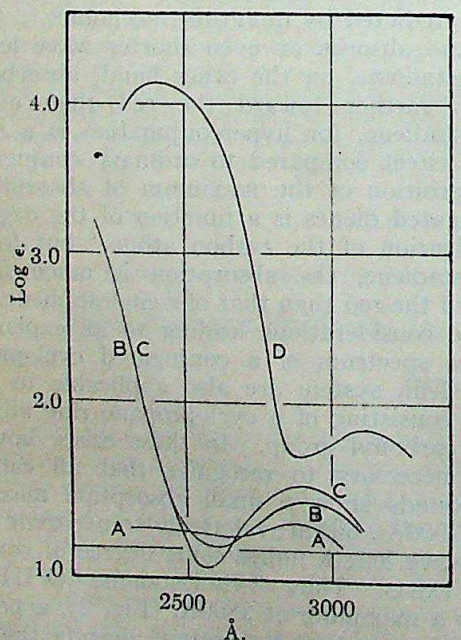


Fig. 2.—Absorption spectra of 3-cholestanone (VIII), A, carone (XI), B, *i*-cholestenone (X), C, and Δ^4-3-cholestenone, D. D is from H. Mohler, *Helv. Chim. Acta*, 20, 289 (1937).

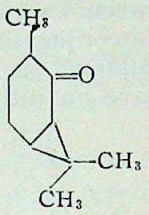
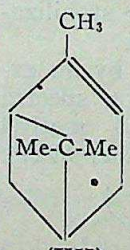
Spectroscopic evidence of conjugation between a cyclopropane ring and a carbonyl group is not limited to the steroid series. There are a number of terpene molecules which have similar conjugated structures, and we have examined the ultraviolet absorption of one of these substances, carone (XI). This compound exhibits a spec-



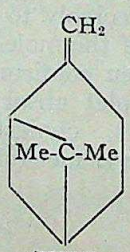
(XI)

trum extremely similar to that of *i*-cholestenone (Fig. 2). There is very little difference in the spectra of the two substances despite the fact that the cyclopropane ring in the terpene is relatively flexible whereas that in the steroid is locked in very rigidly because it is attached to two other rings. Similarly, the great difference in the bulk of the molecules is not accompanied by a significant difference in the ultraviolet absorption spectra. Apparently the resonance energy due to hyperconjugation is approximately the same in both the steroid and terpene and is influenced but little by the remainder of the molecule.

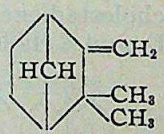
Preliminary data also have been obtained for a number of hydrocarbons, α-pinene (XII), β-pinene (XIII), camphene (XIV) and bicyclo-[2,2,1]-2-heptene (XV), containing a four- or five-membered ring adjacent to an olefinic linkage. In these cases the effect of hyperconjugation (or of strain in the classical point of view) is less than in the cyclopropane compounds



(XII)



(XIII)



(XIV)

(XV)

and the spectrum should be shifted progressively toward shorter wave lengths. In the compounds examined, the pinenes absorb in the region between the cyclopropane and cyclopentane compounds. The separation between the spectra is rather large, and there are indications that it may be possible to determine ring size in hydrocarbons by examining the spectrum of the compound containing the ring conjugated to an olefinic bond. However, the region farther in the ultraviolet must be investigated, and many more substances must be studied to substantiate this correlation. The necessary work is now in progress.

Experimental

The ultraviolet absorption spectra were obtained with a Beckmann quartz spectrophotometer. This instrument

(7) R. B. Woodward, THIS JOURNAL, 63, 1123 (1941); 64, 76 (1942).

uses a hydrogen arc as a source of ultraviolet radiation and a photocell-amplifier combination as a detector. The spectral region covered was from 2230 to 4000Å.

Solutions of known concentration were made by dissolving weighed quantities of solute in ethyl ether in a volumetric flask. At least two different concentrations of solute were used in most cases since a wide range in molecular extinction coefficient was encountered. The solution was poured into one of two matched silica absorption cells and the second cell was filled with solvent. Both cells were then inserted into the spectrophotometer and the intensity of light passing through each of them was recorded. The temperature of the solutions was maintained between 22 and 25°.

Extinction coefficients were calculated from the familiar equation

$$\epsilon = \frac{1}{cd} \log_{10} (I_0/I)$$

where I_0 is the intensity of the light passing through the solvent, I, the intensity of the light passing through the solution, c, the concentration of solute, in moles per liter, and d the thickness of the cell, in centimeters.

The compounds examined were prepared in the following ways.

Cholesteryl Methyl Ether.—The normal ether was prepared by the reaction of cholesteryl *p*-toluenesulfonate with methanol. Repeated crystallization from acetone gave platelets melting at 84–84.5°.

***i*-Cholesteryl Methyl Ether.**—The isomeric methyl ether was prepared from cholesteryl *p*-toluenesulfonate by the method of Stoll.[8] The crude ether was crystallized many times from acetone. Long, thin rods were obtained and melted at 79–79.8°.

***i*-Cholestenone.**—3(α)-Chlorocholestanone-6 was converted into *i*-cholestenone by the method of Windaus and Dalmer.[9] After several crystallizations from methanol, the ketone was sublimed at 75–80° at 10^{-4} mm. Crystallization of the sublimate from methanol gave a product melting at 93–96°. The above compounds were prepared by Dr. Edwin W. Meyer.

3-Cholestanone.—The method used for the preparation of 3-cholestanone was that described by Bruce.[10] The compound was crystallized from dilute ethanol until spectrographically pure. Dr. Irving Allan Kaye prepared this ketone.

(9) A. Windaus and O. Dalmer, *Ber.*, **52**, 168 (1919).
(10) W. F. Bruce, "Org. Syntheses," Coll. Vol. II, p. 139.

Δ⁶-*i*-Cholestadiene.—This material melted at 73–73.5° and gave a specific rotation of −60.9°. Its method of preparation and chemical characterization will be described in a publication[11] that will appear shortly.

***d*-5-Carone.**—Dihydrocarvone, b. p. 116–118° (17 mm.), was prepared in 62% yield from carvone by the method of Wallach.[12] It was converted to dihydrocarvone hydrochloride by passing in dry hydrogen chloride until 120% of the theoretical amount had been absorbed. This crude product was converted directly to *d*-5-carone by the method of Richter, Wolff, and Presting.[13] The crude *d*-5-carone was dissolved in 5 to 6 volumes of Skellysolve F (petroleum ether, b. p. 30–60°) and the resulting solution was washed with an excess of neutral potassium permanganate solution (20 g. of potassium permanganate and 25 g. of sodium bicarbonate per liter of solution), heated on the steam-bath to remove the Skellysolve F, and distilled under reduced pressure. The yield was 67%, b. p. 115–116° (15 mm.), d^{26}_4 0.933, $[\alpha]^{25}D$ +155.6° ($\alpha^{25}D$ 143.3°, *l*, 1 dm.). The *d*-5-carone was prepared and purified by Dr. R. I. Jackson.

α-Pinene.—A commercial product was distilled and a fraction which boiled at 158.5–159.0° was used.

β-Pinene.—A very pure commercial sample was used without further treatment; b. p. 165.8°.

Camphene.—The product examined was obtained from *i*-borneol by dehydration. It had a melting point of 50°.

Bicyclo-[2,2,1]-2-heptene.—This compound was obtained by treating cyclopentadiene and ethylene by the method described by Joshel and Butz.[14] A sample was redistilled and then recrystallized twice from an ethyl alcohol–water mixture. The product melted at 53°.

The samples of α-pinene, β-pinene, camphene and bicyclo-[2,2,1]-2-heptene were supplied by Dr. H. Pines.

Summary

The absorption spectra of a number of compounds containing a cyclopropane ring adjacent to an olefinic or carbonyl group have been examined and have been interpreted in terms of resonance due to hyperconjugation.

Ascorbic and Iso-ascorbic Acids as Photographic Developing Agents

BY T. H. JAMES

Ascorbic and iso-ascorbic acids represent a type of developing agent chemically quite distinct from the conventional aromatic agents. The developer activity of ascorbic acid was first reported by Maurer and Zapf[1] in 1934. Shortly afterwards, Bills[2] published formulas in which ascorbic acid was the active developing agent, and Rzymkowski[3] and Pavolini[4] published similar formulas for iso-ascorbic acid. Reaction mechanism studies have not been reported.

The present paper is concerned chiefly with establishing the general kinetics of development by ascorbic and iso-ascorbic acids, preliminary to using these substances in an investigation of the electric charge effect[5] in development. They show certain definite advantages over the aromatic agents usually employed for this purpose. The most important advantage is that the oxidation products of the ascorbic acids do not

interfere with the development process. The kinetic conditions are thus considerably simplified.

Materials and Methods

Ascorbic Acids.—Eastman Kodak Company *l*-ascorbic acid and *d*-iso-ascorbic acid were used.

Alkali and Salts.—General Chemical Company reagent grade potassium hydroxide and salts were used.

Water was redistilled in an all-Pyrex glass apparatus.

All development operations were carried out at 20 ± 0.05° under an atmosphere of oxygen-free nitrogen, using the general procedure previously described.[5] A series of development tests made on solutions which had been kept in the development apparatus for times varying from ten minutes to twenty-four hours gave satisfactorily constant results.

The photographic material was a normal motion picture positive (silver bromide) emulsion. Strips of film were given standard exposures in the Eastman Type IIb sensitometer. The step corresponding toan exposure of $\log E = 1.15$ (where E is in meter-candle-seconds) was employed in general for rate determinations. This exposure step was consistently on the "straight-line" portion of the exposure curve.[6] Rates are given in terms of R, the slope of the density–time curve of development at $D = 0.80$; and $1/t$, where t is the time required to obtain a density of 0.20.

Comparison of Ascorbic and Iso-ascorbic Acids.—At *p*H 10.3, the R values for iso-ascorbic acid in several experiments varied from 1.30 to 1.37 times those of ascorbic acid, with an average of 1.32. The ratio of $1/t$ values varied from 1.34 to 1.50, with an average of 1.45. In 0.04 M excess potassium hydroxide solution, the R values for iso-ascorbic acid varied from 1.0 to 1.09 times those of ascorbic acid, with an average of 1.03. The ratio of $1/t$ values varied from 1.1 to 1.2, with an average of 1.14. Thus, the iso-ascorbic acid develops appreciably faster than the ascorbic at *p*H 10.3, but only slightly faster in the caustic solution. No difference was noted in the rate of fog formation by the two substances.

Experiments carried out under varying conditions showed no significant difference in the general developing properties of the two acids. More complete data were obtained for the iso-ascorbic acid, and only these results will be reported subsequently.

Effect of Bromide Ion.—The addition of potassium bromide to the developing solution decreased the rate of image development, but had a much greater effect in depressing the rate of fog formation. Data are listed in Table I. The rate of fog formation is indicated by the last column. In the subsequent work, sufficient bromide was employed to suppress fog formation to a small, and generally negligible, quantity.

TABLE I

EFFECT OF BROMIDE ON DEVELOPMENT BY ISO-ASCORBIC ACID

*p*H	KBr concn.	R	$1/t$	Time for fog D = 0.10

.04 M	.0020	.065	.050	28
.04 M	.0067	.05	.040	>42

(6) Details on the standard exposure treatment and general photographic terminology are given in "The Theory of the Photographic Process," by C. E. K. Mees, the Macmillan Co., New York, N. Y., 1942.

Effect of Concentration and *p*H.—The variation in rate with concentration of iso-ascorbic acid is given in Table II. The salt environment was maintained essentially constant. The solutions of *p*H 10.34–10.38 contained 0.167 M potassium carbonate and sufficient bicarbonate or hydroxide to adjust the *p*H. The caustic solutions contained 0.333 M potassium nitrate. The total potassium-ion concentration was approximately 0.35 in the carbonate solution and 0.39 in the caustic solution.

The variation in rate with *p*H is given in Table III. A carbonate buffer was used in all experiments except the one at *p*H 7.96, where a phosphate buffer was employed.

TABLE II

VARIATION OF DEVELOPMENT RATE WITH ISO-ASCORBIC ACID CONCENTRATION

TABLE III

EFFECT OF *p*H UPON DEVELOPMENT RATE

Iso-ascorbic acid, 0.005 M; KBr, 0.00067 M

*p*H	R	$1/t$	% A⁻
7.96	...	0.002	...
10.08	0.042	.025	3.5
10.25	.051	.036	5.1
10.35	.065	.041	6.3
10.55	.083	.056	9.6

Effect of Oxidation Products and Copper.—The oxidation products of iso-ascorbic acid were without any effect upon the rate of development, so far as could be detected. The addition of partially oxidized iso-ascorbic acid and the admission of small amounts of oxygen were without effect other than a minor one due to some alteration in the concentration of the developing agent. The addition of copper salts, which markedly catalyze the oxygen oxidation of ascorbic acid (at least in acid and neutral solutions), produced, if anything, a slight *decrease* in the development rate.

Temperature Coefficient.—At *p*H 10.15, the 10° temperature coefficient over the range 8–20° was about 2.55 for R rates, and 1.85 for $1/t$ rates. In the caustic solution, the coefficient

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

was 1.90 for R, and 1.75 for $1/t$ over the same temperature range. In each case, the solution contained 0.333 M potassium nitrate and approximately 0.04 N potassium carbonate or potassium hydroxide.

Neutral Salt Effect.—A careful control of the salt environment proved to be essential to the kinetic investigation. The rate of development is markedly dependent upon the concentration of neutral salts. The magnitude of this effect is indicated by the results given in Tables IV and V.

The increase in the development rate was accompanied by some increase in the photographic emulsion speed. The nature of this increase, together with a more complete investigation of the salt effect, will be considered in a subsequent paper. Both have a bearing upon the general question of the effect of the electric charge upon the over-all kinetics of development.

Discussion

In the presence of a suitable amount of bromide ion, ascorbic and iso-ascorbic acids yield good image development with only slight fog formation. The acids show no unusual properties as developing agents. In general, they resemble hydroquinone. The one important point of difference is the lack of any measurable effect of the oxidation products upon the course of development.

At pH 8.0, where the ascorbic acid exists almost entirely as the univalent ion, development is feeble. In the more alkaline solutions, the bivalent ion is responsible for almost all of the developing activity. This is shown by the data in Table III. A plot of log R against log $A^=$, where $A^=$ is the percentage of bivalent ion calculated on the basis of a dissociation constant of 3×10^{-12}, yields a nearly straight line of slope 0.75. A similar plot of log R against log C for varying concentrations of the acid at pH 10.35 gives a straight line of slope 0.78. Thus, the rate is determined by the concentration of the bivalent ion. The fact that the dependence is less than linear suggests adsorption of the ion prior to reaction with the silver halide. Similar results were obtained previously with hydroquinone.[7]

The $1/t$ rates are nearly proportional to the ascorbic acid concentration, but show a somewhat smaller dependence upon the $A^=$ values for varying pH. It is possible that the rate of diffusion through the double-layer region of the silver bromide grain is already of importance in determining the measured rate during this initial stage of development. The lower temperature coefficient of the $1/t$ values in comparison with the R values supports this possibility.

Diffusion rates become important in the caustic solution. The rates of development are only about one-fourth as great as those expected on the basis of the rates at pH 10.35. Comparisons must be made, of course, at equal salt concentrations, but the necessary data are available in Tables IV and V. Moreover, R is nearly proportional to the ascorbic acid concentration in the caustic solution. This is in contrast to the situation in the lower pH region, and is not to be expected if reaction rates are the determining factor. The decrease in temperature dependence observed in passing from pH 10.3 to a caustic solution is in line with the preceding interpretation, although the temperature dependence in development is complex and theoretical interpretations based upon it at the present time are of doubtful value. Finally the fact that ascorbic and iso-ascorbic acids show nearly equal rates in the caustic solution, in contrast to the observations at lower pH, favors diffusion as an important rate-determining factor. An alternative interpretation, that the second dissociation constant of iso-ascorbic acid is larger than that of ascorbic acid, is not supported by published data.[8]

The data on the effect of neutral salts show how important this factor can be in determining the rate of development by ascorbic acid (and other doubly-charged negative ions). Increases in rate up to five- and sixfold were produced solely by added neutral salt. Trace catalysis

produced by impurities in the salts is not involved in this effect. Samples of potassium nitrate obtained from three very different sources gave identical salt effects. Two samples of sodium sulfate, one impure, the other highly purified, gave results identical within the limit of experimental error.

The salt effect is caused by a depression of the double-layer zeta-potential of the silver bromide.[5] This permits a greater penetration of the bivalent ascorbic acid ions through the double-layer region to the surface of the grain, where the development reaction takes place.

Summary

The course of photographic development by *l*-ascorbic and *d*-iso-ascorbic acids is not affected by the oxidation products. The iso-ascorbic acid reacts at a somewhat greater rate than the ascorbic acid.

At *p*H 10 or above, the active developer consists almost entirely of the bivalent ion. This ion is adsorbed prior to reaction with the silver bromide. In caustic solution, diffusion rates become important in determining the measured development rate.

The rate of development is markedly dependent upon the nature and concentration of the salts present. The rate increases with increasing salt concentration.

The Molecular Structures of Dimethyl Silicon Dichloride, Methyl Silicon Trichloride and Trifluoro Silicon Chloride[1]

BY R. L. LIVINGSTON AND L. O. BROCKWAY

Previous study of the mutual interaction of groups attached to a central silicon atom left several unanswered questions. For example, the substitution of one or two hydrogen atoms into silicon tetrachloride has no detectable effect on the length of the Si–Cl bond,[2] but in silicon tetramethyl the replacement of one methyl group by a silicon atom (as in the molecule $(CH_3)_3SiSi(CH_3)_3$[3] apparently shortens the Si–C bonds by one and one-half per cent. An extension of the study of the interaction between atoms attached to silicon was made possible by the availability of samples of methyl silicon trichloride and dimethyl silicon dichloride. Another question of interest in silicon compounds is the interaction of attached fluorine atoms. In the organic fluorides the presence of two or more fluorine atoms on the same carbon shortens the C–F bond by 0.06Å. below the length observed in the monofluorides,[4] while the effect of the CF_3 group in CF_3Cl[5] on the attachment of the chlorine atom is equally marked in comparison with the bond lengths in carbon tetrachloride. This effect in the analogous silicon compound has now been studied. The methyl silicon chlorides were supplied by W. F. Gilliam of the General Electric Research Laboratories, and the trifluoro silicon chloride was supplied by H. S. Booth of Western Reserve University.

Electron diffraction photographs of the vapors were prepared in the usual way using an electron wave length of 0.0592Å. and a camera distance of 10.29 cm. The specimens were handled on a vacuum line and transferred to the camera without admitting air in order to reduce possible hydrolysis by water vapor. For each compound the s_0 values $(4\pi(\sin\theta/2)/\lambda)$ calculated from the visually measured ring diameters are tabulated together with the coefficients used in the radial distribution function, $D(r) = \Sigma C_k \sin s_k r/s_k r$. The radial distribution curves (Fig. 1) indicate by their stronger maxima the values of interatomic distances associated with the more important scattering terms.

Methyl Silicon Trichloride.—Photographs of methyl silicon trichloride taken with the sample held near 25° show nine rings in the range out to $s = 23$. The measurements on the last eight are listed in Table I. The fourth maximum appears as a satellite to the stronger third maximum; its measured position is accordingly unreliable. The sixth maximum is broad with a faint inner shelf which was not measured. The eighth minimum is broad without a well-defined lightest point.

Scattering curves were calculated for four models in each of which the Si–C bond was assumed to lie on an axis of trigonal symmetry, the methyl group was assumed to have the regular tetrahedral bond angles with C–H = 1.09 Å., and the Si–Cl distance was set at 2.00 Å. to fix the scale of the models. In three models the Si–C/Si–Cl ratio was 0.970 with the ∠ClSiCl equal to 113° (model A), to 109½° (model B) and to 106° (model D). In model C the bond distance ratio was 0.935 with a chlorine bond

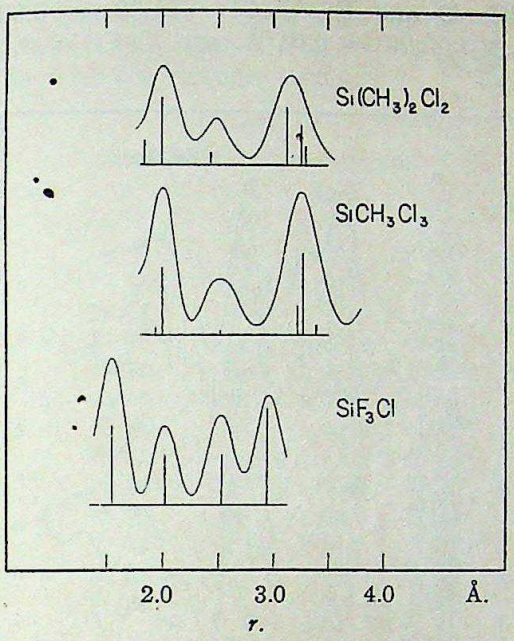

Fig. 1.—Radial distribution curves. The vertical lines show the relative scattering power associated with the interatomic distances in the final models.

angle of $109^1/_2°$. The coefficients of the Si–C and C–Cl terms were so small relative to those for the SiCl and Cl–Cl terms that the change from model B to C is scarcely detectable in the curves (Fig. 2). This means that the scattering power of the carbon atoms is so small in comparison with the silicon and three chlorine atoms that its position cannot be fixed by the diffraction data.

Curves B and C reproduce the characteristic features of the photographs: the weaker fourth ring, the sixth with the inner shelf, and the indefinite eighth minimum observed in the photographs falling on a very weak peak in both of the curves. The $3^1/_2°$ change in bond angle either up or down leads to curves which are somewhat less satisfactory. Curve A (113°) shows the fourth peak too strong, no inner shelf on the sixth and the seventh is followed by an equally prominent ring which does not appear on the photographs, curve D shows faults of the opposite sense at the same positions although its deviations from B are not as marked as those of A. Accordingly, we choose for the Cl–Si–Cl angle the value 109 ± 3°. The comparison of observed and calculated s values (Table I) leads to the value 3.27 ± 0.03 Å. for the Cl–Cl distance and to 2.01 ± 0.02 Å. for the Si–Cl distance. No definite value is given for the Si–C distance since the uncertainty in its direct determination would be greater than 0.1 Å. The values reported here are shown by vertical lines in the radial distribution figure together with a line marking the position of C–Cl if Si–C were 1.9 Å.

	5	9.07	−34	0.994	1.011
5		10.07	25	1.005	1.012
	6	11.22	− 7	1.005	1.009
6		13.66	16	1.007	1.012
	7	14.83	−24	1.005	1.006
7		16.07	8	1.000	1.002
	8	(17.76)	− 7		
8		19.45	7	1.015	1.014
	9	21.00	− 6	0.994	0.995
9		(22.45)	5		
			Average	1.002	1.006
			Average deviation	0.007	0.008
			Cl–Cl, Å.	3.27	3.28
			Si–Cl, Å.	2.00	2.01

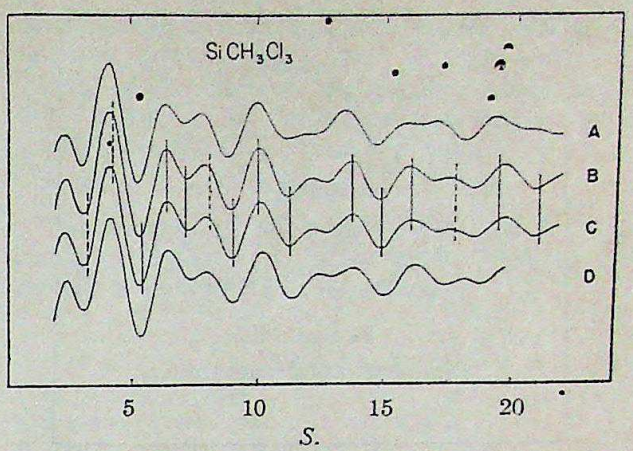

Fig. 2.—Theoretical electron scattering curves for $SiCH_3Cl_3$. The positions of the maxima and minima observed on the photographs are indicated.

Dimethyl Silicon Dichloride.—The dimethyl silicon dichloride was photographed at temperatures from 0 to 40°. Fifteen maxima and minima were measured out to $s = 19.3$ as listed in Table II. The less reliable s_0 values are enclosed in parentheses and shown on the curves (Fig. 3) by dotted lines. The radial distribution curve (Fig. 1) shows strong peaks at 1.98 Å. and 3.16 Å. The first is due to the bonded pairs, Si–Cl and Si–C, while the second is due mainly to C–Cl and Cl–Cl.

Scattering curves were calculated for the seven models in Table III, the Si–Cl distance being fixed at 2.00 Å. and the methyl group with the regular $109^1/_2°$ bond angle and C–H = 1.09 Å. in each. Of the five curves with $109^1/_2°$ angles on the Si atom only D and E show the right qualitative features. The fourth maximum is too strong in B and C and too weak in F; the inner shelf on the sixth is too small in B and C and does not appear at all in F. Model A

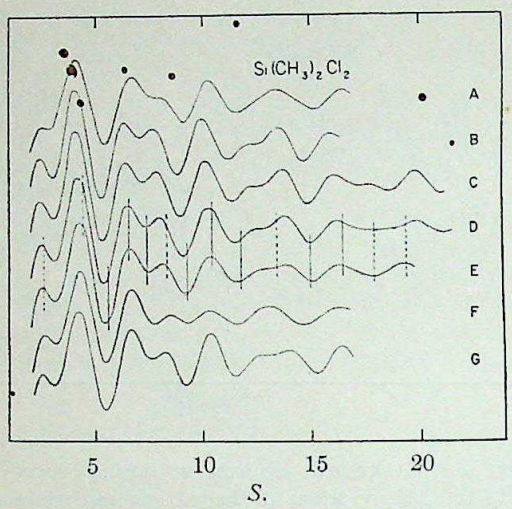

Fig. 3.—Theoretical scattering curves for $Si(CH_3)_2Cl_2$.

with a Cl–Si–Cl angle of 113° is also not good while Model G (∠Cl–Si–Cl = 106°) shows fair qualitative agreement. No systematic variation of the C–Si–C angle was attempted because of the small contributions of the Si–C and C–C terms. The quantitative comparison of observed and calculated s values given in Table II makes model G unsatisfactory because of the large average deviations from the mean value of the s/s_0 ratios. Definite values are reported for the three strongest terms on the basis of models D and E; Si–Cl = 1.99 ± 0.03 Å.; Cl–Cl = 3.25 ± 0.04 Å. and C–Cl = 3.12 ± 0.06 Å.

TABLE III

MODELS FOR $Si(CH_3)_2Cl_2$

	Si–C	∠Cl–Si–Cl	∠C–Si–C
A	1.87Å	113°	105½°
B	2.04	109½	109½
C	1.94	109½	109½
D	1.87	109½	109½
E	1.80	109½	109½
F	1.67	109½	109½
G	1.87	106	112½

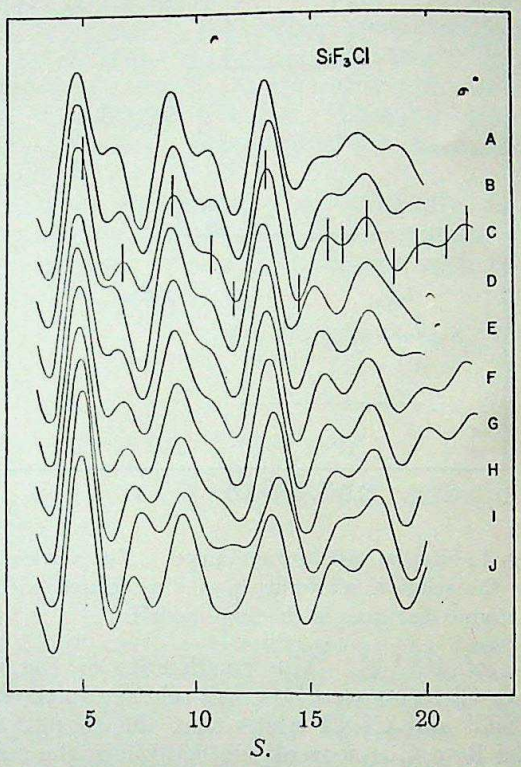

Fig. 4.—Theoretical scattering curves for SiF_3Cl.

The carbon atom positions are somewhat indefinite, although the relative importance of the carbon atom scattering is more favorable than in the trichloride. The carbon–chlorine term is nearly equal to the silicon–chlorine term, and the C–Cl distance reported above is reliable within the range given. The Si–C distance, however, can be calculated only if one of the bond angles involving carbon can be fixed. It may be supposed that since the Cl–Si–Cl angle has the regular tetrahedral value within 2 or 3° the bond angle between the two Si–C bonds will also not differ much from the regular value. With the assumption of 109½° for the angle C–Si–C, the Si–C distance becomes 1.83 Å. with an estimated uncertainty of ±0.06 Å., allowing some for a deviation of the angle from the assumed value.

Trifluoro Silicon Chloride.—Nine distinct rings appear in the photographs of trifluorosilicon chloride taken with the sample at temperatures from −115 to −85°. The distinctive features of the pattern are a faint shelf on the outer edge of the third and a very faint second maximum followed by successively stronger third and fourth peaks. The measured s_0 values are given in Table IV.

The radial distribution curve (Fig. 1) has two strong peaks at 1.55 and 2.95 Å. and two weak ones at 2.02 and 2.53 Å. These may be immediately recognized as associated with the distances Si–F, Cl–F, Si–Cl and F–F in the order

given. The weaker terms are probably less reliable since they lack about 1% of being compatible with the stronger terms.

TABLE V

MODELS FOR TRIFLUOROSILICON CHLORIDE

Model	∠F–Si–Cl	Si–Cl/Si–F
A	112°	1.350
B	112°	1.312
C	110½	1.312
D	109½	1.390
E	109½	1.350
F	109½	1.329
G	109½	1.312
H	109½	1.270
I	109½	1.230
J	106	1.312

Ten models were calculated having a trigonal axis through the Si–Cl bond and the bond angles and bond distances given in Table V. The Si–F distance was set at 1.54 Å. except in models C and F where it was 1.55 Å. None of the curves D to I (109½° models) is entirely satisfactory. In D the weak second maximum is not sufficiently resolved from the first and the shelf on the third is too weak. The other 109½° models in order get better in the first respect but worse in the second while the fifth and sixth peaks merge into one. Of these curves G is the best. A decrease in the F–Si–Cl angle to 106° (J) leads to a worse curve than any of the 109½° models. Three models (A, B and C) with larger angles were tried and of these model C (∠F–Si–Cl = 110½°) is entirely satisfactory. From the way in which changes in the two shape parameters affect the scattering curves it is possible to fix the F–Si–Cl angle at 110½ ± 1° and the Si–Cl/Si–F ratio at 1.31 ± 0.02. The s values for the best model C and for models F and G are compared with the s_0 values in Table IV. The average s/s_0 ratio for model C leads to the following values: Si–F = 1.55 ± 0.02 Å., Cl–F = 2.94 ± 0.03 Å., Si–Cl = 2.03 ± 0.03 Å., F–F = 2.50 ± 0.05 Å. These agree well with the corresponding radial distribution results, the largest discrepancy being a little more than 1% in the F–F term.

Discussion

The results on the three compounds are collected in Table VI together with distances observed in some related compounds.

TABLE VI

OBSERVED BOND DISTANCES

	Si–Cl	Si–C	Si–F
$Si(CH_3)_2Cl_2$	1.99 ± 0.03 Å.	1.83 ± 0.06 Å.	
$Si(CH_3)Cl_3$	2.01 ± 0.02		
SiF_3Cl	2.03 ± 0.03		1.55 ± 0.02 Å.
SiF_4[a]			1.54 ± 0.02
$SiCl_4$[a]	2.02 ± 0.02		
$Si(CH_3)_4$[b]		1.93 ± 0.03	
$Si_2(CH_3)_6$[c]		1.90 ± 0.02	
SiC (carborundum)[d]		1.90 ± 0.005	
Radius sum		1.94	
Radius sum with electronegativity correction[e]		1.88	

[a] L. O. Brockway and F. T. Wall, THIS JOURNAL, **56**, 2373 (1934). [b] L. O. Brockway and H. O. Jenkins, *ibid.*, **58**, 2036 (1936). [c] Ref. 2. [d] Ewald and Hermann, "Strukturbericht," 1931, p. 146. [e] V. Schomaker and D. P. Stevenson, THIS JOURNAL, **63**, 37 (1941).

The silicon–chlorine distances in the new compounds are not much different from the values previously observed. This result is especially interesting in the case of SiF_3Cl where the Si–Cl bond length is the same as in $SiCl_4$. In the corresponding carbon compounds the C–Cl bond length in CF_3Cl is 0.05Å. or 3% shorter than in CCl_4.[5] This effect of the substitution of three fluorine atoms on the attachment of the remaining chlorine is apparently specific to the carbon compound since it does not occur in the silicon compound. The stabilizing effect of CF_3 groups on organic molecules is therefore not to be expected in analogous silicon compounds. The Si–F distance is the same in SiF_3Cl as in SiF_4.

The dimethyl silicon dichloride has the smallest Si–Cl distance yet observed but the uncertainty in the determination (0.03 Å.) is as large as the decrease below the most common value (2.02 Å.). The Si–C bond length, however, is apparently much shorter than in other silicon–carbon compounds. The value reported depends on the assumption of a regular tetrahedral angle between the two Si–C bonds. If this indeterminate angle is 115 or 120°, the bond distance is fixed at 1.87 Å. or 1.90 Å., respectively. Since an angle as large as 120° seems improbable the bond distance is probably less than that in $Si_2(CH_3)_6$ and certainly less than that in $Si(CH_3)_4$. Accordingly it appears that when a methyl group in $Si(CH_3)_4$ is substituted by Cl or $Si(CH_3)_3$ the Si–C bond length decreases; when a second Cl is substituted a further decrease takes place.

It is noted in the table that the covalent

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

radius sum for Si and C is 1.94 Å., or 1.88 Å. if an empirical correction is made for the electronegativity difference; but neither of these values can be correlated with the several Si–C distances observed. If the repulsion between Cl and CH_3 both attached to a silicon atom were less than between two methyl groups, the decrease in the Si–C length when two chlorines are substituted in $Si(CH_3)_4$ could be accounted for. In that case, however, an increase in the Si–Cl distance and a decrease in the Cl–Si–Cl angle would be expected in $Si(CH_3)_2Cl_2$ as compared with $SiCl_4$; this is not observed.

Summary

Electron diffraction measurements have been made on the vapors of dimethyl silicon dichloride, methyl silicon trichloride and trifluoro silicon chloride with the results shown in Table VI.

The observed Si–C distance is shorter than in $Si(CH_3)_4$, while the Si–Cl distances are not much different from the values observed in other silicon chlorides. The SiF_3 group in SiF_3Cl does not bind the chlorine more tightly than in $SiCl_4$ in contrast to the effect observed in CF_3Cl compared with CCl_4.

Hysteresis and the Capillary Theory of Adsorption of Vapors[1]

BY LEONARD H. COHAN

Introduction

The Zsigmondy capillary theory[1a–6] was one of the earliest of the theories[7–13] which have been proposed to explain the adsorption of vapors on solids. It will be the purpose of this paper to reëxamine, in the light of recent experiments, how satisfactory an explanation this theory offers.

The Zsigmondy capillary theory is based on the Kelvin equation

$$P = P_0 e^{-2\sigma V\cos\theta/r_c RT} \qquad (1)$$

which relates r_c, the radius of a capillary, to P, the pressure of a vapor in equilibrium with liquid condensed in the capillary. P_0 is the normal saturation vapor pressure of the liquid at the temperature T; σ and V are, respectively, the surface tension and molal volume of the liquid; and θ is the angle of contact between the surface of the liquid and the walls of the capillary. If the liquid wets the walls of the capillary completely, $\theta = 0°$ and $\cos\theta$ is one and drops out of the equation.

Due to the presence of capillary pores of varying radii, a solid can hold a condensed liquid at vapor pressures below the normal condensation pressure. The distribution of pore sizes in the solid will determine the amount of liquid held at any vapor pressure, *i. e.*, it will determine the adsorption isotherm. Objections to this theory are, first, the difficulty of explaining adsorption results at low relative pressures which in some cases[14] require r_c to be smaller than the diameter of the adsorbed molecule; and, second, the scarcity of quantitative predictions which could be tested experimentally.

Some investigators have reasoned that the first objection is not critical because σ and V of equation (1) might be much larger for liquids in small capillaries than for the same liquids in bulk. If this were the case P/P_0 might reach very low values even in capillaries where r_c is much larger than molecular dimensions. Shereshefsky[15] determined the rate of evaporation from capillaries only 2 μ in radius. From the rate of evaporation, $\Delta P = P - P_0$ was calculated and found to be about eight times that predicted by equation (1). On this basis, there would be but little difficulty in ascribing adsorption at low relative pressures to condensation in capillaries. However, the usefulness of equation (1) as an aid in determining the structure of sorbents would largely disappear since σ and V would have to be known as a function of r_c before pore radius distribution could be calculated from adsorption isotherms.

More recently, Cohan and Meyer[16] determined σ and V in capillaries 2 μ in radius and found no deviation from normal values for the liquids used by Shereshefsky. In view of these results, Shereshefsky's experiments cannot be considered a serious limitation to the usefulness of equation

(1) in the study of sorbent structure; neither, on the other hand, can they help to eliminate our first objection to the Zsigmondy capillary theory. One must conclude that the capillary theory can only be applied to vapor adsorption provided we consider that an adsorbed layer is formed on the surface of the sorbent before capillary condensation begins.

Evidence will be presented in this paper to show that a great many experimental results can be explained if we assume that the mechanism of adsorption on a porous solid consists in the formation of a monomolecular layer followed by capillary condensation. In the following, this mechanism will be referred to simply as the capillary theory. While such a model is too simple to be more than a first approximation, a considerable amount of experimental data can be correlated. It will also be shown in a subsequent paper that fairly accurate surface area values can be determined on the basis of this hypothesis.

The above mechanism is free from the first objection to the Zsigmondy capillary theory at least in so far as the necessity for considering pores smaller than molecular dimensions is concerned. There may still be some difficulty in visualizing the application of the concepts on which equation (1) is based, such as surface tension and angle of wetting to capillaries of a few molecular diameters in radius. Nevertheless, the results reported in this paper indicate that a relation of the same form as equation (1) in which σ and V are approximately equal to the normal surface tension and molar volume and $\cos \Theta = 1$, appears to hold for capillaries whose radius is only twice the diameter of the sorbate molecule.

Turning now to the second objection, the only prediction that has been made on the basis of the Zsigmondy capillary theory is that at relative pressures equivalent to equal values of r_c as calculated from equation (1), the volume of liquid adsorbed should be constant for all sorbates and should be independent of the temperature. In some systems, this has been found to be the case, but discrepancies have occurred.[5,6,14,19] In fact, considering the capillary theory mechanism given above, the volumes need be strictly constant only if monomolecular adsorption is negligible compared to capillary condensation. Other predictions are, however, possible on the basis of the capillary theory. As will be shown below, these predictions are in good agreement with experimental data.

In the light of the foregoing discussion, reconsideration of the capillary theory certainly appears in order. This is all the more true since the capillary theory is the only adsorption theory which at present can offer an explanation for sorption hysteresis in rigid gels. The importance of such an explanation has been greatly increased by recent work[17,18] which demonstrate that hysteresis is a reproducible phenomenon and is not, as thought by previous workers,[13,20,21] merely due to the presence of gases in the apparatus or to failure to obtain true equilibrium.

Theories of Hysteresis

Three explanations, all based on the capillary theory of adsorption, have been advanced to explain hysteresis in rigid sorbents.[22]

1 **Incomplete Wetting Theory.**[2,6]—Hysteresis is due to θ of equation (1) being greater during adsorption than during desorption probably due to the presence of permanent gases. In favor of this theory is the fact that in some systems[23-26] it has been found possible to eliminate hysteresis by the painstaking removal of permanent gases. However, the sharply reproducible results of Rao and Higuti can hardly be explained in this way.[27]

2. **Bottle Neck Theory.**[28,29]—For a pore having a narrow neck of radius, r_n, and a wider body of radius, r_b, adsorption occurs in accordance with equation (1) with $r_c = r_b$. Once the pore is filled, provided no break in the liquid column occurs, desorption cannot take place until the pressure falls to the value corresponding to equation (1) with $r_c = r_n$ and, therefore, hysteresis occurs.

(21) A. S. Coolidge, THIS JOURNAL, **46**, 596–627 (1924), p. 600; also ref. 6, p. 961–977.

(22) The theories of W. W. Barkas, *Trans. Faraday Soc.*, **38**, 194–209 (1942); R. S. Bradley, *J. Chem. Soc.*, 1798–1804 (1936), p. 1801; A. R. Urquhart, *J. Textile Inst.*, **20**, 125–32T (1929); A. E. Benton and T. S. White, *ibid.*, **53**, 2807–2808 and 3301–3314 (1931); G. H. Piper, *Trans. Faraday Soc.*, **29**, 538–543 (1933); C. O. Seborg and A. J. Stamm, *Ind. Eng. Chem.*, **23**, 1271–1275 (1931); and M. Gordon, I. Lavine and L. C. Harrington, *ibid.*, **24**, 928–932 (1932), would apply only to non-rigid systems. The theory of B. Von Il'in, *Z. physik. Chem.*, **A155**, 403–416 (1931), is a mathematical statement of the observed facts for a given isotherm and not a mechanism on the basis of which general predictions can be made. The hypothesis of H. Engelhard and W. Stiller, *Z. Elektrochem.*, **40**, 833–836 (1934), does not apply to a system which has reached equilibrium. The explanation proposed by A. G. Foster, *Proc. Roy. Soc. Edinburgh*, **A146**, 129–140 (1934), and also by A. R. Urquhart and A. M. Williams, *J. Textile Inst.*, **15**, 433–42T (1924), p. 440, is a qualitative statement similar to the quantitative deductions of the third theory discussed in the text.

(23) S. J. Gregg, *J. Chem. Soc.*, 1494–1512 (1927).

(24) W. A. Patrick and J. McGavack, ref. 6, p. 961–967.

(25) R. Fricke and H. Marquhardt, *Kolloid-Z.*, **60**, 124–129 (1932).

(26) H. A. Hamm and W. A. Patrick, *Textile Research*, **6**, 401–409 (1936).

(27) The bulk of the evidence in the literature indicates that in systems containing permanent gases hysteresis extends over the entire isotherm while hysteresis observed in the absence of permanent gases extends only over a limited portion of the isotherm. Thus there appears to be at least two phenomena involved; namely, unlimited hysteresis which can be in part explained by this theory and limited hysteresis which cannot. It is only the latter type (see Fig. 3) in which we are interested in this paper.

3. Open Pore Theory.—In the case of a pore open at both ends, liquid cannot condense at the equilibrium vapor pressure given by equation (1) because a meniscus cannot form. As previously shown,[30] the pressure, P_a, at which the meniscus forms depends on the radius of curvature, r, of the cylindrical film on the wall of the capillary, that is

$$P_a = P_0 e^{-\sigma V/rRT} = P_0 e^{-\sigma V/(r_c - D)RT} \qquad (2)$$

where r_c is the radius of the pore and D the thickness of the adsorbed film which according to the capillary theory would be monomolecular; *i. e.*, D would be the height of a sorbate molecule in a direction perpendicular to the surface.[31]

Once condensation has occurred a meniscus is present and the pressure, P_d, at which evaporation occurs is given by equation (1).[32] Assuming that wetting is complete, $\cos\theta = 1$ and

$$P_d = P_0 e^{-2\sigma V/r_c RT} \qquad (3)$$

Some objection has been offered to the open pore theory because the theory as originally stated applied only to pores open at both ends, a type of structure which would not be expected to occur very commonly.[33] In this connection it is important to point out that the above considerations also apply to closed capillaries possessing constrictions. Such constrictions could be of the hour-glass type or merely the upper portion of a cavity. For example, in the cavity depicted in Fig. 1 a meniscus cannot form in the upper portion of the cavity until the lower of the two pressures $P_{a_1} = P_0 e^{-2\sigma V/r_v RT}$ or $P_{a_2} = P_0 e^{-\sigma V/(r_s - D)RT}$ is reached. P_{a_1} corresponds of course to the pressure at which the meniscus finally reaches the widest part of the cavity at r_v and P_{a_2} corresponds to the pressure in equilibrium with the cylindrical film at the smallest radius, r_s, of the upper half of the cavity. Thus P_a equals the lower of P_{a_1} or P_{a_2} and P_d is given by equation (3). For P_{a_1} equal to or less than P_{a_2} hysteresis will only occur in accordance with the bottle neck theory. However, for P_{a_2} less than P_{a_1} hysteresis will occur in accordance with the open pore theory.

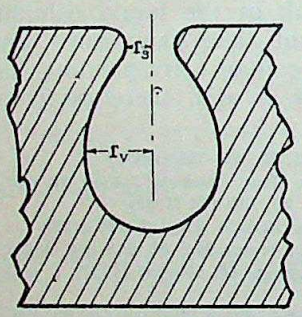

Fig. 1.

Based on the open pore theory, and, hence, on the capillary theory, two important predictions can be made. The first concerns the point on the isotherm at which hysteresis begins, and the second, the relation between adsorption and desorption pressures obtained on scanning the hysteresis loop.

Point of Hysteresis Inception

Considering equations (2) and (3), it is seen that for $r_c > 2D$, P_a is greater than P_d and hysteresis results but that for $r_c = 2D$

$$P_a = P_d = P_0 e^{-\sigma V/(r_c - D)RT} \qquad (4)$$

and no hysteresis occurs.[34] Thus if sufficiently small open or constricted capillaries are present the pressure, P_h, at which hysteresis begins should correspond to the equilibrium pressure for $r_c = 2D$. From equation (4)

$$P_h = P_0 e^{-\sigma V/DRT} \qquad (5)$$

or

$$D = \frac{-\sigma M}{dRT \ln P_h/P_0} \qquad (6)$$

where M is the molecular weight of the sorbate and d the density.

In Table I the values of D calculated by means of equation (6) from experimentally determined values for P_h are compared with D_{cubic} calculated for the sorbate in question from the expression $(M/Nd)^{1/3}$ and $D_{\text{spherical}}$ calculated from the molecular weight and density of the sorbate assuming spherical molecules and hexagonal close packing in the normal liquid. Except where otherwise indicated, room temperature was used. All available experimental evidence applying to hysteresis of the limited type in rigid sorbents has been included. However, it is felt that the greatest weight should be attached to the results of Higuti as in this series of experiments the point of hysteresis inception was specifically investigated for a great many sorbates on the same sorbent.

The author's value for P_h for water on silica gel was obtained at 28 ± 0.2°. The isotherm

(30) L. H. Cohan, *ibid.*, **60**, 433–435 (1938).

(31) In reference 30, it was assumed that D was negligible compared to r_c and therefore $r_c = r$. For the purposes of the present work, this assumption is not justified.

(32) Since an adsorbed layer of thickness D forms prior to capillary condensation and is more stable than the condensed liquid there is some argument for assuming that the curvature of the meniscus is independent of this adsorbed layer and therefore $r_c - D$ should be substituted for r_c in equation (1). If this assumption is made hysteresis would occur whenever capillary condensation in open pores occurs and the limited nature of hysteresis would then have to be explained by the fact that surface adsorption or capillary adsorption in wedge shaped pores is entirely responsible for adsorption below the hysteresis region. This in itself is perfectly plausible; however, the equation that would arise in place of equation (7) below is not in as good agreement with experimental results. Furthermore, as will be shown in a later paper, surface area values determined on the basis of this theory would not be in as good agreement with other methods. For these reasons, we will assume for the present that the curvature of the meniscus is not independent of the adsorbed layer and that equation (1) applies.

(33) P. H. Emmett and Thomas W. DeWitt, THIS JOURNAL, **64**, 1253–1262 (1942).

(34) If $r_c < 2D$ adsorption and desorption occur at the same pressure regardless of whether the sorbate is held by surface adsorption or capillary condensation. If capillary condensation is assumed to take place in pores of this size adsorption would occur at P_a' given by equation (4). Likewise desorption must also occur at this same pressure since a comparison of equation (3) with equation (4) shows that the pressure calculated by means of equation (3) is actually higher than P_a. That is, the vapor pressure of the cylindrical film is less than for the spherical meniscus and equation (3) cannot apply to capillary condensation in this case.

for this system appears in Fig. 2. The reversible hysteresis region is bounded by the desorption and resorption curves (heavy lines).[35] Although insufficient points were taken in the region of hysteresis inception, the true inception point cannot be far from that indicated in the figure.

TABLE I

Sorbent	Sorbate	D cubic, Å.	D spherical, Å.	D, Å., calcd. from Eq. 6	Investigator

In judging the agreement obtained in Table I between D calculated from equation (6) and D_{cubic} or $D_{spherical}$ calculated from the density of the liquid sorbate the following points must be considered:

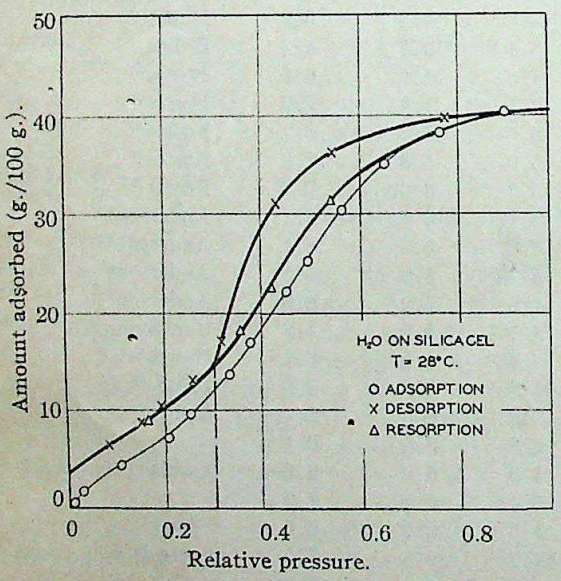

Fig. 2.

1. In order to apply the open pore theory to the determination of the point of hysteresis inception, open (or constricted) pores of radius just larger than 2D must be present in the sorbent. If pores in this region are absent, hysteresis cannot begin until pressures are reached corresponding to the open pores which are present. In such a case, the value of $D(= r_c/2)$ calculated from equation (6) would be larger than either D_{cubic} or $D_{spherical}$ and would be a measure not of the thickness of the adsorbed layer but of the radius, r_c, of the smallest open pores present. This may be the case for some of the Fe_2O_3 gels and particularly for Lambert and Foster's[40] Fe_2O_3 gel B which was prepared by heating gel A several hours at 148° in the presence of water vapor. On the other hand, the behavior of Higuti's TiO_2 gel with many different sorbates indicates that for this sorbent sufficiently small pores are present.

2. The capillary theory according to which adsorption consists of monolayer formation followed by capillary condensation is, as stated in the introduction, only a first approximation. Depending on the conditions—specific nature of the sorbent and sorbate, temperature, etc.—more or less than a monolayer could conceivably form prior to capillary condensation. For example, suppose that conditions are such that the multilayer adsorption mechanism yields a value P_3 for the equilibrium pressure for the essential completion of the third adsorbed molecular layer. Now if P_3 is less than P_d calculated from equation (3) with $r_c = 3D$ then generally speaking condensation will occur at P_3 instead of P_a, evaporation will also occur at P_3 instead of P_d and no hysteresis will be present at this pressure. In such cases, if one should try to calculate P_h from equation (5) the result would be lower than the observed value for P_h. Conversely if the observed value for P_h were used in equation (6) to calculate D, a higher value than the molecular diameter would be obtained. This is another possible explanation of the behavior of some of the Fe_2O_3 gels.

3. Equation (6) assumes that wetting is complete ($\theta = 0$) and that true equilibrium is attained. Any impurity, such as permanent gases in the apparatus, which would prevent the realization of these conditions would exclude the system as a suitable one for testing the theory. For this reason, isotherms determined in the presence of permanent gases are not included in Table I. As pointed out previously, such isotherms usually show an unlimited hysteresis which is not completely reversible. The low results for charcoal may be due to the presence of gases which could not be removed by ordinary evacuation.

4. For sorbents which cannot be considered

rigid, both the surface area and pore volume are different on adsorption than on desorption and hysteresis cannot be explained on the open pore theory alone. Hysteresis in such a system is likely to be unlimited and will be further complicated by drift if the swelling is not entirely reversible. Because of these difficulties systems which swell markedly such as wood and cotton cellulose have not been included.

5. Finally, exact agreement between D and D_{cubic} or $D_{\text{spherical}}$ should not be expected for unsymmetrical molecules. For molecules oriented perpendicularly to the surface, D should be greater than D_{cubic} or $D_{\text{spherical}}$. Examination of the table shows that molecules such as CH_3OH which might be expected to orient perpendicular to an oxide surface do have higher values for D than indicated by D_{cubic} or $D_{\text{spherical}}$.[47]

Examination of Table I reveals that except for the few cases pointed out in the preceding discussion, equation (6) is in good agreement with the experimental results and in particularly good agreement with Higuti's series of measurements on TiO_2 gel.

Additional support for equation (6) is found in the effect of temperature on the point of hysteresis inception. As long as temperature changes are not so great that the way in which the molecule is attached to the surface is altered, D should not vary with the temperature to a greater extent than does the density. Higuti has determined P_h for most of the systems reported in Table II from 0 to 30°. Although P_h/P_0 varies in this range by 25% or more for some of the sorbates, D, in most cases, varies by less than 5%, which may be considered within experimental error.

Scanning the Hysteresis Loop

"Scanning" the hysteresis loop is the name given by Rao[17] to the experimental process in which desorption is begun from an adsorption equilibrium point below saturation such as point (1), Fig. 3. The system follows the path labeled "b" in Fig. 3 and meets the desorption branch of the isotherm at some point (2) above the point of hysteresis inception.[48]

Considering a sorbent system consisting of a continuous range of open cylindrical pores and also a range of conical pores, the equilibrium pressure, P_a/P_0, at the point (1) will correspond to a capillary radius, r_c given by equation (2).

(47) It is worth noting that higher alcohols such as C_2H_5OH and C_3H_7OH have values for D closer to D spherical than does CH_3OH. Possibly chain bending may result in the former molecules occupying a less unsymmetrical volume element. It so happens as will be shown in another paper that the values for the area of Higuti's TiO_2 gel calculated from the data for the 18 different sorbates in Table I are remarkably consistent if one uses the asymmetry factor indicated by the value of D for the different sorbates. Consistency is not nearly so good if the sorbates are assumed symmetrical.

(48) On adsorbing from a desorption equilibrium point, a similar scanning curve, "a" in Fig. 3, is obtained. Rao found that for the sorbents he used scanning curves of this type did not rejoin the adsorption curve until saturation was reached.

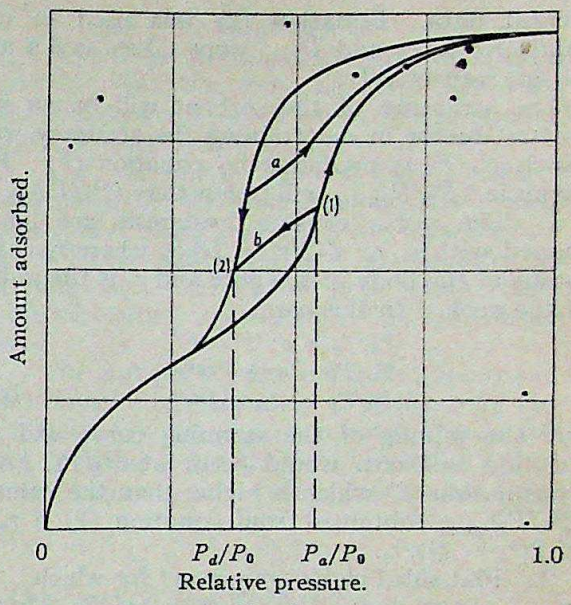

Fig. 3.

In this case, r_c is the radius of the largest open capillary to have filled at point (1). As the pressure is reduced, desorption occurs at once from the conical pores but not from the open pore of radius r_c until the pressure, P_d/P_0, given by equation (3) is reached.[49] At this point, the system will be in the same condition in which it would have been had desorption occurred from saturation. In other words, P_d/P_0 is the pressure at point (2) where curve "b" meets the desorption branch of the isotherm. From equations (2) and (3) the relation between P_d/P_0 and P_a/P_0 is[50]

$$P_d/P_0 = (P_a/P_0)^{2(r_c-D)r_c} \qquad (7)$$

In Table II values for P_d/P_0 calculated from equation (7) are compared with available experi-

TABLE II

Sorbent	Sorbate	$(P_a/P_0)_{exp.}$	$(P_d/P_0)_{exp.}$	$(P_d/P_0)_{calcd.}$	Investigator

Fe_2O_3 gel	CCl_4	.57	.43	.43	Rao[17]
Fe_2O_3 gel	CCl_4	.49	.40	.37	Rao[17]
SiO_2 gel	H_2O	.55	.42	.44	Van Bemmeln[38]
SiO_2 gel	H_2O	.53	.39	.43	Van Bemmeln[38]

(49) Sorbate held reversibly in mono or polylayers would also begin to desorb as soon as the pressure is reduced. For an adsorption equation including both polylayer adsorption and capillary condensation see A. A. Schuchowitzki, *Kolloid-Z.*, 66, 139–147 (1934). A small amount of sorbate would also be lost from open capillaries due to a change in curvature of the meniscus.

(50) In a previous paper[30] the relation $P_a^2 = P_0P_d$ was given for D negligible compared to r_c. In this case equation (7) reduces to the simple form.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

mental data. Equation (2) was used to calculate r_c; D_{H_2O} and D_{CCl_4} were taken as 4.4 and 6.3 Å., respectively.

The structure of the sorbent will be an important factor in determining the accuracy with which P_d/P_0 is predicted by equation (7). For example, $(P_d/P_0)_{calcd.}$ will be less than $(P_d/P_0)_{exp.}$ if:

1. The pores causing hysteresis are bottle shaped with $r_b/r_n < 2(r_c - D)/r_c$ where r_b is the radius of the body of the pore and r_n is the radius of the neck. In this case

$$P_n/P_0 = e^{-2\sigma V/r_b RT}$$
$$P_d/P_0 = e^{-2\sigma V/r_n RT}$$
$$P_d/P_0 = (P_n/P_0)^{r_b/r_n} \quad (8)$$

and the joining of the scanning curve and desorption isotherm would occur at P_d/P_0, given by equation (8) which is higher than the value—$(P_d/P_0)_{calcd.}$—obtained from equation (7) if $r_b/r_n < 2(r_c - D)/r_c$.

2. Flat sided clefts are present for which

$$W < r_v < 2(W - D) \text{ or approximately } W < r_v < 2W \quad (9)$$

where W is the distance between walls in the flat sided cleft and r_v is the largest radius in the cavity below the cleft, the cavity being assumed to have a circular cross section. For the flat sided cleft portion of the pore shown in Fig. 4

$$P_n/P_0 = e^{-2\sigma V/r_v RT} \quad (10)$$
$$P_d/P_0 = e^{-\sigma V/(W/2)RT} \quad (11)$$

whence

$$P_d/P_0 = (P_n/P_0)^{r_v/W} \quad (12)$$

Thus P_d/P_0 will be greater than $(P_d/P_0)_{calcd.}$ obtained from equation (7) when $r_v/W < 2(r_c - D)/r_c$. Comparing equations (2) and (10) an open cylindrical pore which will have the same P_n/P_0 as the cleft of Fig. 4 must have $r_c - D = r_v/2$. Substituting for r_c in terms of r_v the cleft will have a higher P_d/P_0 than $(P_d/P_0)_{calcd.}$ when

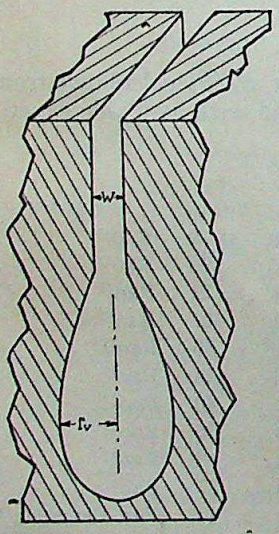

Fig. 4.

$$r_v/W < r_v/(r_v/2 + D) \quad (13)$$

or

$$r_v < 2(W - D) \quad (14)$$

from which equation (9) follows since for $r_v \gtrless W$ the cleft does not contribute to hysteresis.

In the above instances almost all the pores present must be of type (1) or (2) since even a small fraction of open cylindrical pores would prevent the scanning curve from actually joining the desorption branch until $(P_d/P_0)_{calcd.}$ is reached. A glance at Table II shows that in the few cases in which $(P_d/P_0)_{calcd.}$ differs from $(P_d/P_0)_{exp.}$ by more than experimental error, $(P_d/P_0)_{calcd.}$ is greater, not less than $(P_d/P_0)_{exp.}$[51]

On the other hand $(P_d/P_0)_{calcd.}$ will be greater than $(P_d/P_0)_{exp.}$ if:

3. Bottle shaped pores having $r_b/r_n > 2(r_c - D)/r_c$ are present.

4. Clefts are present for which

$$r_v > 2(W - D) \text{ or approximately } r_v > 2W \quad (15)$$

where W and r_v have their previous meaning. Equation (15) can be derived in the same manner as equation (9) by replacing the less than signs by greater than signs.

For pores of type (3) and (4), P_d/P_0 as given by equations (8) and (12), respectively, is lower than $(P_d/P_0)_{calcd.}$ from equation (7). Thus the scanning curve will join the desorption branch below the point corresponding to $(P_d/P_0)_{calcd.}$. Moreover the presence of only a small fraction of either of these pore types even in a system of predominantly open or constricted pores will prevent joining at $(P_d/P_0)_{calcd.}$ thus causing $(P_d/P_0)_{exp.}$ to be less than $(P_d/P_0)_{calcd.}$.[52]

In assuming that bottle shaped pores of type (1) and (3) above affect the scanning curves it is assumed that the bottle neck theory of hysteresis is valid, *i. e.*, that during desorption the liquid column in a bottle shaped pore remains intact and equilibrium is not reached. This may be open to argument; however, the effect of clefts on the scanning curve is, of course, quite independent of the validity of the bottle neck theory.

The results in Table II provide a fairly good check on equation (7). The tendency for $(P_d/P_0)_{calcd.}$ to be larger than the experimental value for Rao's SiO_2 gel may indicate presence of some clefts of type (4) even down to fairly small pore sizes. Additional data with other systems would be desirable. The preceding discussion also indicates how scanning curves may be used to throw light on the structure of the pores of a sorbent.

The evidence presented in support of equations (6) and (7) implies that: (1) The capillary theory is a satisfactory first approximation for most of the systems considered. (2) Both σ and V are about the same in capillaries as fine

(51) The experimental values in Table II had to be taken from published curves as tables of data were not available. The accuracy of determining P_n and P_d is probably not much better than several per cent. of the saturation pressure.

(52) Clefts for which $r_v >> W/2$ are not likely to affect type "b" curves (Fig. 3) because r_v is so large that adsorption cannot occur until close to saturation. However, such structures would markedly influence type "a" curves (Fig. 3) since they would remain filled until fairly low pressures and would prevent the coincidence of the "a" curves with the adsorption branch until close to saturation. The behavior of Rao's type "a" curves can be explained in this way. A. J. Allmand, P. G. T. Hand and J. E. Manning, *J. Phys. Chem.*, **33**, 1694–1712 (1929), pp. 1706–1708, report type "a" scanning curves for charcoal which rejoin the adsorption isotherm at pressures below the upper end of the hysteresis loop. Unfortunately, no data are given from which calculations can be made. It appears plausible that clefts and large cavities are more likely to be present in oxide gels such as used by Rao than in charcoal.

as $r_c = 2D$ as they are in bulk. (3) The open pore theory appears to be in most cases a satisfactory explanation of hysteresis. However, departure of experimental values from predicted values in a few instances indicates that the presence of other factors must also be considered.

The author wishes to thank J. F. Mackey and M. Steinberg of the Continental Carbon Company staff for their assistance in the preparation of the tables and figures. The helpful criticisms of P. H. Emmett, Johns Hopkins University; S. Brunauer, U. S. Dept. of Agriculture (at present U. S. Navy); C. R. Johnson, Ridbo Corp.; and T. Brownyard, Portland Cement Association (at present U. S. Navy); who were kind enough to review a preliminary draft of this paper, are gratefully acknowledged.

Summary

1. Several predictions based on the capillary theory of adsorption and the open pore theory of hysteresis have been shown to agree reasonably well with experimental data.

2. The agreement between theory and experiments indicates that the capillary theory of adsorption which postulates the formation of a monomolecular layer followed by capillary condensation is a fairly good first approximation for the adsorption mechanism in the systems considered.

3. The surface tension and molal volume of a liquid confined in a capillary of radius only twice the diameter of the liquid molecule appear to be about the same as for the liquid in bulk.

Molecular Surface Energy of Sulfur Dioxide Addition Compounds. III[1]

BY JOSEPH J. JASPER AND J. RUSSELL BRIGHT[2]

The effect of temperature on the molecular surface energy of several liquid addition compounds of tertiary aliphatic amines with sulfur dioxide has been described in earlier articles.[3]

A more complete interpretation of the temperature effects described necessarily involves the extension of this series of studies to tertiary amine–sulfur dioxide addition compounds of still greater molecular weight. The purpose of this investigation, therefore, was to determine, for comparison with those preceding, the same physico-chemical constants for the respective equi-molecular mixtures of tripropylamine and tributylamine with sulfur dioxide.

Preparation of the Liquid Molecular Addition Compounds

The methods for purifying the materials were similar to those previously described.[3] Pure anhydrous sulfur dioxide was bubbled slowly through a known quantity of the best grade of Eastman Kodak Company tripropylamine ($n^{25}D$ 1.4151) until equi-molar quantities of the reactants were present. Since considerable heat was evolved during the reaction, the temperature was maintained at about 18° to prevent decomposition of the product. Upon further cooling, the product crystallized into light yellow needles, which melted at 15.3°. Distillation, even under reduced pressure, was impossible. The freshly prepared addition compound ($n^{25}D$ 1.4740) was analyzed for nitrogen by a modified Kjeldahl method; calculated for $(C_3H_7)_3N:SO_2$, N, 6.76. Found: N, 6.35, 6.46.

This compound is stable for an indefinite period as a light yellow solid at ice-box temperatures. It is very hygroscopic, changing to a red-brown liquid upon exposure to moist air. At temperatures above 45°, it changed to a black liquid whose density and surface tension deviated considerably from the linear relations given in a following paragraph.

Cryoscopic determination of the molecular weight, using purified benzene (f. p. 5.4°) as the solvent, gave 207.7, 208.4, 207.6 in 0.0327 weight molal solutions; theoretical 207.27. Increasing concentrations gave the molecular weights; 0.163 M, 2115.5; 0.327 M, 318.3; 0.411 M, 322.5. Similar association was observed by Bright and Fernelius[4] with the addition compound dimethylaniline–sulfur dioxide in the solvent dimethylaniline. Since the addition products are very hygroscopic, special precautions were used in their transfer to the various apparatus employed. Density and surface tension measurements were made, using the same apparatus and technique previously described.[3b] The viscosimeter used was constructed according to the design and specifications of Jones and Fornwalt.[5]

Experimental data are presented in Tables I and II. From these it is evident that the density d and surface tension γ are linear functions of the temperature for the compound tripropylamine-sulfur dioxide over the range 18 to 45°. These relations are given by the following equations

$$d = 1.0174 - 1.069 \times 10^{-3}t$$
$$\gamma = 32.72 - 0.125t$$

The average deviation of the data from the d-curve and γ-curve is, respectively, 0.02 and 0.08%. The Eötvös constant is −3.77 and, therefore, is less than the average value of −2.12, which is commonly assigned to non-polar liquids. This would seem to indicate considerable association, according to the criteria of Walden and Swinne.[6]

An observed value of 488.7 for the parachor of the $(C_3H_7)_3N:SO_2$ compound is in good agreement with the value of 503 obtained from the sum of

25.0	11.78
30.0	9.50
38.0	6.57
44.0	4.98

(7) Sugden, "The Parachor and Valency," Alfred A. Knopf, New York, N. Y., 1930, p. 38.

Similarly, an equi-molar mixture was prepared from tributylamine and sulfur dioxide. The liquid was orange in color; a slight excess of sulfur dioxide changed it to deep red, while a correspondingly small additional quantity of tributylamine restored the orange color. The product was very viscous. It was found impossible to distil this equi-molar mixture, even at very low pressures, and attempts to crystallize it resulted in the formation of a glass. Efforts to crystallize it from benzene solution were likewise unsuccessful.

The following linear relationships exist for the temperature range 0 to 40° for the equi-molecular mixture of tributylamine and sulfur dioxide, *viz.*

$$d = 0.9915 - 9.562 \times 10^{-4}t$$
$$\gamma = 33.25 - 0.1317t$$

Average deviations from the data of the d-curve and γ-curve are, respectively, 0.03 and 0.11%. The Eötvös constant −4.24 is less than any of the preceding lower molecular weight addition compounds studied. The observed parachor, 602.8, agrees satisfactorily with the theoretical 620.

35	.95803	....
40	.95308	28.032

Summary

The effect of temperature on the molecular surface energy of the addition compounds, $(C_3H_7)_3N:SO_2$, and the equi-molar mixture of $(C_4H_9)_3N$ and SO_2 has been determined. Data are presented for the density, surface tension and viscosity over the temperature range of 17 to 45° for the former and 0 to 40° for the latter.

The Eötvös constants were calculated and found to be less than any of the lower molecular weight addition compounds studied. Thus, the temperature coefficient of the molecular surface energy seems to decrease with increasing molecular weights of the addition compounds, and the tendency to associate increases.

Parachor data furnish additional evidence for the existence of a nitrogen to oxygen to sulfur (N–O–S) linkage in this type of compound.

The Conductance of Some Salts in Ethylenediamine[1]

BY WILLIAM H. BROMLEY, JR.,[2] AND W. F. LUDER

I. Introduction

In considering various solvents for use in an investigation of the ionization of metallic salts as acids according to the Lewis theory of acids and bases,[3,4] ethylenediamine seemed to offer interesting possibilities. However, due to the present emergency the work had to be abandoned after securing conductance measurements on three salts: silver nitrate, silver iodide and potassium iodide. The data obtained are presented herewith.

Ethylenediamine is a stronger base than ammonia, having a dissociation constant of 8.5×10^{-5} in water.[5] One would expect then that acidic metallic salts would be soluble in it. However, its high basicity makes it extremely difficult to work with because of its rapid absorption of carbon dioxide and water.

Some conductivity measurements have been made in ethylenediamine,[6] but at concentrations much too high to permit evaluation of Λ_0 or K. Apparently none of these have been made below 0.2 molar; our measurements go down to 1×10^{-4} molar or below.

Because of the reactivity of the ethylenediamine the solvent conductance becomes an appreciable factor in the conductance of solutions at such low concentrations. This introduces considerable uncertainty in the extrapolated values of Λ_0, as compared with the very precise results which may be obtained with such relatively inert solvents as ethylene chloride.[7] In such solvents it is possible to reduce the solvent conductance to a value entirely negligible in comparison with the conductance of the lowest concentration of solution measured. This is impractical in ethylenediamine. The best previously reported solvent conductance[6] is 1.4×10^{-6} mho. With the most drastic drying methods carried out in the absence of air in an all-glass sytem, we were only able to reduce this value to 9×10^{-8} mho.

This is not surprising since from the structure of ethylenediamine one would expect a rather high conductivity even if carbon dioxide and water could be completely removed. But such a value of solvent conductance means that its value may be as much as 5% of the total conductance of a solution at 1×10^{-4} molar. Since there is considerable uncertainty as to how the solvent correction should be made this will affect the reliability of Λ_0 values. In our data the solvent conductance was subtracted from the conductance of the solution at each concentration.

II. Apparatus, Materials and Method

The bridge[8,9] and procedure of conductance runs[7] have been described previously. The temperature of the oil thermostat was held at $25 \pm 0.01°$ by an electronic relay.

Salts.—C. P. potassium iodide was recrystallized from conductivity water. C. P. silver nitrate was dissolved in hot conductivity water and recrystallized by slowly adding freshly distilled ethyl alcohol. Silver iodide was prepared by mixing equivalent silver nitrate and potassium iodide solutions and washing the precipitate repeatedly with conductivity water. No further precautions were considered necessary because of the high solvent conductance.

Solvent.—95% ethylenediamine was stored over sodium hydroxide and barium oxide for several days, kept over sodium for a day, then fractionated off freshly activated alumina into a receiver containing alumina and sodium hydroxide. This receiver was provided with a ground glass cap carrying a tube through which the solvent could be discharged by dry nitrogen pressure. The solvent was kept from contact with moisture and carbon dioxide by a slow stream of dry nitrogen coming through a side arm and out the top of the receiver. About three-fourths of the ethylenediamine came over at constant temperature. This portion was used for runs.

The solvent thus obtained was placed in an all-glass system consisting of two stills, a solvent conductance cell, and a closed receiver. Each still was fitted with a fractionating column. The only opening to the atmosphere during the distillation was through a drying train consisting of phosphorus pentoxide, soda lime, and calcium chloride tubes and a concentrated sulfuric acid trap. This train was also used to dry nitrogen flowing through the system and out the filling tube of the first still while it was being loaded with solvent. The two successive distillations were carried out over alumina in an atmosphere of moisture and carbon dioxide-free nitrogen. The conductance was read from a sealed-in cell as the solvent was collected in the receiver from the second still. The best value was 9×10^{-8} mho. Solvent was forced into the cell[7] used in runs by nitrogen pressure while a slow stream of nitrogen emerged from the top of its long neck to prevent the entrance of air. The same procedure was followed when making dilutions. Solvent constants used were: d_{25} 0.891,[6] n_{25} 0.0154,[10] and D_{25} 12.9.[11]

III. Results

The experimental results are given in Tables I–III and are shown graphically in Fig. 1. It was hoped that potassium nitrate could also be measured to enable comparison of Λ_0 values, but it proved to be too insoluble. Λ_0 and K were calculated according to the method of

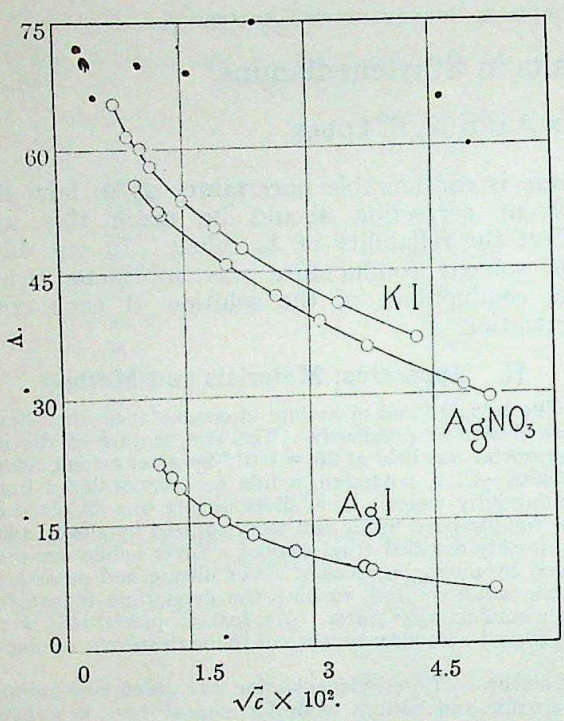

Fig. 1.

Fuoss.[12] The resulting extrapolations are shown in Fig. 2. The values obtained together with the "ion sizes" calculated from K[13] are given in Table IV. The accuracy of the measurements was probably about 0.1%, but, due to the uncertainty in the solvent conductance correction, values of Λ_0 may be off several per cent. However the values of K are apparently as good as most of those in the literature.

AgI	48.8	0.431	3.84[a]

[a] This value has no meaning since other than coulomb forces are involved.

The purpose of the investigation was to secure data relevant to the electronic theory of acids and bases.[3,4] In spite of the fact that only three salts were measured, due to the premature termination of the work, some interesting conclusions may be drawn. It is not surprising that the solubility of potassium nitrate is too low for conductance measurements. The potassium ion has very little tendency to associate with bases. Silver nitrate because of the acidic silver ion, and potassium iodide because of the acidic nature of the iodide ion (in expanding its valence shell to form coördinate bonds with bases) behave about as expected. "Normal" conductance behavior is observed in that greater ion size as indicated by lower Λ_0 is associated with a larger value of K (Table IV).

At first glance, the behavior of silver iodide seems rather surprising. The low Λ_0 value indicates larger ions as would be expected since both ions should be solvated rather than only one as in the case of potassium iodide and silver nitrate. But instead of a larger value of K it

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

is actually only about one-fifteenth the values for the other two salts. The explanation doubtless lies in the fact that the model, upon which the expectation of a high K value accompanying low mobility is based, assumes only the presence of coulomb forces between the ions.[13] In the case of silver iodide there are additional forces present which make K less than predicted when coulomb forces alone are involved. These forces are of the acid–base type.[3,4] The amphoteric nature of the iodide ion is well known[14] and is here substantiated. The results for silver nitrate and potassium iodide indicate that both silver and iodide ions are acting as acids in their association with the highly basic solvent. But toward the acidic silver ion the iodide ion acts as a base, tending to donate a pair of electrons to give partial covalent character[15] to the bond between the two ions. The presence of these additional forces decreases K to a value far below that expected from the low value of Λ_0.

(14) R. B. Sandin, *Chem. Rev.*, **32**, 249 (1943).

IV. Summary

The conductances of three salts, potassium iodide, silver iodide, and silver nitrate in ethylenediamine have been measured, at concentrations low enough to permit calculation of Λ_0 and K. The best solvent that could be obtained had a conductance of 9×10^{-8} mho. An explanation based on the electronic theory of acids and bases is offered for the extraordinarily low value of K for silver iodide.

Isomerization of Tri-alkyl Phosphites

BY GENNADY M. KOSOLAPOFF

The isomerization of tri-alkyl phosphites in the course of the reaction with alkyl halides, according to the scheme

$$(RO)_3P + R'X \longrightarrow (RO)_3PR'X \longrightarrow RX + R'P(O)(OR)_2 \quad (1)$$

was first studied rather extensively by Arbuzov,[1] who utilized this reaction as an elegant method of preparation of a number of phosphonic acid esters.

Usually the reaction is carried out by heating the reagents in a sealed tube, followed by distillation of the products. Under these conditions there are usually formed varying, and sometimes considerable, amounts of $RP(O)(OR)_2$, apparently formed through interaction of RX with either unreacted $(RO)_3P$ or the intermediate $(RO)_3PR'X$. It was felt that if the RX formed in the reaction were to be removed as rapidly as possible from the reaction mixture, not only should the course of the reaction be cleaner, but the measurement of RX evolved should offer a ready method for following the course of the reaction.

It was also felt that a technique employing the above principle could be utilized in obtaining additional information on the course of the reaction between tri-alkyl phosphites and paraffin dihalides. This reaction may be expected to follow both of the possible courses

$$2(RO)_3P + X(CH_2)_nX \longrightarrow \begin{matrix} RO \\ RO \\ RO \end{matrix}\!\!>\!P(CH_2)_nP\!<\!\begin{matrix} OR \\ OR \\ OR \end{matrix} \longrightarrow 2RX + (RO)_2P(O)(CH_2)_nP(O)(OR)_2 \quad (2)$$

(1) A. E. Arbuzov, "On the Structure of Phosphorous Acid," N. Alexandria, 1905.

and

$$(RO)_3P + X(CH_2)_nX \longrightarrow \begin{matrix} RO \\ RO \\ RO \\ X \end{matrix}\!\!>\!P(CH_2)_nX \longrightarrow RX + (RO)_2P(O)(CH_2)_nX \quad (3)$$

Actually, the literature data are rather meager as to information on the course of this reaction. Thus, Arbuzov and Kushkova[2] isolated from the reaction of methylene iodide and triethyl phosphite only the iodomethanephosphonic acid diethyl ester, *i. e.*, the product of reaction (3), among other substances. More recently, Parfent'ev and Shafiev[3] investigated the reaction of triethyl phosphite and trimethylene bromide, obtaining a product corresponding to the γ-bromopropanephosphonic acid diethyl ester, which could not be distilled without decomposition, and was apparently formed according to reaction (3). Nylen[4] studied the reaction between sodium diethylphosphite and methylene chloride, ethylene bromide and trimethylene bromide, obtaining $CH_2(PO(ONa)(OEt)_2)_2$, ethylene and tetraethyl trimethylenediphosphonate, respectively, as the identifiable reaction products.

From consideration of the available information it was evident that a further study of this reaction was desirable with variation of the proportions of the reactants as a means of influencing the predominance of either reaction (2) or (3).

Triethyl phosphite was selected as the alkyl phosphite, while *n*-butyl bromide and *n*-hexyl bromide were selected as the alkyl halides for the study of reaction (1), while ethylene bromide was taken for the study of reactions (2) and (3).

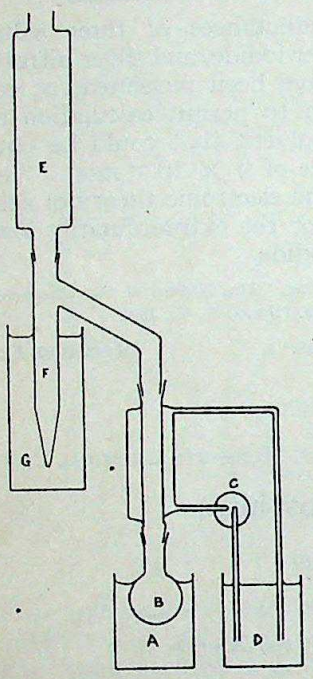

Fig. 1.—A, Oil-bath; B, reaction flask; C, circulating pump; D, heated water reservoir; E, reflux condenser; F, Stark–Dean trap; G, ice-water bath.

Experimental.—The reactants were heated, after mixing, in a small round-bottomed flask connected to an upright condenser, through the jacket of which water, heated to 50°, was circulated by a pump. The upper end of the condenser was connected to a Stark–Dean trap which was immersed in ice-water, while the exit from the trap was surmounted by an efficient spiral condenser. The reaction flask was heated by a thermostatically controlled oil-bath. The amount of ethyl bromide collected in the trap in the course of the reaction was read periodically. The apparatus is shown on Fig. 1.

***n*-Hexyl Bromide.**—Triethyl phosphite (16.6 g., 0.1 mole) and *n*-hexyl bromide (16.5 g., 0.1 mole) reacted at 133 and 150°. The results are shown in curves 1 and 2, respectively, of Fig. 2.

***n*-Butyl Bromide.**—Triethyl phosphite (16.6 g., 0.1 mole) and *n*-butyl bromide (13.7 g., 0.1 mole) reacted at 150°. The results are shown on curve 3, Fig. 2.

Ethylene Bromide.—Triethyl phosphite (16.6 g., 0.1 mole) reacted with the following amounts of ethylene bromide: 0.5 mole (94 g.), 0.2 mole (37.6 g.), 0.1 mole (18.8 g.) and 0.05 mole (9.4 g.) at 150°. The results are shown on curves 4, 5, 6 and 7, respectively, of Fig. 2. The reaction mixtures were subjected to vacuum distillation after completion of the runs. In the first three cases after distillation of excess ethylene bromide there was collected a very small amount of a liquid corresponding in boiling point to diethyl ethylphosphonate. Distillation from that point became impossible due to decomposition even at 1 mm. The last run, however, gave approximately 7 g. of diethyl ethylphosphonate, b. p. 50° at 1 mm., 194–198°.

Discussion of the Results.—In view of the fact that the over-all reaction in all of the cases studied must consist of at least two steps, *i. e.*, the formation of the intermediate addition compound, followed by thermal decomposition of the latter, it is not possible to calculate the reaction constants from our data. However, it is interesting to note the considerable effect of temperature upon both the induction period and the over-all reaction rate in case of *n*-hexyl bromide. The former is apparently the "accumulation" period of the phosphonium compound. The behavior of *n*-butyl bromide may be explained on a similar basis: while appreciable amounts of free butyl bromide exist in the mixture, the temperature of the latter is conditioned by the refluxing butyl bromide, while after the latter had combined substantially with the phosphite, the mixture attains bath temperature and the greater decomposition rate of the butyl phosphonium compound (in comparison with the hexyl compound) is evidenced by the generally steeper reaction curve.

In order to bring the reaction curve of the 0.05–0.1 molar mixture of ethylene bromide and triethyl phosphite to the same scale as that of the other three runs for more apparent visual comparison, the ordinates of curve 7 were multiplied by two and the resultant "hypothetical" curve is shown as curve 8, Fig. 2. It is evident that the suppression of di-substitution is sharply pronounced with greater excess of ethylene bromide. It is conceivable that the use of overwhelmingly large excess of the ethylene bromide may lead to almost complete suppression of di-

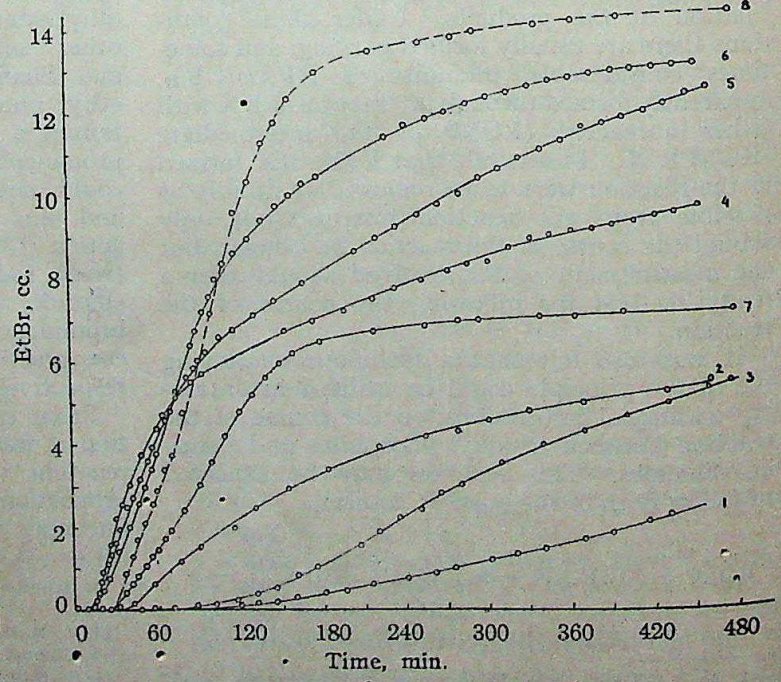

Fig. 2.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

substitution (excess of the order of 20–1 molar ratio). Such a mixture, however, was not practicable for our experimental set-up due to the relatively large bulk of such a reaction mixture. The results obtained from the 0.05–0.1 molar mixture show, apparently, a somewhat different reaction course from the other three runs. The amount of ethyl bromide collected corresponds very closely to the theoretical for complete disubstitution (*i. e.*, 7.25 cc.) according to reaction (2), while the distillation of the reaction mixture yielded approximately one-half of the triethyl phosphite used in the form of diethyl ethylphosphonate. It appears that the amount of the bromoethyl ester formed is very small, but due to its ready decomposition, on attempted distillation, and evolution of hydrogen bromide, the tetraethyl ester, which apparently forms by a normally expected reaction (2), suffers decomposition, either *per se* or influenced by the hydrogen bromide, with diethyl ethylphosphonate being one of the decomposition products. The mechanism of this decomposition is obscure and appears to require a form of disproportionation. The results with ethylene bromide are in general accord with the above cited work of Nylen, who was able to isolate only decomposition products. It is curious to note that the methane member of the series yields a halomethyl product of some stability, as well as the di-substitution product (in modified form), as shown by Arbuzov (see above) and Nylen (see above). It is now shown that the ethane derivative apparently undergoes the normal reaction course for reactions (2) and (3), with the attendant complication of poor stability of the bromoethyl compound (not unexpected, by analogy with β-haloethyl carboxylic acid derivatives), making it impossible to isolate pure reaction products.

Summary

The reaction between triethyl phosphite, on one hand, and *n*-butyl bromide, *n*-hexyl bromide and ethylene bromide, on the other hand, was studied by following the rate of evolution of ethyl bromide. The latter reaction apparently follows the normally expected mono- and di-substitution courses, controllable by proportion of the reactants.

The Relation of Starch–Iodine Absorption Spectra to the Structure of Starch and Starch Components[1]

BY R. R. BALDWIN, R. S. BEAR[2] AND R. E. RUNDLE

The activity of iodine in solution in the presence of starch has been shown to be a function of the nature of the starch, *i. e.*, of the proportion of amylose (or unbranched) component, the chain length of the amylose and the length of the free (or unbranched) portions of the amylopectin component.[3] Changes in starch-iodine color have long been known to accompany starch fractionation and starch degradation. It is to be expected that a more quantitative study of the absorption spectra of solutions of starch and its components should yield information, perhaps more detailed than that provided by the potentiometric study, concerning the structure of starch and its components.

Simerl and Browning made a spectrophotometric study of the iodine complex of a number of starches, dextrins, and starch components,[4] and Lampitt, Fuller and Goldenberg examined the absorption spectra of the starch–iodine complexes given by starch ground in a ball mill.[5] Both examinations were handicapped by the lack, at that time, of adequate methods of fractionating starch and characterizing the resultant fractions. Recent fractionation procedures and a rapid method of analysis of starch fractions[3] have overcome many of the previous difficulties.

Apparatus and Procedure.—Absorption spectra of the various solutions have been examined by means of a Coleman Model 10S double monochromator spectrophotometer, with an accompanying vacuum tube electrometer (Coleman pH meter) serving as an intensity measuring device. A slit selecting a 15 millimicron band of light was used for all transmission data. The solution to be examined was placed in a square cuvette, 13 mm. thick, and compared with a control solution in a matched square cuvette. The control solution contained a concentration of iodine equal to that used in preparing the starch–iodine solution. This procedure overcorrects for the iodine not involved in the complex, but the error is slight because of the negligible absorption of the very dilute iodine solutions used. For highly absorbing solutions a glass prism with optically parallel sides was placed in the cuvette to reduce the solution thickness from 13 to 1.63 mm. The temperature in all cases was kept at 23.0 ± 0.5°.

The perfectly clear solutions required for spectrophotometric work are possible only for very dilute starch solu-

tions. The starch or polysaccharide concentrations used in this investigation were generally 0.01%. In this concentration molecularly dispersed solutions can be approached, if not actually obtained, by the following procedures:

Pastes of native, granular starches were poured into boiling water, boiled for five minutes, and autoclaved for an hour at 18 lb. pressure. In strictly neutral solutions, degradation during this interval did not appear to be serious.

Amylose preparations are more difficult to disperse. A weighed amount of dried amylose was allowed to stand in dilute potassium hydroxide until a perfectly clear solution was obtained. It was found that 5 ml. of 0.5 *N* potassium hydroxide would readily disperse 50 mg. of amylose. The time required depended on the plant source of the amylose, but was generally less than an hour. The amylose solution was neutralized with aqueous hydriodic acid. If the solution was neutralized immediately before use retrogradation was not significant during the time required for the spectrophotometric observations.

Materials.—The whole starches used were generally milled in this Laboratory. The "crystalline amylose" was furnished by Kerr. Its preparation and properties have been described by Kerr and Severson,[6] and in papers from this Laboratory.[3,7] The term amylose is used to designate the unbranched component of starch. The amyloses discussed here were prepared by the fractionation procedure of Schoch.[8] Although this procedure proved the most successful of the methods tried for the separation of starch components, the amyloses thus prepared were generally contaminated by a small amount of amylopectin, or the branched component. Analyses of these fractions have been reported.[3] The amylopectins were likewise obtained by Schoch's fractionation, and the last traces of amylose were removed by cotton adsorption columns where necessary.

The amylodextrin used in this investigation was a Nageli dextrin[9] further fractionated by butanol–methanol precipitation, and is identical with the amylodextrin fraction examined by Foster and Hixon[10] and the fraction examined by Bates, French and Rundle.[3] It digests to 90% with β-amylose, retrogrades readily to give a crystalline diffraction diagram and in its change of viscosity with concentration it resembles the amyloses rather than the amylopectins.[10] All these properties indicate that it possesses unbranched chains. Its molecular weight is small, however, in the neighborhood of 44 glucose residues, or only about one-tenth as great as for the amyloses from whole starches.

Absorption Spectra of Amylose- and Amylopectin–Iodine Solutions.—The difference in ability of amylose and amylopectin to form complexes with iodine and the difference in color of the complexes[3] makes it necessary to regard starch as a complex substance in the study of iodine absorption spectra. These two components of starch were, therefore, studied separately. In Fig. 1 typical transmission curves of amylose and amylopectin are shown. The wave length of minimum transmission is greater for the amylose, and the % transmission under similar conditions is always far less. These factors make possible the colorimetric analysis of starch for amylose and amylopectin, and such an analysis has been described for potato starch.[11] It will be clear from what follows concerning specific amylose and amylopectin materials that such an analysis cannot be applied generally to starch without a preliminary investigation of the properties of the specific amylose and amylopectin making up the particular starch to be analyzed. This is, of course, a serious limitation on the method.

Outstanding is the difference in the behavior of amylose and amylopectin with different concentrations of iodine. In this respect the absorption curves are similar to the iodine titration curves, and are to be expected from that work.[3] In Fig. 2 are shown the spectrophotometric titrations characteristic of amylose and amylopectin materials. For both substances log *T* was chosen for the wave length of minimum transmission for that substance. The wave length of minimum transmission does not change materially with iodine concentration. The potentiometric titration of amylopectin with iodine indicates that not much of the iodine combines with the amylopec-

tin, and as indicated in Fig. 2, the transmission of the iodine solution is affected far less by the presence of amylopectin than by the presence of amylose. Both the potentiometric and spectrophotometric titrations indicate that a complex of a definite composition is formed between amylose and iodine. The spectrophotometric titration could be made the basis of an analysis of starch for amylose, but it appears to have no advantages over and is more laborious than the potentiometric titration. Apparently the spectrophotometric titration would not suffer from the limitations of the colorimetric analysis[11] if the end-point were determined by the break in the titration curve. Both the potentiometric and the spectrophotometric titrations indicate a discontinuous difference between amylose and amylopectin. Differences in degree of branching of amylose and amylopectin cannot then be continuous.

Iodine–Iodide Relationships in the Amylose–Iodine Complex.—In the potentiometric titration it was found that the % iodine in the amylose–iodine complex at the end-point decreased as the iodide concentration was increased.[3] This is confirmed by the spectrophotometric titration. In Fig. 3 are titration curves for "crystalline amylose" at various iodide concentrations. In Fig. 4 the number of glucose residues per iodine molecule is plotted against a function of the iodide concentration. It is seen that the curve extrapolates to approximately 6 glucose residues per iodine molecule in infinitely dilute iodide solutions.

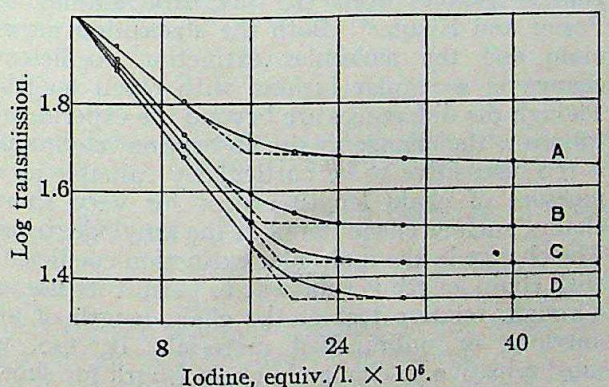

Fig. 3.—Spectrophotometric titration of crystalline amylose at various iodide concentrations: iodide concn. of A, 0.5 *M*; B, 0.05 *M*; C, 0.005 *M*; D, 0.001 *M*; cell depth, 1.63 mm.; amylose concn., 0.01%.

This value is, we feel, very significant. It has been found that the starch–iodine complex consists of helical starch chains with iodine molecules arranged along the helix axis.[7] The periodicity along the helix is probably 6 glucose residues. Apparently in the complex, free of iodide, one iodine molecule occupies one turn in the helix. It was found that dry amylose in the helical configuration takes up iodine vapor to the extent of one iodine molecule per 6 glucose residues.[7]

The reason for the decrease in iodine in the complex with increasing iodide concentration appears clear from the structure of the complex. With increasing iodide concentrations triiodide ions must enter the helix, probably accompanied by positive ions. A turn in the starch helix is 8 Å. long.[7] The space required for an iodine molecule is about 6.6 Å. along the helix, and the space required by a triiodide ion plus a positive ion must be considerably larger than 8 Å. For lack of space the amount of iodine in the helix must decrease as iodide enters. A more quantitative study based on the analysis of the complex for iodide is under way.

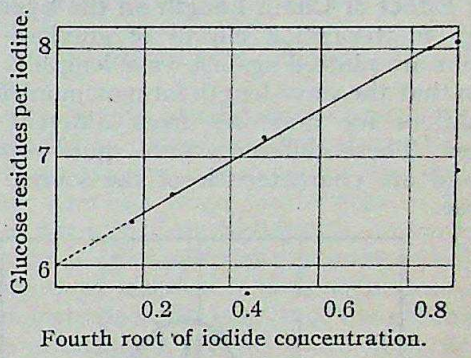

Fig. 4.—Glucose residues per iodine molecule at the end point of the spectrophotometric titration of "crystalline amylose" as a function of iodide concentration.

There is an interesting difference in the amount of iodine found to be bound in complex formation at the end-points of the spectrophotometric and potentiometric titrations (Table I). In all cases the spectrophotometric value is the higher. We believe that the difference can be explained in terms of the structure of the complex and the choice of the two end-points. The iodine activity of an amylose–iodine solution is fairly constant as long as the main body of the helices is being filled. From the ends of the helices, however, it would be expected that the iodine molecules could be removed more readily. An increase in the iodine activity then occurs before the last possible iodine molecules are put in the helices. The end-point of the potentiometric titration is taken at the first rapid increase in iodine activity and hence before complex formation is fully completed. In the spectrophotometric titration all iodine is counted as present in complex formation if it contributes to the increase in the absorption of the solution over that of an iodine–water solution.

TABLE I

GLUCOSE RESIDUES PER IODINE MOLECULE IN THE AMYLOSE–IODINE COMPLEX PRODUCED AT VARIOUS IODIDE CONCENTRATIONS AS DETERMINED BY SPECTROPHOTOMETRIC AND POTENTIOMETRIC METHODS

Iodide concn., moles/liter	Glucose residues per iodine molecule	
	Spectrophotometric	Potentiometric
0.5	8.0	9.9
.05	7.2	8.4
.005	6.7	7.8

Since amylopectin is quite different from amylose in its complex-forming ability with iodine, and

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

since the % iodine in the complex varies with iodide concentration it is clear why previous attempts to determine a formula for the starch–iodine complex by using whole starch, or poorly fractionated starch, and various iodide concentrations have failed.[12]

In Fig. 3 it is seen that the transmission of amylose–iodine solutions increases with added iodide. This effect is probably due to a change in the nature of the complex; more triiodide and/or iodide ions enter the helices at higher iodide concentrations.

The Effect of Chain Length on the Spectra.—In Fig. 5 absorption curves of amylose–iodine solutions are plotted against wave length. It can be seen that the wave length for maximum absorption differs for amyloses from different plant sources. These differences are quite reproducible, and are characteristic of the source of the amylose.

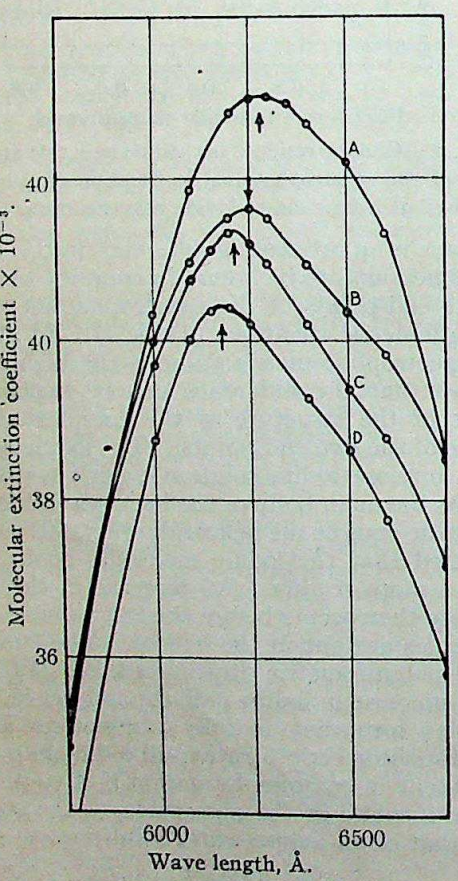

Fig. 5.—Molecular extinction curves of iodine in various amyloses: A, potato amylose; B, tapioca amylose; C, lily amylose; D, corn amylose; cell depth, 1.63 m.; iodine concn., 0.00005 *M*; amylose concn., 0.01%.

Even more variation is found in the molecular extinction coefficients of amylose–iodine solutions from different plant sources. For comparison purposes amylose must be kept in excess. The absorption is then a function of added iodine. In their spectrophotometric study of starch–iodine Lampitt, Fuller and Goldenberg found that an increased iodine concentration caused an increased value of the extinction coefficient.[5] If, however, the absorption is calculated as molecular extinction coefficient, the greater values are obtained with lower iodine concentrations. In Table II the molecular extinction coefficients are calculated for solutions 0.0001 *N* with respect to iodine and 0.01% with respect to starch.

It is to be noted that low iodine concentrations are particularly important in this comparison, for near the end-point of complex formation the molecular extinction coefficient is influenced profoundly by the per cent. amylopectin impurity which was never negligible in our work. At low iodine concentrations, however, the iodine first forms a complex with amylose, and the molecular extinction coefficient is nearly independent of the amylopectin impurity.

The amylose–iodine complexes listed have been found to differ in the activity of iodine in water solution of the complexes.[3] This difference was interpreted as due to the difference in chain lengths of the amyloses, and this point has been confirmed by the viscosity studies of Foster and Hixon.[10] In Table II are listed observed absorption maxima, molecular extinction coefficients, characteristic potentials for complex formation of an iodine half cell measured against a normal calomel half cell,[3] and estimates of chain length in glucose residues from the viscosity studies of Foster and Hixon.[10] Both the absorption maximum and the molecular extinction coefficient change in a regular fashion with chain length. Though the differences are beyond the experimental error, the change in the absorption maximum is too insensitive to be particularly valuable as a measure of chain length except for very short chains, such as encountered in the amylodextrins. The change in the molecular extinction coefficient with chain length is sufficient to permit its use as a rough, relative test of the chain length of an amylose, or unbranched material. It, too, is most sensitive to change in chain length for short chains. It is also a secondary method whose use depends upon the establishment of the molecular weights of a series of amyloses by other methods. It would appear advisable to await the further

TABLE II

Amylose	Molecular size	Wave length of absorption maximum	Molecular extinction coefficient	Characteristic potential
Potato	500	6280	43,000	0.197
Tapioca	450	6250	41,600	.200
Lily	310	6220	41,400	.202
Corn	250	6180	40,400	.203
Crystalline	175	6050	40,100	.205
Synthetic	85	5900	32,900	.204
Amylodextrin	44	5800	25,400	.218

development of such standards before use of the molecular extinction coefficient for the determination of anything but the relative molecular weights of the amyloses.

The wave lengths of maximum absorption of the amylopectin–iodine solutions are all at much shorter wave lengths than those found for the amylose–iodine solutions. The wave lengths are again a reproducible function of the source of the amylopectin. There is a great deal of similarity in the wave length, molecular extinction coefficient, and general character of the absorption spectra of the amylopectins and the low molecular weight amylodextrin. The latter appears to have all the characteristics of an unbranched, but short chain material. The amylopectin, on the other hand, is of high molecular weight. The similarity in the absorption spectra seems to result from a similarity in the length of the free, unbranched portions of the chains in the amylopectin molecules and the length of the amylodextrin chains. It is believed that the wave length of maximum absorption and the molecular extinction coefficient of the amylopectin–iodine solutions are measures of the average length of the unbranched portions of the amylopectin chains. On this basis it appears that glycogen is most highly branched, and following in order, waxy rice, waxy maize, waxy barley, potato- and corn-amylopectin. Where tetramethyl end-group assay is known it is in agreement with this assignment. This order is also in agreement with the results of the potentiometric titration.[3]

Summary

Study of absorption spectra confirms the great difference in behavior of amylose and amylopectin with iodine found by the potentiometric iodine titration,[3] and provides another means of analyzing for the two components in whole starch. The differences in individual amyloses and amylopectins from different starches make a simple colorimetric analysis for the two components unreliable however.

The amount of iodine bound in complex formation with amylose increases as the concentration of iodide decreases, becoming one iodine molecule for six glucose residues for infinitely dilute iodide solutions.

The wave length of maximum absorption of an amylose solution shifts toward the red as the chain length of the amylose is increased. The shift is in the same direction when the lengths of the unbranched portions of an amylopectin are increased. An increase in the molecular extinction coefficient accompanies an increase in the length of an amylose or an increase in the lengths of the unbranched portions of an amylopectin. Both these properties permit the relative evaluation of molecular weight of an amylose and degree of branching of an amylopectin. The change in the molecular extinction coefficient is the more sensitive.

The relative molecular weights of a few amyloses and the degree of branching of some amylopectins have been examined. Results are in agreement with other determinations.

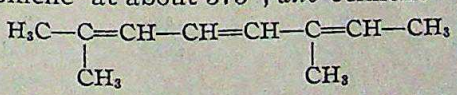
Raman Spectra of Two Forms of *allo*-Ocimene

BY J. J. HOPFIELD,[1] S. A. HALL[2] AND L. A. GOLDBLATT

Among the products obtained in the pyrolysis of α-pinene[3] at about 375°, *allo*-ocimene



(2,6-dimethyl-2,4,6-octatriene), is of the greatest interest, both from a practical and theoretical viewpoint.

On careful re-fractionation of the portion of α-pinene pyrolysate boiling in the *allo*-ocimene range, two components were obtained, a major component boiling at 89.0° at 20 mm. pressure and a minor component boiling at 91°. Both components yield with maleic anhydride the same adduct (m. p. 83–84°) but the two components exhibit differences in their freezing points, densities and Raman spectra.

It may be reasonably assumed that these are two forms of *allo*-ocimene, of which there are four possible geometric isomers, arising from the double bonds at the 4 and 6 positions. Models (Fisher–Herschfelder) of the four geometrical isomers show that the *cis* form arising from the double bond at the C_4 carbon atom (regardless of whether the configuration at C_6 is *cis* or *trans*) is one of very limited rotation. The probability of its formation and continued existence during the high temperature pyrolysis of α-pinene would appear to be slight.[4] Such a configuration would be more likely to form a stable ring compound, such as one of the pyronenes which are also ob-

(4) In the case of pentadiene-1,3 (piperylene), however, Robey, *Science*, 96, 470 (1942), reports that the *cis* isomer, which is similarly more hindered than the *trans* isomer, is much more prominent in mixtures from high temperature processes.

Digitized by Arya Samaj Foundation Chennai and eGangotri

tained in the pyrolysis of α-pinene, or be "cracked" at the high temperature (375°) prevailing, thus accounting for the small percentage of very low-boiling substances always obtained during pyrolysis. On the other hand, the model of the *trans* form at C_4 shows relative freedom of rotation for all groups. Of the *cis* and *trans* configurations at the C_6 carbon atom, the model of the *cis* form appears to be slightly more compact, which should, of course, be reflected in a slightly greater density.

Although methods for the assignment of the *cis* or *trans* configuration to isomers of an olefin on the basis of their physical properties are admittedly of doubtful use,[5a] nevertheless, it is usually true that the *cis* isomer of an olefin has the lower melting point[5b] and the higher boiling point and higher density.[6]

If the two forms of *allo*-ocimene obtained are indeed the *trans*-(C_4)-*cis*-(C_6) and the *trans*-(C_4)-*trans*-(C_6) isomers, then we might expect from their physical properties to find as the *cis* isomer the hydrocarbon of higher boiling point, higher density, and lower melting point. The Raman spectra of these isomers tend to support this interpretation.

Materials.—125 grams of a fraction of *allo*-ocimene boiling at 89.0° at 20 mm. and melting at −24.3 to −22.6° was recrystallized twice from absolute alcohol; 125-cc. portions of the alcohol were used and crystallization was effected by cooling the solution in a bath of dry-ice in acetone. Filtration was accomplished in the usual manner, but in a refrigerated room (0°) using a Buchner funnel previously chilled in dry-ice. The occluded alcoholic mother liquor was readily removed by distillation and as a final purification the material was vacuum distilled. During and after distillation a blanket of nitrogen gas was used to avoid exposure to air for the *allo*-ocimene, after an induction period of about two hours, absorbs oxygen quite rapidly.

Approximately 50 g. of the isomer boiling at 91° at 20.0 mm. pressure and melting at −35.9 to −33.4° was subjected to the same procedure except that only one crystallization from alcohol was made.

The fractions thus purified have the following physical properties:

	B. p. at 20 mm.	M. p., °C.	d^{20}_4	$n^{20}D$
"A" form	89.0°	−21.0 to −20.6°	0.8060	1.5446
"B" form	91°	−35.4 to −34.0°	0.8118	1.5446

Procedure.—The Raman spectrograms were obtained with a Gaertner L-256 spectrograph having a dispersion of 39.5 A./mm. at 4500 Å. The Raman cell was specially constructed of a 12 mm. o. d. Pyrex tube enclosed by an outer tube to give a 30 mm. thickness of filter. A Hanovia fused quartz mercury arc lamp (Model 2444, 110 volt d. c., 4.5 amp.) was used for excitation. The filter solution for isolating the Hg 4358 A. line was the one recommended by Edsall and Wilson.[7] The slit opening was 100 μ and effective aperture F:4.5. Eastman II-J plates, developed at 20° for six minutes with developer DK-50, were used. The respective spectrograms of the "A" and "B" forms of *allo*-ocimene were taken on the same plate to obviate any differences in line densities arising from differences in plate gamma or in development time. Three different exposure times were used, namely, four, sixteen and thirty-two minutes. The spectrograms of the shorter exposures were used for the measurement of the strongest lines; but such measurements were checked with measurements of longer exposures. Also, doublets which were not well resolved were checked by examination of the spectra excited by the Hg 3650 Å. triplet. Because of the greater dispersion of the spectrograph at the lower wave lengths, a much better resolution of such doublets was effected. The lines were measured with a Gaertner comparator. The wave length shifts were calculated from these data by a three-constant quadratic equation[8] based on the measured positions and

wave numbers of three selected lines of the iron spectrum. Thus, instead of interpolating to the nearest iron line (which might not be well defined or, in some cases, might be an appreciable distance from a Raman line) the wave numbers were obtained from this equation and a correction curve based on some of the other iron lines in the region. For well-defined Raman lines an accuracy to 1 cm.$^{-1}$ was obtainable; but for broad or diffuse lines the accuracy was limited to about 3 cm.$^{-1}$.

Results

The results obtained for the two isomers are listed in Table I and shown graphically in Fig. 1. A photograph of the three exposures for each isomer is shown in Fig. 2. *allo*-Ocimene gives a very strong Raman spectrum in an unusually short exposure time.

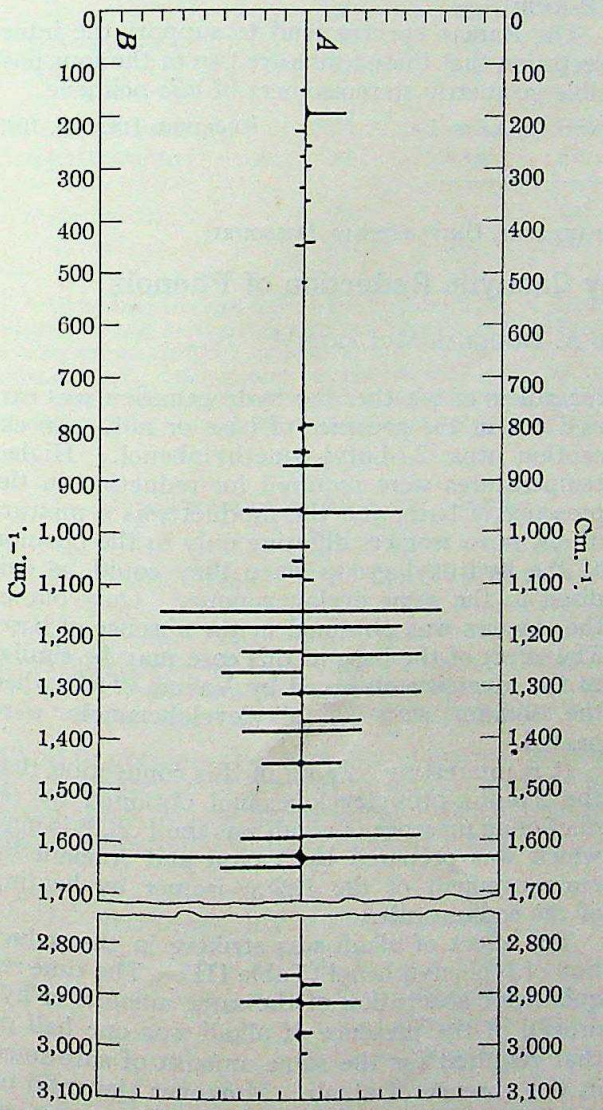

Fig. 1.

The strongest line at about 1631 cm.$^{-1}$, due to the double-bond vibration, is easily discernible after an exposure time of only twenty seconds. The isomeric triolefin, myrcene (2-methyl-6-methylene-2,7-octadiene), requires at least eight minutes exposure time under the same conditions to make visible its corresponding strong line at

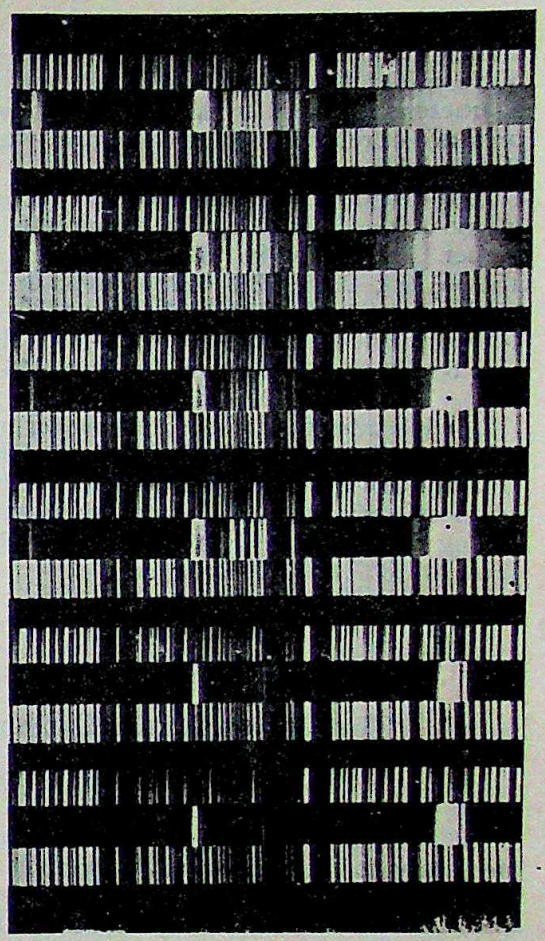

Fig. 2.

about 1636 cm.$^{-1}$. With *allo*-ocimene, four minutes exposure brings out 11 Raman lines; sixteen minutes brings out 26 lines; and thirty-two minutes brings out 28 lines. Longer exposures appear to be unprofitable, for the increasingly prominent background tends to obscure any additional weak lines.

Discussion

The line at 1307 cm.$^{-1}$, which is much more intense in the "A" than in the "B" isomer, is interpreted as due to a *trans* configuration.[9] The rather strong lines at 1272 cm.$^{-1}$ and at 1648 cm.$^{-1}$ in the "B" form, which have no counter parts in the "A" form, are attributed to a *cis* configuration.[10] A *trans* configuration should be reflected in a Raman line[11] at about 1673 cm.$^{-1}$, lowered somewhat by the influence of conjugation. Curiously this line is absent in both the "A" and the "B" isomers. Nor has it been reported by Dupont and co-workers in their work[12] on the Raman

spectrum of *allo*-ocimene. These authors did not distinguish between the two forms of *allo*-ocimene but consideration of the Raman data and physical characteristics cited by them would indicate the presence of relatively large concentrations of both the A and B components.

It is also apparent that there is a tendency for many of the lines in the "A" isomer to shift to higher frequencies in the "B" isomer, namely, 151 → 196; 227 → 258; 277 → 296; 335 → 361; 961 → 964; 1082 → 1091; 1231 → 1236; 1347 → 1365; 1627 → 1631; 2911 → 2914. The opposite tendency is shown by the lines 446 → 440; 800 → 790 and 1597 → 1590.

For identification of the "A" isomer in a mixture, one could conveniently use the rather strong, well-defined 1365 line, while the "B" form could be most easily detected by its unique and rather strong line at 1272 cm.$^{-1}$, or alternatively by its lines at 1347 and 1648 cm.$^{-1}$.

Acknowledgment.—The continued interest and advice of the late Dr. S. Palkin, Chief of the Naval Stores Research Division, who originally proposed the project, is gratefully acknowledged.

Summary

Two forms of *allo*-ocimene, designated as A- and B- have been isolated.

Both forms yield with maleic anhydride the same adduct but they exhibit differences in boiling point, freezing point, density and Raman spectra.

Both forms give strong Raman spectra in an exceptionally short exposure time. Each may be detected in a mixture by the characteristic Raman lines at 1365 cm.$^{-1}$ (A-form) and 1272 cm.$^{-1}$ (B-form).

The Raman spectra tend to support the interpretation that these forms are two of the four possible geometric stereoisomers of *allo*-ocimene.

The Preparation of Cyclohexanols by Catalytic Reduction of Phenols

BY HERBERT E. UNGNADE AND A. DOUGLAS MCLAREN[1,2]

In connection with another problem it became necessary to prepare alkylcyclohexanols in moderately large quantities. This has been accomplished by the catalytic reduction of alkyl-, alkenyl- and acylphenols with Raney nickel.

Since alkylphenols could be hydrogenated readily to the corresponding cyclohexanols, the chief limitation was the availability of the phenols. The ease of reduction was not greatly affected by substituents in the ring unless two ethyl or *n*-propyl groups occupied the ortho positions (Table I). In the latter cases no cyclohexanols were formed at temperatures above 300°. 2,6-Di-*n*-propylphenol was recovered unchanged but 2,6-diethyl-4-methylphenol underwent hydrogenolysis and reduction of the ring to give 1-methyl-3,5-diethylcyclohexane. The corresponding cyclohexanols could be obtained from the two phenols when the hydrogenation was carried out in the presence of a small amount of a 40% aqueous solution of sodium hydroxide. When the other phenols were reduced in the presence of alkali a slight promoting effect was evidenced in some cases by lower initial reduction temperatures. The promoting effect was lost when the phenolic hydroxyl was methylated (Table II). The formed cyclohexanols consisted predominantly of one of the possible geometric isomers. The same isomer was usually obtained regardless of whether the hydrogenation was carried out in the presence of base or not. An exception was 2-*t*-butyl-4-methylphenol. Higher temperatures were required for reduction in the presence of base, and the product was a mixture of *cis*, *trans* isomers differing only in the position of the hydroxyl group since they could be oxidized to the same cyclohexanone.[3] Only one of the isomers was obtained in the absence of base. The effect of the base in this case may be similar to the inversion observed by Vavon, *et al.*, when the sodium salts of alkylcyclohexanols were heated.[4]

It is interesting to note in this connection that the 2,6-di-*n*-propylcyclohexanol obtained by reduction in presence of alkali was the 1^t,2^c,6^c-isomer which was prepared by Vavon and Anziani by rearrangement of the 1^c,2^c,6^c-isomer by heating of the sodium salt.[5]

The effect of alkali was striking in the reduction of *p*-phenylphenol (Table III). The time required for absorption of the same amount of hydrogen in the presence of alkali was one half of that required for the same amount of substance in the absence of alkali. Moreover the ratio of the products was not the same. The percentage of *p*-cyclohexylphenol and *p*-cyclohexylcyclohexanol was smaller and the amount of *p*-phenylcyclohexanol larger when alkali was used as a promoter. It is therefore possible by means of

[a] Hydrogenation in the presence of 1.6 cc. of 40% aqueous alkali. [b] T_1, temperature of initial hydrogen uptake. [c] T_2, temperature maintained during the hydrogenation.

alkali to promote the reduction of a phenolic ring in the presence of another aromatic nucleus or presumably in the presence of other functions whose reduction is not activated by alkali.

TABLE III

HYDROGENATION OF 4-PHENYLPHENOL

Moles	T_1,[b] °C.	T_2,[c] °C.	Time, hr.	Yield, %	Product
0.295	110	125	6	25.7	4-Cyclohexylphenol
				7.4	4-Phenylcyclohexanol
				59.2	4-Cyclohexylcyclohexanol
.295[a]	95	115	3	16.6	4-Cyclohexylphenol
				30.3	4-Phenylcyclohexanol
				43.2	4-Cyclohexylcyclohexanol

[a] Hydrogenation in the presence of 2 cc. of 40% aqueous alkali. [b] T_1, temperature of initial hydrogen uptake. [c] T_2, temperature maintained during the hydrogenation.

Allyl or propenylphenols which are readily available through the Claisen allyl ether rearrangement have been converted in good yields to alkylcyclohexanols. The reduction was found to take place in two steps. Isolation of the alkylphenol was not necessary. The addition of alkali shortened the time required for the saturation of the side-chain, lowered the initial temperature for the reduction of the ring and reduced the time required for the saturation of the ring. The experimental data are summarized in Table IV.

TABLE IV

HYDROGENATION OF ALKENYLPHENOLS

Phenol	Moles	T_1,[c] °C.	T_2,[d] °C.	Time, hr.	Yield, %	Product
2-Allyl	0.77	30	50	0.4	95	2-*n*-Propylphenol

[a] All hydrogenations with 3 g. of Raney nickel and 100 cc. of ethanol. [b] The authors are indebted to Dr. Austin Patterson for his advice in naming these compounds. [c] T_1, temperature of first hydrogen uptake. [d] T_2, temperature maintained during the hydrogenation. [e] Hydrogenation in the presence of 2 cc. of 40% aqueous alkali.

by reduction with Raney nickel at 200°. More recently Smith and Rouault[7] were able to hydrogenate 2-(2′,6′-dimethylheptanoyl)-4-methylphenol and 2-lauroyl-4-methylphenol in practically quantitative yields by a two stage reduction. In our hands both ortho and para acylphenols gave excellent yields of alkylphenols at about 110° when the hydrogenation was carried out in alcoholic solution. When the temperature was raised to 180° the ring could be saturated without previous isolation of the alkylphenol. Attempts to stop the hydrogenation at the first reduction stage, the (1-hydroxylalkyl)-phenols, were unsuccessful. The products were mixtures of alkyl and acylphenols. In the presence of alkali ortho and para acylphenols absorbed hydrogen rapidly between 45 and 65°. The products consisted of mixtures of alkylphenols and hydroxyalkylcyclohexanols. The second reduction stage (110°) gave a mixture of alkylcyclohexanols and hydroxyalkylcyclohexanols. Further increase in temperature up to 220° did not change the products or their ratio (Table V).

The experimental data allow the conclusion that the hydrogenation of the phenolic ring as well as that of the carbonyl group is activated by alkali. The latter case has been studied previously by Delépine and Horeau.[8]

The results cannot be entirely accounted for unless it is assumed that the hydrogenation of one function is affected by the presence of the other. Thus, the hydrogenation of the phenolic ring during the first reduction stage takes place at temperatures appreciably below those required for alkylphenols even in the presence of base. This effect is ascribed to the acyl group.

During the second stage the hydroxylalkylcyclohexanols are partially converted to alkylcyclohexanols by hydrogenolysis of the side-chain hydroxyl group. Simultaneously the alkylphenols formed in the first stage undergo complete saturation. Since heating to higher temperatures does not bring about further hydrogenolysis (after all phenolic rings have been reduced), it is proposed that this reaction is catalyzed by the sodium phenolate still present during the second stage. The resistance of the dihydric alcohol to further hydrogenation is not surprising since the side-chain hydroxyl group is no longer on a carbon directly connected to an aromatic nucleus[9] and is, therefore, not expected to undergo hydrogenolysis below 200°.[10] Further aspects of these reactions are now under investigation.

Acknowledgment.—The authors wish to express their thanks to the University Research Council for funds to purchase apparatus and chemicals necessary for this investigation.

Experimental[10a]

The hydrogenations reported in the tables were carried out in general at 100–300 atm. with Raney nickel in a steel chamber equipped with a copper liner having a total capacity of 500 cc.[11] The temperature of initial hydrogen absorption was determined by plotting temperature against pressure. The data chosen for the tables were for catalysts with as near the same age as possible since Raney nickel was found to lose some of its activity upon aging, as evidenced by higher initial hydrogenation temperatures required with some older catalysts for the same sample of starting-material.

Hydrogenation of Alkyl and Alkenylphenols.—Most of the phenols were obtained from commercial sources and were purified in addition to the usual methods by distillation from Raney nickel. *o*-*n*-Propylphenol and 2,6-di-*n*-

TABLE VII

ALKYLPHENOLS OBTAINED BY HYDROGENATION OF ALKENYL AND ACYLPHENOLS

Phenol	B. p., °C.	Mm.	Derivative	M. p., °C.
4-Ethyl	213–216	739	Aryloxyacetic acid	94–94.5[24]
2-*n*-Propyl	214–216	740	Phenylurethan	109–110[25]
2,6-Di-*n*-propyl	247.5–249	740	Phenlyurethan	126.5–127[26]
2-Ethyl-4-methyl	131–133	135	Aryloxyacetic acid	130.5–131.5[27]
2,6-Diethyl-4-methyl	133–134	23	Benzoate	100.5–101.5[28]

propylphenol were obtained by hydrogenation of the corresponding allyl compounds, and 2-*t*-butyl-4-methylphenol by alkylation of *p*-cresol with *t*-butyl alcohol.[12] Mesitol was prepared by hydrolysis of bromomesitylene, 4-ethyl- and 2,6-diethyl-4-methylphenol by hydrogenation of the corresponding acylphenols.

All phenols were hydrogenated in the absence of solvents. The pertinent data for the cyclohexanols are given in Table VI.

1-Methyl-3,5-diethylcyclohexane.—B. p. 175–176.5°, $n^{25}D$ 1.4345, d^{25}_4 0.7841; M_D (calcd.) 50.80; M_D (found) 51.21. *Anal.* Calcd. for $C_{11}H_{22}$: C, 85.71; H, 14.28. Found: C, 85.55; H, 14.49.

1-Methyl-4-methoxycyclohexane.—B. p. 146–148.5°, $n^{20}D$ 1.4333.[21]

Hydrogenation of *p*-Phenylphenol.—A solution of 50 g. of *p*-phenylphenol (Eastman Kodak Co.) in 50 cc. of ethanol was hydrogenated in the presence of 3 g. of Raney nickel until a total of 1200 lb. of hydrogen had been absorbed at 115°. A subsequent run with addition of 2 cc. of 40% aqueous alkali was made under identical conditions. After removal of the solvent the mixture of products was taken up in benzene and petroleum ether and extracted with 10% aqueous alkali. Acidification of the alkaline extract gave *p*-cyclohexylphenol which melted at 129.2–130.5° after crystallization from benzene–petroleum ether.[22] Fractional crystallization of the remaining benzene–petroleum ether solution gave *p*-phenylcyclohexanol, m. p. 116–117°, and *p*-cyclohexyl-cyclohexanol, m. p, 98–99°.[22] *p*-Phenylcyclohexanol was converted to the corresponding ketone, m. p. 77–78°, by oxidation with sodium dichromate and sulfuric acid.[23]

Hydrogenation of Acylphenols.—The acylphenols used in this investigation were prepared by the Fries rearrangement of the phenol esters. No special purification was necessary even though carbon disulfide was used in the procedure. The hydrogenations were carried out in 100 cc. of ethanol with 3 g. of Raney nickel catalyst. The products were separated by fractional distillation under reduced pressure. The constants of the phenols are listed in Table VII.

4-(1-Hydroxyethyl)-cyclohexanol.—B. p. 129–133° (2 mm.), m. p. 91–92.2°. *Anal.* Calcd. for $C_8H_{16}O_2$: C, 66.66; H, 11.01. Found: C, 66.32; H, 10.87. 3,5-

Summary

1. Alkylcyclohexanols are readily obtained by the hydrogenation of alkyl-, alkenyl- and acylphenols in the presence of Raney nickel.

2. The hydrogenation of di-ortho substituted phenols is promoted by small amounts of alkali.

3. The hydrogenation of alkenyl and acylphenols may be conducted at low temperatures to give good yields of alkylphenols.

4. The hydrogenation of acylphenols gives alkylphenols or alkylcyclohexanols depending upon the temperature. In the presence of alkali a mixture of alkylphenol and hydroxyalkylcyclohexanol is obtained at low temperatures and a mixture of alkylcyclohexanol and hydroxylalkylcyclohexanol at high temperatures.

COLUMBIA, MISSOURI RECEIVED SEPTEMBER 9, 1943

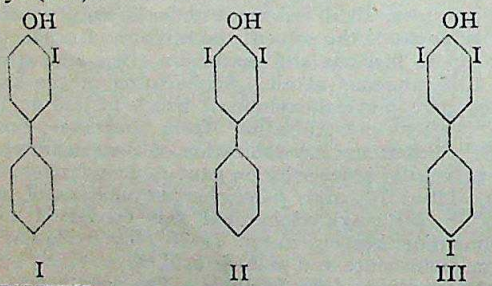
[CONTRIBUTION FROM THE DEPARTMENTS OF CHEMISTRY OF THE UNIVERSITY OF TEXAS AND THE UNIVERSITY OF OKLAHOMA]

The Iodination of 4-Hydroxybiphenyl[1a]

BY J. C. COLBERT,[1b] H. W. HOUGHTON,[1b] H. R. SCHMIDT[2] AND J. L. ABERNETHY[2]

Although the chlorination[3] and bromination[4,5] of 4-hydroxybiphenyl have been investigated, the only iodine derivative of this phenol mentioned in the literature appears to be 4′-iodo-4-hydroxybiphenyl[6] obtained by use of the Sandmeyer reaction.

On the basis of the results of chlorination and bromination, it was anticipated that iodination of 4-hydroxybiphenyl would cause the first iodine atom to enter the 3-position, thereby yielding 3-iodo-4-hydroxybiphenyl (I); the second atom would enter the 5-position, with the resultant formation of 3,5-diiodo-4-hydroxybiphenyl (II); and, finally, the third atom would enter the 4′-position, giving rise to 3,5,4′-triiodo-4-hydroxybiphenyl (III).



I II III

Introduction of a solution of iodine dissolved in potassium iodide into a solution of 4-hydroxybiphenyl in sodium hydroxide[7] gave rise to I. However, when an attempt was made to diiodinate 4-hydroxybiphenyl using the same procedure, II could not be isolated from the reaction products. Instead, a compound which gave an analysis very close to a monoiodinated derivative was obtained. This substance decomposed at temperatures above 170°. Since it is known that on heating diiodinated phenols[8] with sodium hydroxide, two molecules undergo condensation with loss of hydrogen, *i. e.*, aristol formation takes place, it seemed plausible that a similar reaction had taken place during the attempted diiodination of 4-hydroxybiphenyl. Consequently a Rast molecular weight of this product was determined. This indicated that the molecular weight was approximately double that of a monoiodo-4-hydroxybiphenyl and suggested that aristol formation had taken place. No further attempt was made to prove its structure.

Iodination of 4-hydroxybiphenyl in an ammonium hydroxide solution gave rise to I. Further iodination introduced iodine in the 5-position, hence yielding II. This procedure is known to be more satisfactory than the procedure in which sodium hydroxide is used, in that in most instances very little aristol formation takes place with iodinated phenols.

Iodination with iodine monochloride gave rise to I, and further iodination gave rise to II. Attempts to triiodinate 4-hydroxybiphenyl were unsuccessful.

The benzoates of I and II were prepared by benzoylation of these substances with benzoyl chloride in pyridine. It was found that benzoylation of I took place readily, whereas benzoylation of II was somewhat more difficult. This latter

(1a) In 1938 at the University of Oklahoma an attempt was made to apply the detailed method of iodination of a phenol used by Harington in the synthesis of thyroxin to the iodination of 4-hydroxybiphenyl. This method made use of a solution of iodine in potassium iodide which was added to the ammoniacal solution of the phenol. In work initiated independently at the University of Texas in 1942 an attempt was made to iodinate this substance in a sodium hydroxide solution. This was abandoned, however, in favor of iodination with iodine monochloride. Shortly after this latter work was under way it was learned through correspondence that the iodination had been accomplished at the University of Oklahoma. The present paper presents the results of the investigations conducted independently at both institutions.

finding is in accord with earlier investigations[9] involving diortho substituted phenols.

The introduction of one nitro group into 3-iodo-4-hydroxybiphenyl was accomplished by a method[4] previously used in the mononitration of 4-hydroxybiphenyl.

Acknowledgment.—The writers are indebted to Professor G. W. Watt of the University of Texas for a supply of liquid ammonia used in the analysis, and to the Research Institute of the University of Texas for a grant permitting the continuance of this work.

Experimental

3-Iodo-4-hydroxybiphenyl.—(a) 2.0 g. of 4-hydroxybiphenyl was dissolved in warm ammonium hydroxide and cooled as low as possible without causing the phenol to separate. The molecular equivalent (*i. e.*, three grams) of iodine was dissolved in a potassium iodide solution and diluted to the basis of 3.0 g. of iodine per 500 cc. of solution. The reagent was added at the surface of the solution with as rapid stirring as possible, the addition requiring one hour. Best results were obtained using only diffused light. Following filtration, which should be rapid, the filtrate was cooled in an ice-bath and the phenol precipitated by addition of a 10% solution of sulfuric acid. During addition of acid decomposition occurred unless the temperature were held below 35°. The white needle-like precipitate was filtered rapidly, care being taken to avoid drawing air through the residue, *i. e.*, the last of the filtrate was obtained by gravity filtration. The crystals were washed with water and air dried in a dark place. Final drying was completed *in vacuo*. The yield of crude material was 91.1% and the melting point 108–109°. Analysis for iodine was made by sodium peroxide fusion followed by titration with silver nitrate. Recrystallization from chloroform by addition of petroleum ether raised the melting point to 115–116°.

Anal. Calcd. for $C_{12}H_9OI$: I, 42.86. Found: I, 43.16.

(b) 4-Hydroxybiphenyl (17 g.) was dissolved in a solution of 35 g. of sodium hydroxide in 600 ml. of water. This solution was heated in order to dissolve the 4-hydroxybiphenyl completely and was subsequently cooled until the 4-hydroxybiphenyl began to precipitate. Iodine (25.4 g.) dissolved in 200 ml. of an aqueous solution of potassium iodide (25.4 g.) was then added over a period of two hours. At the end of this time the mixture was acidified with dilute hydrochloric acid, causing 27 g. of a white precipitate to separate. After several recrystallizations a small amount of pure 3-iodo-4-hydroxybiphenyl was obtained.

(c) Seventeen grams of 4-hydroxybiphenyl was dissolved in 40 ml. of glacial acetic acid upon being heated on a steam-bath. Iodine monochloride (20.4 g.), Eastman Kodak Co. grade, dissolved in glacial acetic acid (14 ml.) was added dropwise to the above solution over a period of twenty minutes. The reaction proceeded readily with the liberation of hydrogen chloride. Heat was also liberated as the reaction proceeded. After complete addition of the iodine monochloride solution the mixture was heated gently on a steam-bath with constant stirring for an additional two hours. At the end of this time the resultant solution was cooled to room temperature and poured into ice-water. The precipitate which separated was filtered and dissolved in chloroform. The chloroform solution was then washed with an aqueous solution of sodium bisulfite to remove the excess iodine. It was washed with water and dried over anhydrous sodium sulfate. The solution was filtered and approximately three-fourths of the chloroform was removed under reduced pressure. A white precipitate separated on cooling the solution in an ice-bath. After two recrystallizations from a mixed solvent of one-third chloroform and two-thirds petroleum ether (b. p. 30–35°), 18 g. of white needles was obtained which melted at 115–116°; yield of recrystallized material, 60.8%.

A more direct procedure for removal of the excess iodine from the iodinated product involved addition of an aqueous solution of sodium bisulfite directly to the acetic acid solution after iodination had taken place. Removal of the impure 3-iodo-4-hydroxybiphenyl by filtration followed by recrystallization from the mixed solvent named above yielded the pure substance in approximately the same quantity as by the other method.

Anal. Calcd. for $C_{12}H_9OI$: I, 42.86. Found: I, 42.75.

Benzoylation of 3-Iodo-4-hydroxybiphenyl.—To a cooled solution of 2 g. of 3-iodo-4-hydroxybiphenyl in 20 ml. of pyridine, 2 ml. of benzoyl chloride was added slowly, with shaking. The mixture was heated for one hour on a steam-bath. On cooling to room temperature, following which the mixture was poured into a large volume of ice-water, a precipitate separated. The precipitate was filtered and washed successively with 10% sodium hydroxide solution, a dilute hydrochloric acid solution and water. The product was recrystallized from ethanol. The white crystals were obtained in a yield of 1.2 g., or 44.4% and melted at 99.5–100°. The Schotten–Baumann method gave a 68.2% yield of the benzoate melting at 91–92°.

Anal. Calcd. for $C_{19}H_{13}O_2I$: I, 31.71. Found: I, 31.35.

Nitration of 3-Iodo-4-hydroxybiphenyl.—Two grams of 3-iodo-4-hydroxybiphenyl was dissolved in 20 cc. of glacial acetic acid and 0.43 cc. of concd. nitric acid dissolved in 5.0 cc. of glacial acetic acid added slowly to the cooled solution. Nitration occurred slowly and the product was recovered by pouring the solution into ice-water. Recrystallization from 50% alcohol gave a 62.4% yield of 3-iodo-5-nitro-4-hydroxybiphenyl; m. p. 95–100° with decomposition.

Anal. Calcd. for $C_{12}H_8O_3NI$: I, 37.21. Found: I, 37.24.

Attempted Diiodination of 4-Hydroxybiphenyl.—4-Hydroxybiphenyl (8.5 g.) was dissolved in 600 ml. of an aqueous solution containing 36 g. of sodium hydroxide. To this solution was added, dropwise, over a period of two hours, 200 ml. of an aqueous solution containing 25.4 g. of potassium iodide and 25.4 g. of iodine. At the end of the addition dilute hydrochloric acid was added to the resultant mixture until the solution was acid to litmus. A yellow precipitate (17.6 g.) separated which was thought to be 3,5-diiodo-4-hydroxybiphenyl. This material, upon recrystallization from an alcohol–water mixture, melted with decomposition at 170–171°.

An analysis of the above compound indicated that apparently a mono iodinated product was formed. It was assumed then that a second reaction had taken place with the formation of an aristol. A Rast molecular weight determination was then made on the compound. It was found that 0.0132 g. of the compound dissolved in 0.091 g. of camphor lowered the melting point of camphor 9°. This indicated a molecular weight of 637. The theoretical molecular weight of the aristol is 590.

Anal. Calcd. for $C_{24}H_{16}O_2I_2$: I, 43.01. Found: I, 42.08.

No further investigation was made on this compound.

3,5-Diiodo-4-hydroxybiphenyl.—(a) The ammonium salt of this phenol was obtained by dissolving 2.0 g. of 4-hydroxybiphenyl in 350 cc. of warm ammonium hydroxide followed by cooling as low as possible without precipitation. Six grams of iodine in one liter of potassium iodide solution was added with rapid stirring over a period of one hour. Upon the first appearance of a dark residue the dropwise titration was discontinued since otherwise the solution became dark. This appearance which is also mentioned by Harington appears after the addition of about 95% of the iodine. The white precipitate was filtered by gravity, light being excluded. Upon drying in a cool, dark place, a 79.5% yield of the ammonium salt of 3,5-diiodo-4-hydroxybiphenyl was obtained; m. p. for the white crystals, 95–97°. Upon standing the precipitate

slowly turned yellow, the melting point falling to 92–93°. The yellow samples upon analysis appeared to have lost iodine.

Anal. Calcd. for $C_{12}H_8OI_2$: I, 57.86. Found: I, 55.10.

The 3,5-diiodo-4-hydroxybiphenyl set free from a sample of this ammonium salt gave white needles which readily decomposed.

(b) Seventeen grams of 4-hydroxybiphenyl was dissolved in 40 ml. of glacial acetic acid. To this mixture, 45 g. of iodine monochloride dissolved in 25 ml. of glacial acetic acid was added dropwise over a period of one-half hour. The mixture was then refluxed on a steam-bath for two hours. Hydrogen chloride gas was liberated freely during the reaction. After this treatment the mixture was cooled to room temperature and poured into a large volume of ice-water. A pale yellow solid and an oily, brown substance separated. Solid sodium bisulfite was added to the mixture in order to remove the iodine to some extent. The water soluble constituents of the mixture were decanted and the remaining portion extracted with carbon tetrachloride. The carbon tetrachloride solution was washed with sodium bisulfite solution which removed the remaining iodine and was then washed with water and dried over anhydrous sodium sulfate.

After the solution had dried, its volume was reduced to one-fourth the original volume by distillation under reduced pressure. Addition of petroleum ether to the remaining solution caused 21 g. of a white precipitate to separate. After dissolving the precipitate in chloroform and precipitating it from solution by the addition of petroleum ether several times and finally recrystallization from the mixed solvent of one-third chloroform and two-thirds petroleum ether (b. p. 30–35°), the yield was reduced to 4.8 g. The pure white solid melted at 86–87°.

Anal. Calcd. for $C_{12}H_8OI_2$: I, 60.15. Found: I, 60.07.

Benzoylation of 3,5-Diiodo-4-hydroxybiphenyl.—The procedure used to prepare 3,5-diiodo-4-benzoxybiphenyl was the same as given above for the preparation of 3-iodo-4-benzoxydiphenyl. The product was recrystallized from ethanol. The resulting white needles melted at 159–160°.

Anal. Calcd. for $C_{19}H_{12}O_2I_2$: I, 48.24. Found: I, 47.80.

Attempted Triiodination of 4-Hydroxybiphenyl.—Several attempts were made to prepare this compound in the manner described above for the mono- and diiodination of 4-hydroxybiphenyl by varying the solvent, the time of reaction and external heat applied. In each attempt, however, isolation of the desired product was unsuccessful.

Summary

4-Hydroxybiphenyl has been mono- and diiodinated forming 3-iodo-4-hydroxybiphenyl and 3,5-diiodo-4-hydroxybiphenyl, respectively. They were identified by analysis and analogy to the chlorination and bromination products of 4-hydroxybiphenyl.

Attempts to triiodinate 4-hydroxybiphenyl were unsuccessful.

The benzoate derivatives of the above mono- and diiodo-hydroxybiphenyls have been prepared. The mononitro derivative of 3-iodo-4-hydroxybiphenyl also has been obtained.

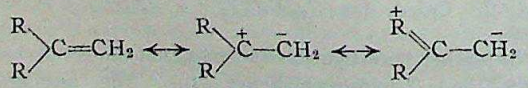
The Condensation of Naphthoquinones with Polar Ethylenes

BY MARSHALL GATES

In 1939 Wizinger and Coenen[1] showed that a carbon–carbon bond could be established by displacement of chlorine from polynitro aromatic chlorides using as displacing agents certain unsymmetrically substituted ethylenes.

The ethylenes involved were of the type whose members readily form halochromic salts and show reactions with other types of electron acceptors.[2] Their reactions indicate large contributions from forms in which the ethylenic link is polarized



Since many of the reactions of quinones involve the addition of a molecule with an unshared electron pair to the conjugated system of the quinone, it might be expected that a carbon–carbon bond could be established by the action of a polar ethylene of the above-mentioned type acting as an electron donor on a quinone acting as an electron accepting center. This expectation was fully realized and a number of condensations of this type were found to take place with ease.

To provide a trial free from the complicating side reactions which might be expected of benzoquinone, the action of 1,1-bis-(*p*-dimethylaminophenyl)-ethylene (I) on α-naphthoquinone was studied. On mixing these two reagents in benzene, acetone or dioxane, an intense deep purple color is produced immediately even at room temperature, and on standing the solution deposits beautiful fine purple needles of 2-(1′,4′-

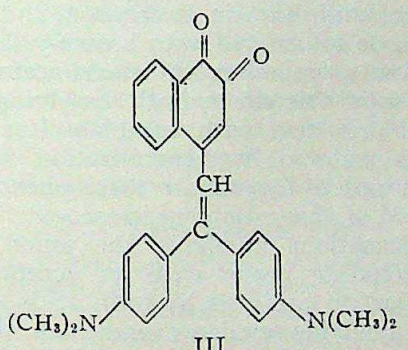
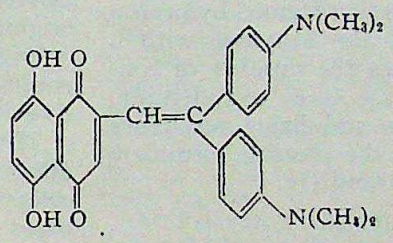
naphthoquinonyl-2′)-1,1-bis-(*p*-dimethylaminophenyl)-ethylene (II). The best preparative procedure for this condensation product involves heating two molecular equivalents of quinone with one of ethylene to 70° for twenty-four hours in dioxane. Under these conditions II separates in a directly pure condition in 59% yield, m. p. 271–272.5° (cor.). From the filtrate α-naphthohydroquinone, characterized as its diacetate and by oxidation to the starting quinone, was obtained in 95% yield (crude). The expected reaction course, in which the intermediate hydroquinone of II is oxidized to the quinone at the expense of a molecule of starting quinone, is followed. The sparingly soluble condensation product II was characterized by analysis and by reductive acetylation to a greenish-yellow leucodiacetate.

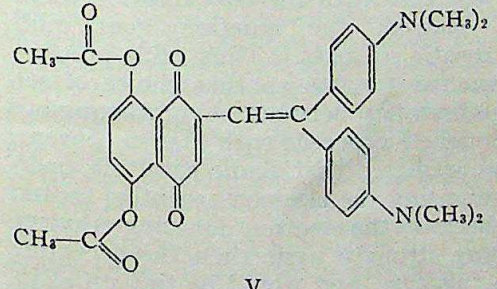
Using freshly prepared β-naphthoquinone, an even more facile condensation afforded 2-(1′,2′-



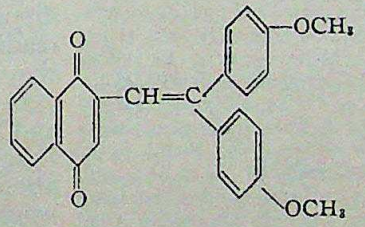
III



IV



V



VI

naphthoquinonyl-4′)-1,1-bis-(*p*-dimethylaminophenyl)-ethylene (III) as deep blue-black needles (indigo blue in solution) in 83.7% yield. It was characterized as its deep red azine and as its canary-yellow leucodiacetate. Other successful condensations using the same ethylene include those with naphthazarin and naphthazarin diacetate, leading to the related condensation products IV and V, respectively.

Although poor yields were obtained in the case of the naphthazarin derivatives, purification losses were high and it is believed that the yields of pure material do not reflect the extent of condensation. The condensation product from naphthazarin crystallizes from benzene in beautiful black needles which exhibit a faint deep green surface luster, m. p. 306–308° (uncor.). Naphthazarin diacetate gives V as an amorphous indigo-blue solid, m. p. 261–264°, which can be hydrolyzed to IV with acid. The sparingly soluble 5,8-diacetoxy-1,4-naphthohydroquinone was isolated in 58% yield as the expected by-product.

Condensation of the desired type was not obtained using 2-methyl-1,4-naphthoquinone and I. A compound apparently derived from two moles of quinone and one of ethylene was obtained in low yield but its structure has not been established. The failure of 2-methyl-1,4-naphthoquinone to undergo easy condensation was not entirely unexpected since Fieser and Seligman[3] showed that the presence of a methyl group in the quinonoid ring of 1,4-naphthoquinone materially reduces its ability to undergo 1,4-additions.

Extension of this reaction to the preparation of condensation products of 1,1-dianisylethylene was successful at least in the case of α-naphthoquinone. In keeping with the less highly polar nature of this ethylene, as exhibited by its weaker proton affinity,[1] condensation took place only slowly to give 2-(1′,4′-naphthoquinonyl-2′)-1,1-dianisylethylene (VI) as fine deep orange-red needles. An attempt to condense 1,1-dianisylethylene with β-naphthoquinone in methanol failed to yield a condensation product containing the ethylene, but in addition to 8% of 2-methoxy-1,4-naphthoquinone, gave rise to 43% of a high melting (275°) hydroquinone, $C_{22}H_{14}O_4$, containing two methoxyl groups. On methylation with dimethyl sulfate this gave the known[4] 3,4,3′,4′-tetramethoxy-1,1′-binaphthyl. The hydroquinone can

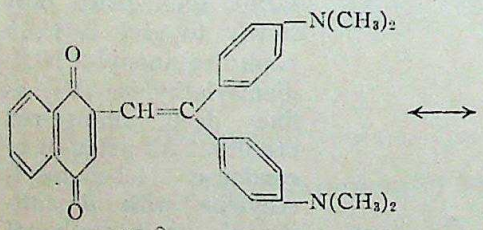
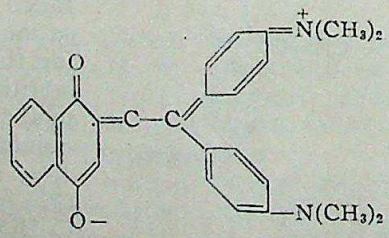
probably be assigned the structure VII, since oxidation with silver oxide gave the hitherto unknown dimethyl ether of Stenhouse and Groves's[5] "dinaphthyl diquinhydrone" as a deep magenta-colored quinone, m. p. 260–262° (VIII).

The deep purple-black condensation product II derived from α-naphthoquinone and 1,1-bis-(*p*-dimethylaminophenyl)-ethylene dissolves readily in 3 *N* hydrochloric acid to give a bright yellow solution. Dilution of this hydrochloric acid solution with a large volume of water causes the original quinone to separate as a purple-black solid. The bright scarlet 3 *N* hydrochloric acid solution of IV likewise precipitates the original blue-black solid on strong dilution. These observations indicate that condensation of 1,1-bis-(*p*-dimethylaminophenyl)ethylene with α-naphthoquinones results in a considerable decrease in basicity. An explanation of this is provided by a comparison of the structure of the free base with that of the cation formed by proton addition. Conjugation of the ethylene with a quinonoid nucleus increases the number of contributing forms of the free base considerably, and thereby increases the stabilizing resonance of the free base. Two of the possible forms are represented by formulas II and IIa.



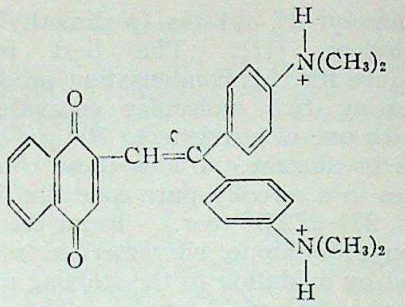
II



II a

On the other hand, this increased resonance is not shown by the cation, in which the electron pairs responsible are tied up by covalent bond formation with the added proton or protons. This results in stabilization of the free base over the cation. The effect is greater in the condensation product than in the original ethylene and thus the condensation product is the weaker base. Formula IX represents a possible structure for the cation.

Related to the above phenomena are the color changes which occur on solution of these condensation products in moderately concentrated solutions of strong acids. Thus the deep purple-black II gives a bright yellow solution, IV gives



IX

a brilliant scarlet-red solution, and III (deep indigo blue) gives an orange-brown solution in 3 *N* hydrochloric acid. Since deep color is associated with the high electronic mobility of extensively conjugated systems to which many forms contribute,[6] elimination of part of these contributing forms as shown above should lighten the color.[7] Qualitatively, at least, elimination of this resonance restores the color attributable to the original quinones alone, since α-naphthoquinone is bright yellow, naphthazarin is crimson, and β-naphthoquinone is golden-yellow to brown-yellow. Even the yellow to yellow-green leucodiacetates of II and III show this effect, both dissolving in dilute hydrochloric acid with complete loss of color which is restored by neutralization with bases. It is hoped to investigate these phenomena with the aid of absorption spectroscopy.

Many condensations involving the union of an electron donating group with an accepting center are subject to catalysis by both acids and bases.[8] The available evidence indicates that this is not the case with the condensation under discussion. Indeed, the reaction goes quite readily in aprotic solvents. Thus while preparative convenience dictates another choice of solvent the condensation between α-naphthoquinone and the ethylene I proceeds with ease in benzene. It might be predicted that acidic catalysis, operating by activating the electron accepting center, would fail because the electron donating ethylene is much more strongly basic than the accepting quinone in this case, and would be tied up as its inactive salt. This prediction is verified by the complete failure of the reaction to proceed when glacial acetic acid is used as solvent.

Somewhat similar considerations indicate that basic catalysis is also unlikely. This type of catalysis, ordinarily effective because of proton capture from the electron donating component, cannot activate the donor in this case, since the donor is already basic and tends to gain rather than lose a proton. Experimentally it is found that even with the least basic ethylene examined (1,1-dianisylethylene), condensation with α-naphthoquinone goes with optimum yields when

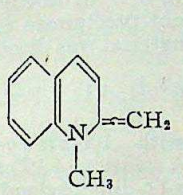
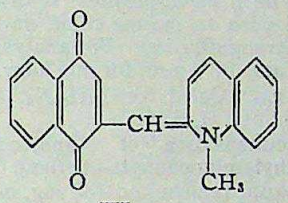
no added basic catalyst (dimethylaniline) is present.

It is planned to extend this work to other series of quinones and polar ethylenes, and at least a start has been made in this direction. Thus with the expectation of obtaining XI, α-naphthoquinone has been condensed with N-methyl-2-methylene-1,2-dihydroquinoline (X), although the condensation product has not been fully characterized



X



XI

The relationship of this condensation product to the cyanine dyes is apparent. Other members of this series should be available by this condensation.

An examination of the oxidation–reduction potentials of these condensed quinones should provide interesting data, and such determinations are to be made at the earliest opportunity.

The interruption of this work for the duration of the national emergency has prompted publication of the present incomplete report.

Experimental Part[9,10]

2-(1′,4′-Naphthoquinonyl-2′)-1,1-bis-(*p*-dimethylaminophenyl)-ethylene (II).—A solution of 1.16 g. of α-naphthoquinone in 15 ml. of warm dioxane was added to 0.973 g. of 1,1-bis-(*p*-dimethylaminophenyl)-ethylene[11] dissolved in 15 ml. of the same solvent. A dark purple-red color appeared immediately. The mixture, protected from light, was heated to 70° for twenty-three hours in a flask closed with a rubber stopper, then allowed to cool for four hours. The beautiful blue-black needles which had separated were collected and washed with cold dioxane; yield 906 mg. (59%), of directly pure material, m.p. 270.5–272°. The condensation product is very sparingly soluble in alcohol, acetone and glacial acetic acid, moderately soluble in boiling dioxane with a deep purple-blue color. Its solution in concentrated sulfuric acid is deep red-brown in color. It dissolves in 3 *N* hydrochloric acid to give a bright yellow solution, which on strong dilution with water gives first a greenish-yellow solution which then deposits the original material as a blue–black solid. A small portion was recrystallized twice from dioxane and dried at 78° and 0.1 mm. for analysis, m.p. 272–273.5°.

Anal. Calcd. for $C_{28}H_{26}O_2N_2$: C, 79.59; H, 6.20; N, 6.63. Found: C, 79.45; H, 6.04; N, 6.72.[12]

The original dioxane filtrate was diluted with somewhat more than an equal volume of water, then strongly acidified with dilute hydrochloric acid. The dirty brown solution thus obtained was extracted twice with ether, the ether layers washed with dilute hydrochloric acid, saturated brine, decolorized with norite, filtered through anhydrous sodium sulfate, concentrated and diluted with 30–60° petroleum ether to incipient crystallization. On cooling, 437 mg. of impure material, m. p. 175–179° with decomposition, was obtained. A second crop of 119 mg. was obtained from the filtrate; yield 95% (crude). Attempts to recrystallize this material from dilute alcohol in the presence of a little stannous chloride and hydrochloric acid were unsuccessful. Accordingly, 177 mg. was dissolved in 1 ml. of pyridine and treated with 0.5 ml. of acetic anhydride. After standing two hours, the mixture was heated to boiling and poured into water. The precipitated material was taken into ether, washed with dilute alkali several times, then with brine, filtered through anhydrous sulfate, and concentrated nearly to dryness. The residue on crystallization from alcohol afforded 127 mg. of light tan blades, m. p. 128–130°. Recrystallization gave 92 mg., m. p. 129–130°. Korn[13] records 128–130° for the m. p. of 1,4-diacetoxynaphthalene.

The remainder of the material, dissolved in alcohol–acetone, was treated with 1 g. of ferric chloride dissolved in dilute hydrochloric acid. A crop of orange-brown needles separated. These were collected, taken into ether, the ethereal solution treated with norite, filtered, concentrated, and diluted with petroleum ether. A crop of acicular blades separated, 86 mg., m. p. 121.5–125°. After recrystallization from ether, the material melted at 123.5–125.5° and did not depress the melting point of an authentic sample of α-naphthoquinone.

The original orienting experiments on this condensation were carried out using benzene as a solvent. The condensation takes place readily under these conditions but the by-product α-naphthohydroquinone is sparingly soluble in this solvent and contaminates the product. It can also be carried out in refluxing acetone to give good yields. However, the procedure given above yields the best product and is preferred.

The following describes an unsuccessful attempt to carry out the condensation using glacial acetic acid as a solvent. To the brilliant deep blue-green solution of 976 mg. of 1,1-bis-(*p*-dimethylaminophenyl)-ethylene in 6 ml. of glacial acetic acid was added a warm solution of 1.16 g. of α-naphthoquinone in 4 ml. of glacial acetic acid. Another 2 ml. of acid was used to wash in the quinone. The mixture was heated to 70° for sixty-seven hours, then allowed to cool. No crystalline material had deposited after standing for twenty-four hours. The desired product is very sparingly soluble in glacial acetic acid (74 mg. in 100 ml. at room temperature).

2-(1′,4′-Diacetoxynaphthyl-2′)-1,1-bis-(*p*-dimethylaminophenyl)-ethylene.—The condensation product II was reductively acetylated as follows: 502 mg. of II dissolved in 10 ml. of hot pyridine was treated with 0.4 g. of zinc dust and 5 ml. of acetic anhydride. On addition of the acetic anhydride the deep purple-black color changed to a light yellow-tan marked by an intense greenish fluorescence.

After standing ten minutes, the zinc was filtered off and washed with ether, the filtrate diluted with ether, washed three times with water, then three times with dilute alkali, once with water, finally with brine, and filtered through anhydrous sodium sulfate. The yellow solution thus obtained had the same intense greenish fluoresence observed in the reaction mixture. After removal of the ether the residual deep brown viscous oil on triturating under hexane solidified to a brown-yellow solid, 628 mg. (605 theoretical) m. p. 201–211°. In contrast to the starting quinone, this leucodiacetate crystallizes only with difficulty and purification was costly. The crude material (550 mg.), dissolved in the minimal quantity of hot dioxane was treated with a little hot water and allowed to cool. The first crop separated as a glassy crust, 205 mg., m. p. 227–230°, with decomposition. Dilution of the filtrate with alcohol gave 97 mg., m. p. 225–226°, dec. These two crops were combined, dissolved in the minimal quantity of hot dioxane, diluted with an equal volume of hot alcohol and allowed to crystallize. The solution still showed an intense fluorescence. Small compact prisms adhering to the walls of the flask were obtained, 181 mg., m. p. 228–230° with decom-

(9) All melting points are corrected except those specifically described as uncorrected.

position. Two further crystallizations gave small yellow-tan prisms, m. p. 230–231° with decomposition. The m. p. depends somewhat on the rate of heating. For analysis the material was dried for three hours at 78° and 0.1 mm. It is sparingly soluble in alcohol, fairly soluble in acetone, and readily soluble in dioxane. Its solution in concentrated sulfuric acid is orange-red appearing canary-yellow to greenish-yellow in thin layers. It is soluble with complete loss of color in 3 *N* hydrochloric acid. Neutralization with dilute alkali gives a bright yellow precipitate of the unchanged leucodiacetate.

Anal. Calcd. for $C_{32}H_{32}O_4N_2$: C, 75.56; H, 6.34. Found: C, 75.20; H, 6.23.

2-(1′,2′-Naphthoquinonyl-4′)-1,1-bis-(*p*-dimethylaminophenyl)-ethylene (III).—To 2.32 g. of β-naphthoquinone[14] in 30 ml. of warm methanol was added a solution of 1.95 g. of 1,1-bis-(*p*-dimethylaminophenyl)-ethylene in 50 ml. of warm methanol. An immediate deep blue-green color was produced which on heating to boiling rapidly gave way to a deep indigo blue. At the end of a few minutes the product began to separate as fine violet-black prismatic blades. The reaction mixture was allowed to stand overnight at room temperature, then the product was collected and washed with cold methanol until the filtrate was clear blue with no reddish-purple tinge. After air drying, 2.58 g. (83.7%) of material, m. p. 194–196° was obtained. It is rather sparingly soluble in methanol, fairly soluble in hot acetone and dioxane to give deep indigo blue solutions. Its solution in concentrated sulfuric acid is a deep ultramarine color. It dissolves in 3 *N* hydrochloric acid with a brown color. Dilution has no effect on this color, nor does it cause precipitation of the free base. A small sample was recrystallized twice from acetone–methanol, then dried at 100° and 10^{-4} mm. for one hour, m. p. 199–201°, with gas evolution.

Anal. Calcd. for $C_{23}H_{26}O_2N_2$: C, 79.59; H, 6.20; N, 6.63. Found: C, 79.40; H, 6.10; N, 6.81.[15]

2-(1′,2′-Diacetoxynaphthyl-4′)-1,1-bis-(*p*-dimethylaminophenyl)-ethylene.—To 630 mg. of the condensation product III suspended in 5 ml. of acetic anhydride was added 0.4 g. of zinc dust, then 10 ml. of pyridine. The deep blue suspension rapidly gave way to a greenish-yellow fluorescent solution. After standing for fifteen minutes, the zinc dust was filtered off, washed with ether, then twice with hot pyridine, then again with ether. The light yellow filtrate was diluted with water, the yellow ethereal layer was separated, washed three times with water and then extracted twice with dilute hydrochloric acid. The nearly colorless acid layer on neutralization with solid sodium bicarbonate yielded a canary-yellow solid. A third acid extract gave no precipitate on neutralization. After air drying, this precipitate amounted to 738 mg. (97.4%), m.p. 95–102°. The material is sparingly soluble in cold methanol, readily soluble in benzene and chloroform. Its solution in hot acetone on cooling deposits the material as beautiful canary yellow needles, m. p. 92.5–94.5°, but the yield on crystallization is poor. Successive crops afforded a total of 541 mg. (71.5%), m. p. 93–94°. To avoid prohibitive crystallization losses, a mixture of acetone–hexane was used for subsequent purification of an analytical sample. The material is obtained in partially solvated form from mixtures containing acetone. Thus a sample of the above material after two further crystallizations melted at 96–96.8°, but after drying one hour at 78° and 10^{-4} mm., the m. p. was raised to 105.6–106.8°. It is soluble in concentrated sulfuric acid with a deep orange-red color which changes to red-purple on standing. Its solution in 3 *N* hydrochloric acid is colorless. Neutralization precipitates the bright yellow solid.

Anal. Calcd. for $C_{32}H_{32}O_4N_2$: C, 75.56; H, 6.34. Found: C, 75.59; H, 6.64.

Azine of Condensation Product III.—A solution of 619 mg. of III and 168 mg. of *o*-phenylenediamine in 10 ml. of benzene was treated with 1 ml. of glacial acetic acid. On addition of the acetic acid and slight warming, the color changed from the original blue to a deep red-brown. The mixture was heated under reflux for ten minutes, then diluted with an equal volume of hexane and set aside. Collection of the crystallizate afforded 645 mg. (89%) of deep red prismatic needles, m.p. 244–246°, softening from 241°. Three further crystallizations of a small sample from benzene–hexane gave ruby-red blades, m. p. 246–247.5°. The azine is rather sparingly soluble in alcohol and acetone, readily soluble in hot acetic acid, hot dioxane or hot benzene. Its solution in concentrated sulfuric acid is a deep black-purple. It dissolves in 3 *N* hydrochloric acid with an orange color, and does not precipitate even on strong dilution. For analysis the material was dried at 78° and 10^{-4} mm. for one hour.

Anal. Calcd. for $C_{34}H_{30}N_4$: C, 82.56; H, 6.11. Found: C, 82.94; H, 6.15.

Condensation of Naphthazarin with 1,1-Bis-(*p*-dimethylaminophenyl)-ethylene (IV).—A solution of 190 mg. of naphthazarin and 133 mg. of 1,1-bis-(*p*-dimethylaminophenyl)-ethylene in 15 ml. of benzene was brought to boiling, then heated for twenty-four hours at 74° in the dark. The resulting deep red-purple solution was concentrated somewhat and set aside to crystallize. The crude material which separated was collected and recrystallized from benzene to give 54 mg. of black needles, m. p. 303–305° (uncor.). Recrystallization from hot benzene (deep blue-purple solution) gave 37 mg. of beautiful black needles with a faint deep green surface reflex, m. p. 306–308° (uncor.). Its solution in concentrated sulfuric acid is a beautiful intense deep purple color. It dissolves in 3 *N* hydrochloric acid with a deep crimson color, and on strong dilution separates out as a blue-black solid. A small amount suspended in alcohol (very sparingly soluble) gives a deep cornflower blue color on treatment with a drop of dilute alkali. The cornflower blue alkali salt thus formed is rather insoluble in water, but has some solubility in alcoholic solutions. The color produced is very similar to that produced when naphthazarin itself is treated with alkali. For analysis the material was dried at 78° and 10^{-4} mm. for one hour.

Anal. Calcd. for $C_{28}H_{26}O_4N_2$: C, 73.99; H, 5.77. Found: C, 74.27; H, 5.40.

A larger run using dioxane as a solvent gave 233 mg. of crude material, m. p. 290–296° (uncor.), starting from 500 mg. of naphthazarin, but attempts to purify this by solution first in dilute alcoholic alkali, then in dilute hydrochloric acid resulted in prohibitive losses, although a small amount of excellent material was obtained.

Condensation of Naphthazarin Diacetate with 1,1-Bis-(*p*-dimethylaminophenyl)-ethylene (V).—A solution of 402 mg. of naphthazarin diacetate[16] in 8 ml. of hot dioxane was treated with 192 mg. of 1,1-bis-(*p*-dimethylaminophenyl)-ethylene in 2 ml. of dioxane and heated to 78° for ninety hours protected from light. The reaction mixture became brown immediately, then gradually darkened to purple-red. Some very small well-formed colorless prisms separated along with some dark purple-red solid. The mixture of solids was filtered off (air dried, 286 mg.) and recrystallized once from dioxane and once from ethyl alcohol to give 133 mg. of colorless prismatic plates of 5,8-diacetoxy-1,4-naphtholhydroquinone,[17] m. p. 249–250°. The filtrate was diluted with water and the blue-black solid which precipitated was filtered off. In contrast to the other condensation products described, this material was not easily obtained in crystalline form. From its strongly concentrated dioxane solution only amorphous material separated (88 mg., m. p. 253–257°). Very slow recrystallization of this material yielded amorphous material along with some needles. A further crystallization gave 60 mg. of blue-black amorphous material, m. p. 261–264°. It is very sparingly soluble in alcohol, soluble in acetone, dioxane or benzene. Its solution in sulfuric acid is a beautiful deep purple color. It dissolves in 3 *N* hydrochloric acid to give a bright yellow solution which acquires a

greenish tinge on dilution but fails to precipitate. For analysis the material was dried at 78° and 10^{-4} mm. for two hours.

Anal. Calcd. for $C_{32}H_{30}O_6N_2$: C, 71.36; H, 5.61. Found: C, 71.25; H, 5.23.

The material is readily hydrolyzed to the parent naphthazarin derivative as the following experiment shows.

A solution of 42 mg. of crude condensation product (m. p. 250–255°) in 3 ml. of dilute hydrochloric acid was heated to boiling for five minutes. As the solution was heated, the color changed from yellow-green to deep crimson. The hydrolytic mixture was diluted with water, neutralized with solid sodium bicarbonate, the precipitated blue-black solid was taken into benzene, filtered, concentrated and set aside to crystallize. Beautiful black needles of IV (20 mg.), m. p. 307–308° (uncor.), were obtained.

Condensation of 2-Methyl-1,4-naphthoquinone with 1,1-Bis-(*p*-dimethylaminophenyl)-ethylene.—The reddish purple methanol solution of 645 mg. of 2-methyl-1,4-naphthoquinone and 500 mg. of 1,1-bis-(*p*-dimethylaminophenyl)-ethylene was heated to boiling, then allowed to stand at room temperature. A considerable portion of the ethylene separated on cooling. After standing in the dark without attention for one month, the original color had changed to a deep green and small nodules of dark crystalline material had separated. These were quite insoluble even in the boiling solvent, and on collection appeared greenish gray. The material was taken into dioxane to give a deep purple solution which on crystallization yielded 311 mg. of light tan platelets, m. p. 285–295° (uncor.). Two further crystallizations from dioxane gave 105 mg. of yellow plates which when introduced into a copper melting point block at 290° melted at 298–300° (uncor.) after drying at 78° and 10^{-4} mm. for two hours. The melting point depends on the rate of heating. This material is soluble in dilute hydrochloric acid but is insoluble in alkali even on boiling. Its solution in concentrated sulfuric acid is a bright purple-blue which fades to a paler green-blue on standing. Analytical figures indicate that it is derived from two moles of quinone and one of ethylene. It has not been further characterized.

Anal. Calcd. for $C_{40}H_{40}O_4N_2$: C, 78.40; H, 6.58. Calcd. for $C_{40}H_{38}O_4N_2$: C, 78.66; H, 6.27. Found: C, 78.47; H, 6.57.

2-(1′,4′-Naphthoquinonyl-2′)-1,1-dianisylethylene (VI).—A solution of 500 mg. of α-naphthoquinone and 38 mg. of 1,1-dianisylethylene[2] in 10 ml. of methanol was refluxed for six days, when a small amount of the ethylene remained undissolved. After a day, the mixture had turned a dirty gray-green color and small amounts of bright orange fluffy solid could be discerned. At the end of the refluxing period the reaction mixture was filtered hot, the insoluble material washed thoroughly with hot methanol, then taken into hot benzene. After filtration to remove a small amount of dark green-brown material insoluble in benzene, the filtrate was diluted with hot methanol and allowed to crystallize. Fluffy balls of very fine orange needles separated, 139 mg. (35% based on ethylene utilized), m. p. 209–210°. A second crop of 18 mg., m. p. 208–210° was obtained from the filtrate; total yield 39.4%. Two further crystallizations from benzene–methanol gave 105 mg. of fluffy balls of very fine orange needles, m. p. 211.8–212.3°. The substance is very sparingly soluble in methanol, readily soluble in hot benzene. Its solution in concentrated sulfuric acid is a deep blue to blue-green color. It is not soluble in dilute acids. The sample was dried at 78° and 10^{-5} mm. for two hours for analysis.

Anal. Calcd. for $C_{26}H_{20}O_4$: C, 78.77; H, 5.09; 2 OCH_3, 15.66. Found: C, 78.85; H, 4.76; OCH_3, 15.59.

The original methanol filtrate on concentration and crystallization yielded 138 mg. of recovered ethylene as tan plates, m. p. 140–141.5°.

Earlier attempts to carry out this preparation in dioxane using anhydrous zinc chloride as a catalyst were unsuccessful, although the reaction was not heated so long as in the example given above.

An effort to speed up the condensation and improve the yield by use of dimethylaniline as a catalyst was likewise unsuccessful, although a small amount of the desired product was obtained. A description of this experiment follows:

A mixture of 500 mg. of α-naphthoquinone, 380 mg. of 1,1-dianisylethylene, 4 drops of dimethylaniline and 25 ml. of methanol was heated in a closed pressure bottle at 78–80° for forty-eight hours. After cooling, the precipitated solid was filtered off and washed with methanol. The insoluble residue amounted to 257 mg. and contained particles of the characteristic orange condensation product. It was taken into boiling benzene, filtered from some dark gray-brown insoluble material (49 mg.) and diluted with an equal volume of hot methanol. The desired condensation product was obtained in poor condition as orange brown fluffs, 37 mg., m. p. 206.5–208°, mixed m. p. with material obtained as above, 207–208.5°.

The filtrate from this crop on concentration and crystallization afforded 100 mg. of felty, fine gray-tan needles, m. p. 136–139°, which after two crystallizations from pure methanol formed nearly colorless plates, m. p. 141–141.5°. A mixed m. p. with the starting ethylene was not depressed.

The original methanol filtrate on concentration and crystallization yielded 226 mg. of nearly black very impure material, m. p. 123–128°, probably largely unchanged ethylene.

Attempted Condensation of β-Naphthoquinone and 1,1-Dianisylethylene.—A solution of 1.00 g. of β-naphthoquinone and 760 mg. of 1,1-dianisylethylene in 30 ml. of methanol was heated to boiling and set aside in the dark. A part of the ethylene separated on cooling. After standing for one month, the solution was again heated to boiling. The ethylene dissolved, but considerable insoluble material remained. This was filtered off, dissolved in boiling dioxane to give a wine-red solution, and crystallized. Compact, red-brown prisms were obtained, 469 mg. (43% crude), m. p. 273–276°. While this material dissolved in boiling dioxane to give a deep wine-red solution, it was noticed that the refluxing solvent washed crystalline material adhering to the flask walls almost colorless. Therefore a small amount of stannous chloride dissolved in hydrochloric acid was added. This caused complete removal of the wine-red color, and after two crystallizations, 355 mg. of very pale pink prisms was obtained, m. p. 277.5–278.8°, becoming brown a degree or so below the melting point. One further recrystallization from dioxane containing stannous chloride and hydrochloric acid gave 313 mg. of nearly colorless material of the same melting point. Its solution in concentrated sulfuric acid was a very deep black to black green color. For analysis one sample was dried two hours at 100° and 10^{-3} mm., and another sample was sublimed at 200° and 10^{-3} mm.

Anal. Calcd. for $C_{22}H_{18}O_4$: C, 76.27; H, 5.24; 2 OCH_3, 17.92. Found: (crystallized sample) C, 76.18; H, 5.41. Found: (sublimed sample) C, 76.37; H, 5.24; OCH_3, 17.41.

Eighty-three mg. of this material was suspended in a small amount of potassium hydroxide solution containing some sodium hydrosulfite. Complete solution did not occur even after further dilution with water, but the hard prisms gave way to a very fine suspension. This suspension was treated with 0.2 ml. of dimethyl sulfate, stoppered, and vigorously shaken. The methylation was repeated, using additional dimethyl sulfate and more alkali. The agglomerated solid material was filtered off, washed with water, then with methanol, and crystallized from methanol. A considerable portion was lost accidentally, but the remainder afforded 27 mg. of small plates, m. p. 145–147°. One further crystallization gave material melting at 146.5–148.5° which showed no depression in melting point when mixed with an authentic sample of 3,4,3′,4′-tetramethoxy-1,1′-binaphthyl[4] prepared by methylating a vatted sample of dinaphthyldiquinhydrone[5] with dimethyl sulfate.

The original methanol filtrate on concentration yielded 428 mg. of unchanged ethylene, m. p. 139–141°, mixed m. p. 140.5–142°. The filtrate from this crystallization on

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

standing deposited 147 mg. (8%) of brick-red material, m. p. 177–180.5°. Recrystallization from methanol with the aid of charcoal gave 109 mg. light yellow needles, m. p. 180.5–181.5° whose mixed m. p. with an authentic sample of 2-methoxy-1,4-naphthoquinone of m. p. 181.2–182° was 180.5–181.7°.

Oxidation of VII.—A suspension of 40 mg. of VII, 200 mg. of silver oxide and some anhydrous magnesium sulfate in dioxane was warmed to facilitate solution. A brilliant deep magenta-purple was produced almost at once. After shaking for thirty minutes the suspension was heated to boiling and filtered. The deep magenta filtrate was concentrated to a small volume and set aside. An amorphous dark precipitate separated which was collected and washed with cold dioxane, yield 17 mg., m. p. 260–262°. When held above its melting point for a few minutes, the beautiful deep red melt fades to a yellow-brown. The material when dry possesses a deep greenish-bronze surface reflex. Its magenta-purple solution in dioxane on standing fades to a brown solution. A small amount in dioxane on treatment with dilute aqueous alkali fades through a tan to a light green-yellow solution. It dissolves in concentrated sulfuric acid with a deep green-black color. For analysis, the material was dried at 78° and 10^{-4} mm. for one hour.

Anal. Calcd. for $C_{22}H_{16}O_4$: C 76.73; H, 4.68; 2 OCH_3, 18.02. Found: C, 76.26; H, 4.79; OCH_3, 16.33.

Summary

1. Condensation reactions between 1,1-bis-(*p*-dimethylaminophenyl)-ethylene and α-naphthoquinone, β-naphthoquinone, naphthazarin, and naphthazarin diacetate as well as a similar condensation between 1,1-dianisylethylene and α-naphthoquinone have been described.

2. These condensations are those expected from a consideration of the electron donating capacity of the ethylene and the electron accepting capacity of the quinones involved. Present evidence indicates that the condensation is not catalyzed by acids or bases.

3. A discussion of certain points of interest in connection with the color and basicity of the condensation products is given.

The Structure of the "B" Modification of Starch from Film and Fiber Diffraction Diagrams[1]

BY R. E. RUNDLE, LESTER DAASCH AND DEXTER FRENCH

Introduction.—Of the unit cells proposed for the "A" (cereal) and "B" (tuber) modifications of a starch, those of Bear and French[2] are supported by the best diffraction data, and are altogether the most reasonable thus far proposed. Yet even their data, as they point out, were necessarily confined to those available from powder diagrams. Such data are not wholly adequate for the support of large unit cells for crystals of low symmetry, so that their results are left open to question.

Though the desirability of obtaining film and fiber diffraction diagrams for starch is obvious, attempts to prepare suitable films and fibers have been unsuccessful because whole starch was employed. The chief constituent of whole starch[3] is a highly branched component, amylopectin in Meyer's nomenclature,[4] where interruptions in the starch chains occur approximately every 20 glucose residues. The resulting unbranched portions of the chains are too short to produce satisfactory films or fibers.

Fortunately, it is now possible to isolate the unbranched (amylose) component present in most starches.[5] The unbranched chains in this component are probably in excess of 200 glucose units long,[6] and upon suitable treatment form both films and fibers. The production of these films and fibers and mention of the importance of their optical properties have been reported previously.[7] Recently Whistler and Hilbert have confirmed this property of amylose, finding that the acetate of this component of starch forms films with properties to be expected only for films of long, linear molecules.[8]

The diffraction diagrams from amylose retrograded at room temperature are quite like those from tuber starch granules and retrograded whole starch, so that the amylose component of starch can be used for the study of the crystalline portions of whole starch.

Preparation of the Samples.—A hot solution containing about 5% amylose is allowed to evaporate slowly, and the surface skins are removed carefully from time to time. The skins are allowed to dry on an aluminum sheet or ferrotype. Dry films thus prepared are only a few hundredths of a millimeter thick. The thicker films usually tend to curl or become distorted, but this can be overcome to some extent by doubling them while they are still wet.

Fibers which produce a "B" diffraction diagram are very difficult to prepare, and none that we have produced is of particularly high quality. The chief difficulty lies in the fact that plasticizers which can be used to aid in stretching produce fibers corresponding to new crystalline modifications of starch. These, of course, are of interest in

themselves, and are reported in another paper.[9] Without plasticizers, amylose films are brittle and cannot be stretched enough to produce a high degree of orientation. So far we have been able to use only water with the starch if a "B" diffraction diagram is to be obtained.

The following method is effective for the preparation of "B" type fibers. A 3% amylose solution is allowed to evaporate near the boiling point until it becomes quite viscous. At this point a wire frame with one side movable is dipped into the solution, and a film is prepared by extending the area of the film as much as possible without breaking the film. The film is then allowed to dry in the frame. Though very thin, the dry film can be removed from the frame and narrow strips cut from it. The strips can be stretched when moistened with water. Those which have been extended 50% or more show definite fiber orientation by X-ray diffraction. Similar techniques can be used with plasticizers added to the solution. Better orientation can then be produced in the fibers, but the plasticizers thus far employed alter the diffraction diagram of the amylose.[9]

Optical Properties.—The amylose films are highly birefringent, both wet and dry, and in convergent polarized light they show a typically uniaxial, optically negative, interference pattern. Fibers produced from the strips of amylose film retard light most if its electric vector is along the fiber axis. Optically the fibers are quite like cellulose and protein fibers in this respect. It is now certain that in the "B" modification the direction of greatest polarizability of the starch molecule is along its greatest length.[10]

X-Ray Diffraction Diagrams.—Diffraction diagrams of both films and fibers were made using Cu K radiation, Ni filtered. The amylose films were mounted with the normal to the film at right angles to the X-ray beam. Patterns of the fibers were made with the fiber axis normal to the beam. The patterns are not so sharp as those obtained from wet starch granules, probably because the samples were too dry to produce the best diffraction patterns. Both films and fibers become rather weak and gummy and hard to handle when moist, and wet fibers could not be kept under tension.

Indexing of the Diffraction Diagrams.—The layer line separation of the fiber diagram gives a fiber spacing of about 10.6 Å. This corresponds to none of the dimensions of the unit suggested by Bear and French.[2] Indeed the fiber spacing is not at all explained by any previous cells suggested for starch, yet the maxima are clearly those of the "B" modification of starch (Table I). In indexing the fiber and film patterns, and in the determination of the unit cell for the "B" modification, reference was made to the powder patterns of "B" starch, since on it diffuse maxima could be located with much greater accuracy than on the oriented patterns.

In Table I, column 3, values of $(2 \sin \theta/\lambda)^2 \times 10^4$ were obtained by measurement of patterns from wet potato starch, taken according to the technique suggested by Bear and French.[2] Cu Kα radiation was used. At angles greater than those which they list $[(2 \sin \theta/\lambda)^2 \times 10^4 = 860]$ the maxima are rather diffuse and many are quite weak in intensity. It is probable, therefore, that not all maxima have been observed to the largest spacing given in Table I. However, the more intense maxima in this region can be measured with considerable accuracy on good powder diagrams and are included in the table.

Examination of the equatorial reflections of the fiber pattern indicated that they could be indexed by the equation

$$\sin^2 \theta_{(h0l)} = 0.00230h^2 + 0.00705l^2 \quad (1)$$

This corresponds well with the equation for reflection $(hk0)$ of the Bear and French unit.[2] It was observed that differences in the $\sin^2 \theta$ values of the powder diagram frequently involved 0.00525 and 0.02100, corresponding to $\lambda^2/4b_0^2$ and λ^2/b_0^2, where b_0 is the fiber axis determined by layer line measurement. The equation

$$\sin^2 \theta_{(hkl)} = 0.00230h^2 + 0.00525k^2 + 0.00705l^2 \quad (2)$$

was then tested, both against the measurable reflections of the powder diagrams and the intensifications noted on film and fiber diagrams. The results are recorded in Table I.

The film and fiber diagrams provide the severest test of the indexing. From the fiber diagram the middle index can be determined beyond question, since $k = 0$ in the equator, $k = 1$ in the first layer line, etc.

A film corresponds to rotation of a fiber about a normal to the fiber axis. If b_0 is again taken as the fiber axis the type of intensification of the various planes (hkl) about what would be the powder arcs permits the evaluation of k. On the film diagrams it was possible to note the intensification only for the low order reflections, where $k = 0$ or 1. For reflections $(h0l)$, the intensification is greatest in the equator (Fig. 1). Doublets, with a plane (hkl) and a plane $(h0l)$, showed no

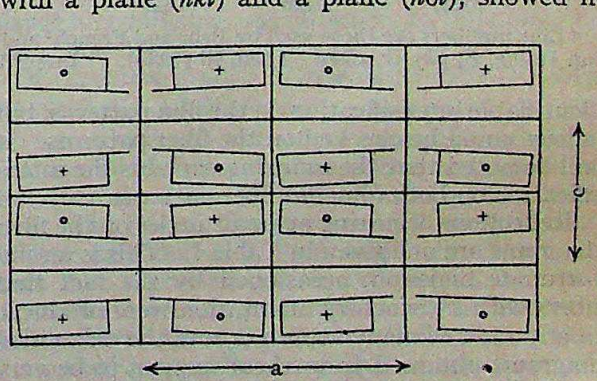

Fig. 1.—Symmetry requirements of space groups D_2^1 and D_2^2: Small circle indicates a chain running in one direction, across the other. For space group D_2^1 all chains running in the same direction are superimposable by translation along a_0 and c_0, together with rotation about b_0. D_2^2 differs only in that alternate chains running in the same direction are also transposed $^1/_2$ along b_0.

(9) R. E. Rundle and L. Daasch, *ibid.*, **65**, 2261 (1943).

(10) This statement has to be limited to certain modifications of starch, for in the "V" or helical configuration the greatest polarizability of the starch molecule is normal to its greatest length. See (7) and R. Rundle and R. Baldwin, *ibid.*, **65**, 554 (1943).

[a] Line numbers are those used by Bear and French[2] and correspond to the original numbering of the lines by Katz and van Itallie, *Z. physik. Chem.*, A150, 90 (1930). [b] Intensity notation—s, strong; m, moderate; f, faint and v, very.

identifiable intensification on the film patterns, but indices could be checked on the fiber patterns. It will be noted that the indexing explains the intensification on both film and fiber patterns.

Reflections occurring at small angles on the fiber diagrams are not given in Table I. This is an unfortunate omission, occasioned by the fact that fibers with satisfactory orientation were produced in but a few of many attempts, and the diffraction diagrams obtained from them happen to be very intense, with reflections at low angles obscured by the heavy background. Fortunately, the film patterns obtained are quite satisfactory for settling the middle index of these reflections.

The Unit Cell.—The unit cell dimensions, determined from the coefficients in equation (2), are

$a_0 = 16.0$ Å. $b_0 = 10.6$ Å. $c_0 = 9.2$ Å.

The cell is, within the limits of our observation, orthorhombic. The possibility cannot be excluded that the unit is monoclinic or triclinic with the angles between the axes very nearly 90°.

Two of the above dimensions, a_0 and c_0, are just those of the unit suggested by Bear and French.[2] Here, however, they are more unambiguously determined by the equatorial reflections on the fiber diagram. The fiber spacing, b_0, results directly from measurement of the layer-line spacings on the fiber diagram.

The volume of the unit cell of "B" starch is 1566×10^{-24} cc. If the density and water content assumed by Bear and French[2] are adopted, the carbohydrate density for starch is 1.23 g./cc. There are then 7.25 glucose residues per unit. The density, 1.50 g./cc., assumed by Bear and

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

French, corresponds to the bulk density of starch. It seems far more likely that the X-ray density of a substance as porous as starch should materially exceed its bulk density. If it be assumed that there are eight glucose residues per unit cell, the X-ray carbohydrate density is 1.36 g./cc., and if it be assumed that tuber starches contain about 15% water, the X-ray density for starch is about 1.60 g./cc., as contrasted with 1.50 g./cc. for bulk starch. It appears entirely reasonable that the X-ray density should exceed the bulk density of starch by this amount.

It is worthy of note, too, that granular starch is by no means 100% crystalline material. Whole starch, from whatever source, contains a branched component, the branch points of which cannot be within the starch crystallites. Preliminary experiments indicate that the crystalline portions of most ordinary, granular starches constitute about 50–60% of the total granule. One would expect the amorphous parts of the starch granule to be less dense than the crystalline regions, so for this reason too the average starch density should be less than the X-ray density reported here.

The Structure of the "B" Modification.—The present fiber patterns from starch are not yet of a quality to be compared with those obtained from cellulose and other naturally occurring fibers, so that any structure proposed for the "B" modification of starch must remain more tentative in nature than those proposed for chitin, cellulose, etc. Nevertheless, the dimensions of the unit cell and the apparent symmetry of the cell suggest the gross aspects of the structure.

Most important is the fiber spacing. It is very surprising to find this spacing perhaps even larger than that for cellulose.[11] Space models of starch using the usual strainless configurations of the pyranose ring or the semiplanar Cox model[12] would make it appear that the starch chains should be far more crumpled than those of cellulose, resulting in a much shorter fiber spacing. Regardless of the validity of the rest of the unit cell, however, the fiber spacing of the "B" modification can no longer be in doubt by more than a few tenths of an Å., and must be very closely equal to that of cellulose. It would appear that closer attention to the special arrangement of the ring than that afforded by building space-filling models is deserved.

The dimensions of the unit cell are quite similar to those of the chitin unit cell,[13] except that the 16 Å. spacing is increased to 19 Å. in chitin. In chitin the glucose residues are arranged with the planes of the glucose rings nearly parallel to the 19 Å. axis, the normals to the rings approximately parallel to the 9 Å. spacing. The width of the chitin unit is about 9.5 Å. It is interesting to note that it decreases to about 8.5 Å. when half the acetyl groups are removed from the residues, as in chitosan.[14] A width of 8 Å., or just half the 16 Å. spacing, would be expected for the glucose unit in starch. It is noteworthy that the periodicity of the starch helix in the starch–iodine complex is 8 Å.[15] It is presumed that this corresponds to the width of the glucose residue.

The thickness of the glucose residue appears to be about 4.5 Å. in both chitin and starch and in the carbohydrates in general; this is half the 9 Å. spacing reported here. The gross structure of starch in the "B" modification probably resembles the chitin structure, in that the planes of the glucose residues are probably parallel to the largest spacing of the cell (Fig. 2).

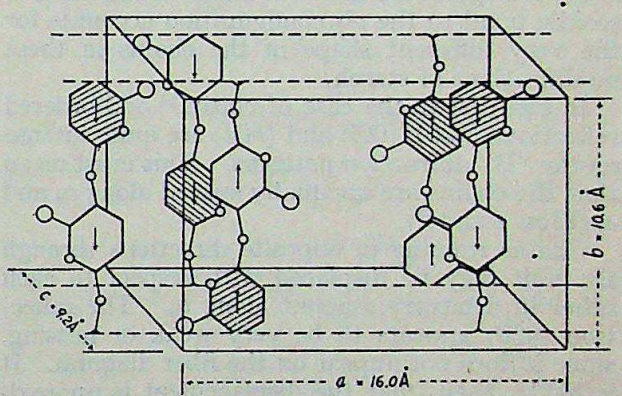

Fig. 2.—Structure of the "B" modification of starch: This structure is based on the space group D_2^1. An equally likely structure based on D_2^2 would differ only in having chains running the same direction in the unit-cell translated with respect to each other $^1/_2$ along b_0.

If the starch structure is orthorhombic, as appears likely, then the space group must be isomorphous with the point group D_2, since all other point groups of the orthorhombic system contain planes of symmetry, not allowable to the optically active starch chains.

Of the space groups isomorphous with D_2, only D_2^1–P222 and D_2^2–$P22_12$ are permitted by the observed reflections. The first requires that there be a two-fold axis parallel to the chains, the second that there be a two-fold screw axis in this direction. The failure to observe reflections (010) and (030) is not sufficient to establish the latter as more than a possibility. In either case the two-fold axes normal to the chains must run between the chains, and in either case half the chains will be running in one direction, half in the other, as indicated in Figs. 1 and 2. The only difference is that for the space group D_2^2 a translation $^1/_2$ along b_0 is also required. In cellulose fibers,[16] chitin fibers,[13] etc., it has been found that half the

chains run in one direction, half in the other direction. This is most probably the case with starch too, and one of the above arrangements of the chains is probably approximately correct even if the starch structure is only pseudo-orthorhombic.

If adjacent glucose residues along the starch chain are identical in their configurations, the periodicity along the chain requires that adjacent glucose residues be rotated about b_0, so that the (CH_2OH) groups on adjacent glucose residues are *trans* to each other (Fig. 2). (This is also found to be the case in cellulose[16] and chitin,[13] where the glucosidic link is β.) The *trans* arrangement for starch in the "B" modification does not necessitate this arrangement in the "V" modification, where the chains assume a helical configuration.[15] Indeed, it is probable that a rotation about the glucosidic bond to the *cis* configuration accounts for the very different shape of the chains in these modifications of starch.

In contrast to the case of chitin,[14] odd-ordered reflections ($h00$), ($00l$) and ($h0l$) are quite intense on the "B" diffraction patterns. This must mean that the chains are unequally spaced along a_0 and c_0 (Figs. 1 and 2).

Chains running in opposite directions through the unit may be displaced with respect to each other in arbitrary amount along b_0. The reflection (020) appears to be very weak or missing, since it does not appear on the fiber diagram. It is likely, then, that the displacement is approximately $^1/_4\ b_0$.

The structure shown in Fig. 2 is in accord with these qualitative observations of intensities. It is based on the space group D_2^1, but a similar structure, based on D_2^2, with every other chain translated $^1/_2$ along b_0 is equally likely. Even if the structure is not truly orthorhombic the spacing and orientation of the chains should approximate, in its gross aspects, the structure shown in Fig. 2.

Bear and French[2] have established a close relationship between the "A," "B" and "C" modifications of starch. This relationship is independent of the validity of their unit cells, so that it should be found that the "A" and "C" unit cells resemble closely that reported here for the "B" modification.

It seems well to point out that in contrast to cellulose, the configuration of the starch chain depends upon how the starch is treated. The chains, fully extended in the "B" modification, become helices in the "V" modification and the starch–iodine complex, and assume an intermediate, crumpled form in the fibers prepared by the use of certain plasticizers.[9]

Summary

1. Methods for preparing films and fibers of the "B" modification of starch are outlined.

2. Film and fiber diffraction patterns of the "B" modification of starch have been prepared. The fiber axis is 10.6 Å.

3. A new unit cell for the "B" modification has been found, with $a_0 = 16.0$, $b_0 = 10.6$, $c_0 = 9.2$ Å. The structure is probably orthorhombic. There are 8 glucose residues per unit; the density of the crystalline portion of starch is about 1.6 g./cc.

4. A rough structure of the "B" modification of starch has been proposed on the basis of the unit cell dimensions and qualitative consideration of the intensities (Fig. 2).

5. It is pointed out that plasticizers useful in producing starch fibers generally alter the starch structure materially, and unlike the case of cellulose, the fiber spacing of starch is easily altered by treatment of the starch.

α,β-Diamino Ketones. I. Reactions of Heterocyclic Secondary Amines with α-Bromo-β-aminoketones[1]

BY NORMAN H. CROMWELL, CHARLES E. HARRIS AND DONALD J. CRAM

The reactions of α-bromo-α,β-unsaturated ketones with primary and secondary amines have been the subjects of several investigations in this Laboratory.[2] The development of an excellent method of preparing mixed α,β-diamino ketones from α-bromo-α,β-unsaturated ketones is one of the results of these investigations. From a knowledge of the mechanisms[2f] of these reactions it is possible to arrange the conditions in such a manner as to allow the preparation of many specific mixed diamino ketones of possible chemotherapeutic interest.

α-Bromo-β-morpholinobenzylacetone[2c] reacted readily with tetrahydroquinoline (which is a weaker base than morpholine) to give good yields of the expected α-morpholino-β-tetrahydroquinolinobenzylacetone (I). The structure of (I) was established by hydrolysis to give α-morpholinoacetone, isolated as its oxime. This same bromo amino ketone reacted in dry ether with piperidine (which is a stronger base than morpholine) to give very poor yields of α-morpholino-β-piperidino-

benzylacetone (II). In alcohol solution the product from this reaction seemed to be a mixture of all of the possible diamino ketones.[2d]

α-Bromo-β-piperidinobenzylacetone[2g] reacted readily either in dry ether or absolute alcohol with morpholine to give fair yields of the expected α-piperidino-β-morpholinobenzylacetone (III). Compound (III) was obtained in a high and a low melting form, probably the two possible racemates. Either of these two forms of (III) lowered the melting point of (II) considerably, when mixed with it. The diamino ketone (III) was hydrolyzed by acid solution to give the known α-piperidinoacetone, isolated as its oxime.[2f]

In the benzylacetophenone series it was found that tetrahydroisoquinoline added readily to α-bromobenzalacetophenone to give α-bromo-β-tetrahydroisoquinolinobenzylacetophenone (IV). This bromo amino ketone (IV) was found to be more stable in the presence of absolute alcohol than the analogous α-bromo-β-tetrahydroisoquinolinobenzylacetone which has been studied in a previous investigation.[2f] However, on long standing, alcoholic suspensions of (IV) did form small amounts of α,β-ditetrahydroisoquinolinobenzylacetophenone (V), indicating a decomposition of the bromo amino ketone, and the subsequent reaction of the tetrahydroisoquinoline, so formed, with unchanged (IV). The diamino ketone (V) was also prepared in good yields in the usual way from tetrahydroisoquinoline and α,β-dibromobenzylacetophenone.

(IV) reacted with morpholine (a base that seems to be weaker than tetrahydroisoquinoline), giving a fair yield of the expected α-tetrahydroisoquinolino-β-morpholinobenzylacetophenone (VI). Acid hydrolysis of this diamino ketone (VI) gave a good yield of the known ω-tetrahydroisoquinolinoacetophenone.[3] This bromo amino ketone (IV) also reacted readily with a weaker base, tetrahydroquinoline, to give a good yield of α-tetrahydroisoquinolino-β-tetrahydroquinolinobenzylacetophenone (VII).

When α-bromo-β-morpholinobenzylacetophenone[2b] reacted with tetrahydroisoquinoline, a mixed product was obtained as expected. From this mixed product a small amount of not quite pure α-morpholino-β-tetrahydroisoquinolinobenzylacetophenone (VIII) was separated.

α-Bromo-β-piperidinobenzylacetophenone[4] reacted with tetrahydroisoquinoline (which is a weaker base than piperidine) to give good yields of α-piperidino-β-tetrahydroisoquinolinobenzylacetophenone (IX). The structure of (IX) was established by acid hydrolysis. When this same bromo amino ketone reacted with cyclohexylamine (a weaker base than piperidine) a fair yield of α-piperidino-β-cyclohexylaminobenzylacetophenone (X) was obtained. This is the first mixed diamino ketone containing a primary amino group that has been prepared in these investigations.

Certain theoretical studies as well as several further practical applications of these reactions to prepare specific compounds are the subjects of other investigations in these Laboratories.

Experimental[5]

Derivatives of Benzylacetone

α-Morpholino-β-tetrahydroquinolinobenzylacetone (I).—To 114 ml. of absolute alcohol were added 57 g. (0.183 mole) of α-bromo-β-morpholinobenzylacetone[2c] and 49 g. (0.371 mole) of tetrahydroquinoline and the mixture allowed to stand at room temperature for two days. At the end of this time the precipitate was filtered, washed and recrystallized from chloroform and alcohol giving 34.3 g. (0.0943 mole) of a white crystalline product. This compound was soluble in benzene and chloroform, slightly soluble in ether, very slightly soluble in alcohol and in dilute hydrochloric acid, and 0.1 g. was soluble in 10 ml. of absolute alcohol containing 0.95 g. of dry hydrogen chloride gas. This preparation was repeated using ether as a solvent. A white crystalline product was obtained, in 20.4% yield, which was identical with (I).

Hydrolysis.—Acid hydrolysis of the diamino ketone (I) in the usual way[2f] gave benzaldehyde, tetrahydroquinoline (isolated as the benzene sulfonamide) and the water soluble α-morpholinoacetone (isolated as its water soluble oxime, recrystallized from petroleum ether and benzene, m. p. 104–106°).

Anal. Calcd. for $C_7H_{14}N_2O_2$: C, 53.14; H, 8.92. Found: C, 53.42; H, 8.98.

α-Morpholino-β-piperidinobenzylacetone (II).—In 10 ml. of dry ether were placed 5 g. (0.0160 mole) of α-bromo-β-morpholinobenzylacetone[2c] and 2.8 g. (0.0320 mole) of piperidine and the mixture allowed to stand in the icebox for two days. At the end of this time the precipitate was filtered but it all proved to be water soluble. The filtrate was evaporated and the resulting oil taken up in alcohol and a white solid obtained which after four recrystallizations from alcohol and water gave 0.5 g. (0.00158 mole) of a white crystalline product m. p. 118–123°. A mixed melting point with α,β-dimorpholinobenzylacetone[2c] gave m. p. 108–132°, and with α,β-dipiperidinobenzylacetone[2g] gave m. p. 100–110°. This reaction was also carried out in alcohol but a mixture impossible to separate was obtained.

α-Piperidino-β-morpholinobenzylacetone (III).—To 25 ml. of absolute alcohol were added 12 g. (0.0387 mole) of α-bromo-β-piperidinobenzylacetone[2g] and 6.74 g. (0.0775 mole) of morpholine and the mixture allowed to stand at room temperature. The reaction took place with evolution of heat and was complete in about three hours. At the end of this time the precipitate was filtered and the product recrystallized three times from alcohol and water giving 2.4 g. of white needles, m. p. 115–117°. A mixed melting point experiment with this compound and α-morpholino-β-piperidinobenzylacetone (II) gave m. p. 90–111°; with α,β-dipiperidinobenzylacetone,[2g] m. p. 95–116°; and with α,β-dimorpholinobenzylacetone,[2c] m. p. 95–140°.

The reaction mixture filtrate was concentrated and cooled and a second crop of crystals came out, which, after recrystallization from alcohol and water, gave 1.5 g. of white crystalline compound, m. p. 100–101°. A mixed melting point of the two racemates gave m. p. 102–114°; a mixed melting point of the lower melting racemate with α,β-dipiperidinobenzylacetone[2g] gave m. p. 92–116°; with α,β-dimorpholinobenzylacetone,[2c] m. p. 93–140°; and with α-morpholino-β-piperidinobenzylacetone (II), m. p. 90–110°.

This reaction was also carried out in ether solution and a 40.2% yield of product was obtained, m. p. 102–114°, which when mixed with a mixture of the two racemates gave m. p. 103–114°. An analysis of this product also agreed with the formula, $C_{19}H_{28}N_2O_2$.

Hydrolysis.—Acid hydrolysis of the mixed racemates of (III) in the usual way gave α-piperidinoacetone, isolated as its oxime, m. p. 122–123°.[2f] No α-morpholinoacetone was detected.

Derivatives of Benzylacetophenone

α-Bromo-β-tetrahydroisoquinolinobenzylacetophenone (IV).—In 20 ml. of a 50% ether–petroleum ether (b. p. 37°) solution was dissolved 10 g. (0.035 mole) of α-bromobenzalacetophenone[2b] and the solution cooled to −10° in an ice–salt mixture. Previously cooled tetrahydroisoquinoline (0.035 mole (4.65 g.)) was added to the cold mixture with shaking. The resulting solution was allowed to stand well-corked for two hours at −10°. The white product (12.5 g.) was filtered off, washed with 50% ether-petroleum ether, and dried *in vacuo*, m. p. 117°, yield 85%.

(5) All m. p. are corrected and determined by placing sample in bath 10° below m. p. and heating at the rate of 3° per minute. Micro Dumas analyses for nitrogen and semimicro carbon–hydrogen analyses by the Analytical Laboratory, Department of Chemistry, University of Nebraska, under the supervision of H. Armin Pagel.

Anal. Calcd. for $C_{24}H_{22}NOBr$: C, 68.57; H, 5.28. Found: C, 68.80, 68.52; H, 5.36, 5.42.

This bromo amino ketone reacted with sodium ethoxide in the usual way to give a red oily product which was probably the α-tetrahydroisoquinolinobenzalacetophenone. All attempts to crystallize this oil failed.

When a sample of (IV) was allowed to stand in absolute alcohol at room temperature for one week a small amount (about 20%) of the addition product decomposed[2f] to give α-bromobenzalacetophenone and tetrahydroisoquinoline. This was shown by the isolation of a 10% yield of α,β-ditetrahydroisoquinolinobenzylacetophenone (V), m. p. 184–186°, identical with that prepared from α,β-dibromobenzylacetophenone as described below.

α,β-Ditetrahydroisoquinolinobenzylacetophenone (V).—In 20 ml. of absolute alcohol was suspended 5 g. (0.0136 mole) of α,β-dibromobenzylacetophenone and the mixture cooled to 0°. Tetrahydroisoquinoline (8 g. (0.060 mole)) was added rapidly while shaking. The solution at first remained white, but then changed to an orange color. After allowing it to stand for two days at room temperature, during which time the mixture was shaken and worked with a spatula, the white precipitate was filtered off and washed well with petroleum ether and then with water. The crude product was recrystallized twice from benzene–petroleum ether (b. p. 80°) mixtures to give 4.4 g. of a white product.

α-Tetrahydroisoquinolino-β-morpholinobenzylacetophenone (VI).—In 15 ml. of dry ether and 5 ml. of absolute alcohol, were suspended 5 g. (0.012 mole) of (IV) and 3.6 g. (0.024 mole) of morpholine added. After standing overnight at room temperature the red-colored solution was filtered, the precipitate washed with petroleum ether and then with water. After three recrystallizations from a chloroform–alcohol mixture and two from a benzene–petroleum ether mixture, 1.7 g. of pale yellow crystals was obtained.

Hydrolysis.—Acid hydrolysis (40 ml., 15% sulfuric acid) of the diamino ketone (VI) (4.0 g.) in the ordinary manner[2e] gave 1.65 g. of ω-tetrahydroisoquinolinoacetophenone, identical with a sample prepared from ω-bromoacetophenone.[3]

Other mixed diamino ketones prepared by essentially[6] this same procedure were: (VII) from (IV) and two equivalents of tetrahydroquinoline; (VIII) from α-bromo-β-morpholinobenzylacetophenone[2b] and tetrahydroisoquinoline (mixed m. p. of (VI) with (VIII), 150–163°; hydrolysis of (VIII) gave mainly ω-morpholinoacetophenone[2b] and traces of ω-tetrahydroisoquinolinoacetophenone[3] along with tetrahydroisoquinoline and benzaldehyde); (IX) from α-bromo-β-piperidinobenzylacetophenone[4] and tetrahydroisoquinoline (hydrolysis of (IX) gave ω-piperidinoacetophenone, isolated as its hydrochloride[2d]); (X) from α-bromo-β-piperidinobenzylacetophenone[4] and cyclohexylamine.

Summary

1. The preparation of one new α-bromo-β-amino ketone and nine new diamino ketones has been described.

(6) The amount of absolute alcohol in the reaction medium and the time for reaction varied slightly in each individual case.

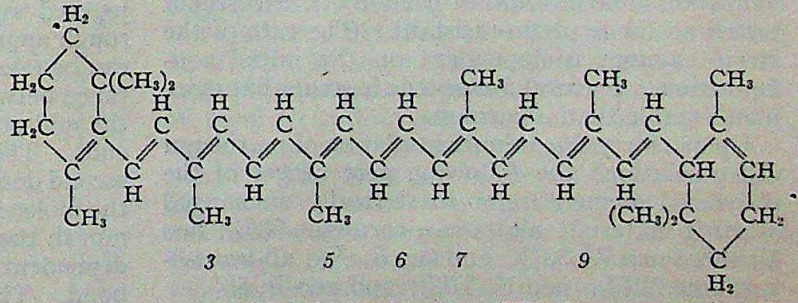
cis–trans Isomerization and *cis*-Peak Effect in the α-Carotene Set and in Some Other Stereoisomeric Sets

BY L. ZECHMEISTER AND A. POLGÁR

As far as we know, no up-to-date study of the stereoisomerization of α-carotene[1] is available while a more detailed investigation has been presented for β-carotene.[2] The α-carotene molecule includes five double bonds which are available for *trans*→*cis* rotations (see the formula), the number of stereoisomers being thirty-two.[3]

It was first assumed[4] that the all-*trans* member of a stereoisomeric hydrocarbon set possesses greater adsorption affinity than any other member of the set but this postulate must now be abandoned for both carotene sets mentioned.

A re-investigation of α-carotene showed the presence of the eleven isomers listed in Table I of which neo-α-carotene U and W have been crystallized.



All-*trans*-α-carotene. (The double bonds available for a *trans*→*cis* shift are numbered.)[5]

The ratio of stereoisomers is dependent on the method of isomerization (Table II).

(4) L. Zechmeister and P. Tuzson, *Ber.*, **72**, 1340 (1939); L. Zechmeister, L. Cholnoky and A. Polgár, *ibid.*, **72**, 1678 (1939).

(5) The following *nomenclature* is proposed. Each double bond of the *conjugated system* will be assigned an *italicized* number in order to avoid confusion with the numbering of carbon atoms: *e. g.*, *3,6*-di-*cis*-β-carotene. The lowest number will be given to the double bond in the β-ionone ring or, if the double bond of this ring is not part of the chromophore, to the conjugated double bond nearest the β-ionone ring. In the absence of such a system an α-ionone ring receives preference over an aliphatic terminal group.

TABLE I

VISUALLY DETERMINED SPECTRAL MAXIMA OF OBSERVED MEMBERS OF THE STEREOISOMERIC α-CAROTENE SET IN THE SEQUENCE OF DECREASING ADSORPTION AFFINITY

Name	Maxima in petroleum ether (b. p. 60–70°), mμ	
Neo-α-carotene U	471.5	441.5
Neo-α-carotene V	465.5	437
Neo-α-carotene W	470.5	441
Neo-α-carotene X	463.5	435
Neo-α-carotene Y	467.5	437
All-*trans*-α-carotene	477	446.5
Neo-α-carotene A	468.5	439
Neo-α-carotene B	466.5	437
Neo-α-carotene C	472.5	442.5
Neo-α-carotene D	460	432
Neo-α-carotene E	461.5	433.5

TABLE II

RELATIVE COLORIMETRIC VALUES OF THE MAIN PRODUCTS OF STEROISOMERIZATION OF ALL-*trans*-α-CAROTENE BY VARIOUS METHODS

Method	All-*trans*	Neo U	Neo W	Neo B	Other isomers
Refluxing	92	4	—	4	—
Iodine catalysis (in light)	65	8.5	8	13	5.5
Acid catalysis (10% HI)	64.5	5	24	4.5	2
Acid catalysis (37% HCl)	50	13	15	9	13
Melting crystals	35	12	19	14	20

For effective iodine catalysis diffuse daylight or illumination is required.

Exposure to sunshine ("insolation") in the absence of catalysts is a recent addition to isomerization methods. Even when gradual destruction takes place, this irreversible change does not hinder the chromatographic study of the stereoisomerization. We wish to emphasize that the configuration of no all-*trans* or partially *cis* carotenoid tested so far is photo-resistant. The rate of the steric changes is dependent on the initial configuration. Natural β-carotene is somewhat more photo-stable than α-carotene.

Upon a forty-five minute insolation of petroleum ether solutions the following percentages of the recovered pigment refer to sterically unchanged starting material: all-*trans*-α-carotene, 93%; neo V, 43%; neo W, 33%; and neo B, 8%; all-*trans*-β-carotene, 98%; neo U, 37%; and neo B, 5%.

A study of the "*cis*-peak" effect has been of aid in establishing the most probable configuration of some stereoisomers. While it had been found by several authors that the extinction maxima of the ordinary carotenoids in the visible region decrease upon isomerization,[6] we observed that a new marked maximum develops simultaneously at some wave length between 320 and 380 mμ ("*cis*-peak").[7] The contribution of individual stereoisomers to the height of the *cis*-peak observed in equilibrium mixtures is very unequal in the β-carotene set. The greatest contribution is made by those neo-compounds which are adsorbed below the all-*trans* pigment while the U isomer contributes much less. We have now carried out a more detailed differentiation of individual *cis*-peak effects in the β-carotene, α-carotene, lutein, and lycopene sets as shown in Figs. 1 to 4.

If an all-*trans* carotenoid undergoes spatial changes, the bending of the molecule causes two different, easily observable optical effects which may be helpful in the assignment of a definite configuration to each isomer formed: (a) the visible maxima shift toward shorter wave lengths and (b) a *cis*-peak with characteristic height appears in the ultraviolet region. In possession of a sound theoretical basis, effect (a) would give us the number of *cis* double bonds and (b) would determine the general shape of the molecule, *i. e.*, the position of the *cis* bonds in the conjugated system. The main difficulty at present lies in the lack of precise information concerning the possible dependence of (a) on the position of the double bonds which have completed a *trans*→*cis* rotation. On the basis of the experimental material available it seems that the *trans*→*cis* rotation of one double bond displaces the longest wave length maximum in petroleum ether about 5 mμ toward shorter wave lengths. If this spectral shift equals approximately 10 mμ the presence of two *cis* double bonds is probable, etc.

It has been reported by Pauling, LeRosen, Schroeder and the authors[8] that a stereoisomer showing a very high *cis*-peak must possess a *cis* double bond at (or near) the center of the conjugated system. It was pointed out that as a rough approximation the intensity of the *cis*-peak can be taken proportional to the square of the distance between the center of the chromophore and the mid-point of the straight line between its two ends. The models show that the rotation of a second double bond into *cis* position will straighten the molecule considerably and accordingly will diminish the *cis*-peak. This effect is essentially independent of the position of the second double bond. The conditions are more complicated in the case of a chromophore containing an even number of conjugated double bonds (α-carotene) than in that of, for example, β-carotene. The center of the α-carotene chromophore is a single bond; two "central" double bonds, *5* and *6*, are present, each of which has four other conjugated double bonds on one side and five on the other. These "central" double bonds, while structurally different in α-carotene, are equivalent from the

stereochemical viewpoint. Therefore, two of the mono-*cis*-α-carotenes can be expected to have much higher *cis*-peaks than any other isomer. Models show that the molecule of *5,6*-di-*cis*-α-carotene, the isomer which contains both "central" double bonds in *cis* position, is considerably straighter than either *5*- or *6*-mono-*cis*-α-carotene.

The following discussion in which some stereoisomers are tentatively given spatial structures is based on the foregoing considerations and on the optical data summarized in Table III. (Should stereoisomers be detected in the future which possess higher *cis*-peaks than any of the members of the set known at the present, a revision of our assignments of spatial structures in that particular set would become necessary.)

TABLE III

TYPICAL SPECTROSCOPIC DATA FOR SOME MEMBERS OF THE STEREOISOMERIC β-CAROTENE, α-CAROTENE, LUTEIN, AND LYCOPENE SETS

Stereoisomeric set	Member of the set	Difference of the visually established longest wave length maximum from that of the all-*trans* form, in petroleum ether (mμ)	Molecular extinction coefficient, in hexane, at the respective *cis*-peaks, $E^{mol.}_{1cm.} \times 10^{-4}$	Difference of $E^{mol.}_{1cm.}$ for member of the set and the all-*trans* form
β-Carotene	neo U	5	1.3	0.5
	neo V	13.5	0.8	0
	all-*trans*	0	0.8	0
	neo B	10.5	3.4	2.6

	neo B	8	3.7	2.3
	unnamed cryst. isomer	28	1.3	−0.1
	prolycopene	34	1.6	0.2
	all-*cis*	38.5	2.2	0.8

β-Carotene Set (Fig. 1).—The visual maxima of neo-β-carotene U differ by 5 mμ and those of neo-β-carotene V by 13.5 mμ from the positions of the maxima of all-*trans*-β-carotene and indicate thereby that neo U is a mono-*cis* and neo V a di-*cis* compound. Neither of them can contain a *6*-*cis* double bond because of their low *cis*-peaks and relatively high thermostability. We suggest as the most probable configurations:[9] *3*-mono-*cis*-β-carotene for neo U, and *3,9*-di-*cis*-β-carotene for neo V; however, for neo V the configuration *5,7*-di-*cis* cannot be excluded.

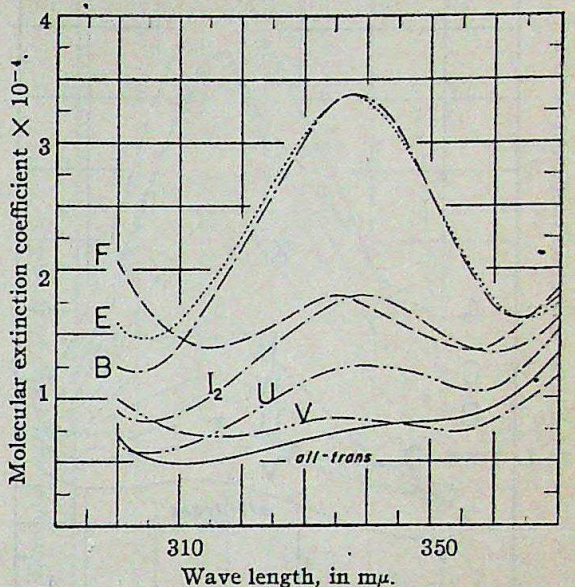

Fig. 1.—Molecular extinction curves of some β-carotene stereoisomers in the *cis*-peak region (in hexane). I_2 indicates the equilibrium mixture obtained upon iodine catalysis.

Neo-β-carotene B, a main isomer, is interpreted as a di-*cis* compound which has one of its *cis* bonds in the *6*-position; this is substantiated by the high *cis*-peak and the relatively slight thermostability. The most probable configuration for neo B is *3,6*-di-*cis*-β-carotene because *5,6* must be definitely eliminated after a consideration of the *cis*-peak and models. The minor isomer, neo-β-carotene E, belongs to the same type as neo B but because of its lability we do not wish to make suggestions concerning its configuration.

α-Carotene Set (Fig. 2).—The neo-α-carotenes U, V, and W show considerable thermostability and very moderate *cis*-peaks. The isomers U and W seem to contain one *cis* double bond while V must reasonably be interpreted as a di-*cis* compound. The most probable configurations are: neo U = *9*-mono-*cis*-α-carotene, neo W = *3*-mono-*cis*-α-carotene, and neo V = *3,9*-di-*cis*-α-carotene. Neo-α-carotene X, a di-*cis* compound, was preponderantly formed upon mild heating of a neo U solution. Therefore, we suggest that one of its *cis* double bonds, *viz.*, *9*, is identical with that in neo U. Since, as will be shown, the configurations *5,9* and *6,9* must be allocated to other isomers, neo-α-carotene X possessing a medium *cis*-peak is probably *7,9*-di-*cis*-α-carotene. Neo-α-carotene C, a labile minor isomer, seems to be *6*-mono-*cis*- or *5*-mono-*cis*-α-carotene.

One of the main observed isomers, neo B, has

(9) Before the *cis*-peak was found we stated that neo-β-carotene U possibly contains a *6*-*cis* double bond (footnote 2). This assumption must be abandoned.

approximately the same *cis*-peak and in the visible region, the same spectral difference from the all-*trans* maxima as neo-β-carotene B. The great height of its *cis*-peak strongly suggests that one of its *cis* positions is central, the other peripheral, since neither two peripheral nor two central *cis* double bonds would explain the height of the peak observed. The very fact, however, that in α-carotene we find two stereochemically equivalent but structurally different central double bonds, leaves for neo-α-carotene B two spatial possibilities open which are, according to the models, *5,9*- and *6,9*-di-*cis*-α-carotene. Since the neo-α-carotenes A and B have practically identical *cis*-peaks, it is reasonable to say that for these two isomers the following four configurations are possible: *5,9*, *6,9*, *3,5*, and *3,6*.

Lutein Set (Fig. 3).—Only the two main isomers, neo A and B, have been investigated. On the basis of Table III neo-lutein A is very probably *6*- or *5*-mono-*cis*-lutein. The extinction at the *cis*-peak of neo-lutein B is less than half that of neo A. Neo B is probably *3*- or *9*-mono-*cis*-lutein.

Lycopene Set (Fig. 4).—As previously mentioned,[8] neo-lycopene A, which possesses the highest *cis*-peak so far observed, must be interpreted as *6*-mono-*cis*-lycopene. The isomer B is evidently a di-*cis* compound which could well be *1,6*- or *3,6*-di-*cis*-lycopene.

It will be an important task for the future to establish the precise nature of the dependence of adsorption affinity on the configuration of polyenes. At present only the following remarks can be made with reference to the adsorbability of stereoisomeric α- and β-carotenes (on calcium hydroxide). If the tentatively proposed spatial structures are correct, it follows that, when the position of the *cis* double bonds is *3* or *9*, the mono-*cis* compounds observed possess greater adsorption affinity than the all-*trans* form. In contrast, mono-*cis* isomers with one centrally located *cis* double bond show a decreased adsorbability. The chromatographic behavior of *3,9*-di-*cis* compounds is like that of the *3*- or *9*-mono-*cis* isomers. No simple rule is available for the case in which one peripheral and one central double bond are present. Isomers with two centrally located *cis* double bonds or with three *cis* double bonds in any combination observed so far possess definitely weaker adsorption affinity than the all-*trans* member of the α- and β-carotene sets.

Experimental

Methods.—The pigment solutions were chromatographed on calcium hydroxide[10] (Shell brand lime, chemical

(10) Since calcium hydroxides from various sources show a great difference in the rate of solvent flow, the following test, suggested by Dr. A. L. LeRosen, is used in our laboratory for standardization: a 7 × 2 cm. column is prepared, petroleum ether is sucked into it, and the time needed for the solvent to travel 50 mm. down the column is measured. A result of 35 to 70 seconds is adequate (pressure 25 mm. Hg).

hydrate; 98% through 325 mesh). For development petroleum ether (Skellysolve B, b. p. 60–70°) containing 0.5% acetone was used. The figures on the left side of the chromatograms described below denote width of the zones in mm. Petroleum ether–alcohol mixtures are suitable eluents. The visual spectral maxima were determined with an Evaluating Grating Spectroscope (Zeiss, light filter BG-7, 2 mm. thick) in petroleum ether unless otherwise indicated. For colorimetric estimations a Pulfrich Gradation Photometer was used (petroleum ether, filter S47). The extinction coefficients were determined in a Beckman Photoelectric Spectrophotometer.[11] For these experiments "Hexane" (Eastman Kodak Co. from petroleum, "practical") was purified by shaking with fuming sulfuric acid and then with alkaline permanganate, and by fractionating; b. p. 62–65°.

The treatment of isomers which were available as solutions was described earlier.[7,8] The curves in Figs. 1 to 4 may be in error to the extent of ±1 to 5% at the maxima.

All pigments listed in the chromatograms as members of the α-carotene set shifted their visually observed spectral maxima to 473.5, 443.5 mμ (±0.5 mμ) after addition of iodine.

(a) ***cis–trans* Isomerization of α-Carotene Solutions on Standing or Refluxing.**—A solution of 3 mg. of pure α-carotene in 30 ml. of petroleum ether was found chromatographically to be nearly unchanged after remaining two hours in diffuse light. Even upon longer standing the extent of isomerization is very moderate. The neo-compounds formed were adsorbed partially above and partially below the unchanged portion. In petroleum ether solution the colorimetric ratio, unchanged all-*trans:* neo-forms was 98:2 after a day. At 5° and in the dark 1% of the α-carotene isomerized within three days.

A 50-ml. petroleum ether solution containing 5 mg. of α-carotene was refluxed in carbon dioxide for thirty minutes in an all-glass apparatus. The cooled solution was developed on a 24 × 5.8 cm. column.

(c) ***cis–trans* Isomerization of α-Carotene with Hydriodic Acid and Hydrochloric Acid.**—A homogeneous solution containing 7.5 mg. of pigment in 30 ml. of petroleum ether was shaken for thirty minutes with 15 ml. of hydriodic acid (Merck Reagent, 55–58% HI, diluted 1:1) in a carbon dioxide atmosphere. The pigment solution

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

was washed acid-free. The chromatogram was similar to that obtained upon iodine catalysis (section b). Above neo-α-carotene U there appeared some irreversibly formed pigment (<1%) but no 5,6-dihydro-α-, or 5,6-dihydro-β-carotene[13] was present. The all-*trans*-α-carotene recovered from a larger scale experiment showed its original rotatory power.

The colorimetric ratio was, unchanged all-*trans*:neo U:neo V:neo W:neo B:neo C... = 64.5:5:1.5:24:4.5:0.5.

In a parallel experiment commercial concentrated hydrochloric acid was applied and the following chromatogram obtained (24 × 4.8 cm.).

35	several yellow, irreversible pigments
25	pale orange, neo U: 472, 442 mμ
2	colorless
3	light yellow, neo V: 465.5, 437 mμ
25	colorless
30	yellow, neo W: 470.5, 441.5 mμ
3	colorless
25	orange, unchanged all-*trans:* 477.5, 447 mμ
5	colorless
12	light orange, neo A: 468.5, 439.5 mμ
2	almost colorless
10	yellow, neo B: 467, 438 mμ
2	almost colorless
4	pale orange, neo C: } 467, 437.5 mμ
5	pale yellow, neo D: }

The colorimetric ratio was, unchanged all-*trans*:neo U:neo V:neo W:neo A:neo B:neo C... = 49:13:2:15:8:9:4.

The quantity of the *irreversibly formed pigments* amounted to about 3% of the total. Longer shaking with the acid promotes their formation (79% after 3 hours). Chromatography on calcium carbonate and subsequent crystallization from benzene-methanol yielded a few milligrams of long orange needles, m. p. 170° (cor.). In the partition test this pigment behaved like cryptoxanthin. The visual maxima follow: in carbon disulfide, 507, 473 mμ (with iodine, 504, 471.5 mμ); in benzene, 488, 456.5 mμ (486, 454.5 mμ); in petroleum ether (b. p. 60–70°), 477, 446.5 mμ (474, 443.5 mμ); and in ethanol, 477.5, 448 mμ (477.5, 448 mμ).

(d) *cis–trans* **Isomerization of α-Carotene by Melting.**—Three milligrams of pigment was melted in a sealed tube filled with carbon dioxide and kept in a bath at 195–200° for fifteen minutes. After cooling in ice water the petroleum ether solution was chromatographed (23 × 4.8 cm.).

15	pale yellow, neo D...: 462, 433.5 mμ

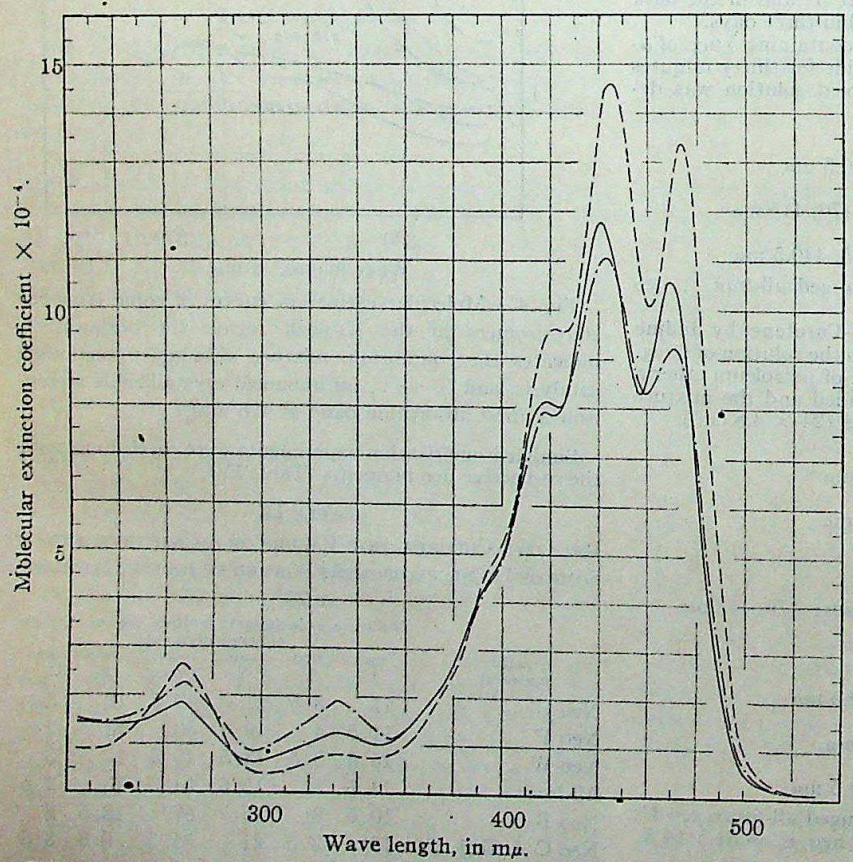

Fig. 5.—Molecular extinction curve of neo-α-carotene U, compared with that of α-carotene, in hexane: ——, neo-α-carotene U; –·–·–, neo-α-carotene U after iodine catalysis; – – – –, all-*trans*α-carotene.

The colorimetric ratio was, unchanged all-*trans*:neo U:neo V:neo W:neo X:neo B:neo D... = 35:12:6:19:7:14:7.

(e) **Neo-α-carotene U.**—To a solution of 110 mg. of α-carotene in 500 ml. of petroleum ether 3 mg. of iodine was added and, after standing at 25° for an hour, the solution chromatographed on two 29 × 8 cm. columns. The light orange neo U zone adsorbed near the top was cut out separately while the other pigments were combined, treated with iodine again and chromatographed. The neo U zones of both chromatograms were eluted together. This pigment was rechromatographed twice (29 × 8 cm.), transferred into petroleum ether and evaporated. The oily residue was dissolved in the minimum amount of benzene, mixed in a centrifuge tube with some methanol and dipped into a dry ice–acetone mixture for a few seconds. Upon scratching, crystals appeared (yield, 26.2 mg. = 24%). A single treatment of α-carotene with iodine yields about 14%. Neo-α-carotene U forms an orange crystal powder; under the microscope light orange 0.01 mm. long prisms appeared (Fig. 6); m. p. 65° (cor.). The compound is more soluble than natural α-carotene. The visually determined spectra are included in Table V. Upon addition of iodine the same maxima were observed as in case of a catalyzed all-*trans*-α-carotene solution, *viz.*, in carbon disulfide, 505.5, 474 mμ; in benzene, 488, 455.5 mμ; in chloroform, 486.5, 454 mμ; in petroleum ether, 474.5, 444 mμ; and

419	8.2	*418*	8.1	*418*	7.9
350	1.03	350	1.03	354	1.17
331	1.25	*330*	1.37	*332*	1.92
298–300	0.6(4)	294	0.6(5)	298	0.8(6)
267	1.85	*268*	1.94	*269*	2.29

A thirty-minute refluxing of neo-α-carotene U in petroleum ether formed the following mixture, expressed as percentage of the recovered pigment: 70% unchanged neo U, 17% neo X, 6.5% neo V, 1% neo B..., and only 5.5% all-*trans*-α-carotene.

Two milligrams of neo U crystals was melted in a sealed tube filled with carbon dioxide and kept in a bath at 74° for fifteen minutes. The chromatogram of the petroleum ether solution contained 66% unchanged neo U, 23.5% all-*trans*-α-carotene (with a trace of neo A), 7% neo X, and 3.5% neo B...

(f) **Neo-α-carotene W.**—Neo W solutions collected from several experiments were twice rechromatographed; the interzone below the U layer was in no case colorless. The separation of neo W from the all-*trans* form succeeds only upon a prolonged development with petroleum ether containing 0.5% acetone. Subsequent crystallization from benzene–methanol in a dry ice–acetone bath yielded narrow prisms, about 0.05 mm. long, showing a dull brownish orange color with brown crossings under the microscope (Fig. 7); m. p. 97° (cor.). The solubility is similar to that of the U isomer; specific rotation, $[\alpha]^{25}_{Cd}$ +365°, in petroleum ether.

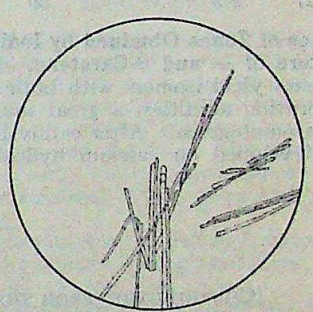

Fig. 7.—Neo-α-carotene W (from benzene and methanol).

(g) **Photo-isomerization.**—The petroleum ether solution (30 ml.) of 5 mg. of all-*trans*-α-carotene was exposed to bright sunlight in a transparent quartz test-tube (diameter, 22 mm.), filled with carbon dioxide, for forty-five minutes (final temperature, 29°). The colorimetric ratio was, unchanged all-*trans*:neo U:neo W:neo B:neo C... = 94:1.5:2:2:0.5.

A petroleum ether solution of 1 mg. of neo-α-carotene U in a quartz test-tube filled with carbon dioxide was exposed to bright sunlight for forty-five minutes and chromatographed (20 × 3.8 cm.).

4 orange, irreversible (could not be eluted)
15 almost colorless
45 light orange, neo U: 472.5, 441.5 mμ
4 colorless
5 yellow, neo V: 465.5, 438 mμ

(h) Sequence of Zones Obtained by Iodine Isomerization of a Mixture of α- and β-Carotene.—Since the two all-*trans* carotenes yield isomers with both increased and decreased adsorption affinities, a great number of zones overlap in a chromatogram. After catalysis the pigment mixture was developed on calcium hydroxide with petroleum ether containing 2% acetone. The chromatogram did not contain colorless sections; nevertheless, sections of different colors enabled the experimenter to cut out suitable zones. The addition of iodine to the solution of each pigment in the spectroscopic cell established the set to which the isomer belonged. This procedure was the basis for the chromatographic investigation of suitable binary mixtures. Such pairs were submitted to a prolonged development with petroleum ether. The sequence established in the order of decreasing adsorption affinity follows: neo-β-carotene U, neo-β-carotene V, neo-α-carotene U, all-*trans*-β-carotene, neo-α-carotene V, neo-β-carotene B, neo-β-carotene E, neo-α-carotene W, neo-β-carotene F, all-*trans*-α-carotene, neo-α-carotene B, and neo-α-carotenes C, D, etc.

Summary

Some data are given concerning *cis–trans* isomerization in the stereoisomeric α-carotene set as compared with the β-carotene, lutein, and lycopene sets. Ten *cis–trans* isomeric α-carotenes were observed which adsorb partly above, partly below the all-*trans* pigment in the Tswett column. Photo-isomerization experiments are described. The contribution of some stereoisomers to the *cis*-peak of the iodine equilibrium mixture was determined. Some spectral data served as a basis for a discussion of configurations.

The Use of Potassium *t*-Amyloxide for the Alkylation of Acetoacetic Ester and its Alkyl Substitution Products

BY W. B. RENFROW, JR.

Alkylation of acetoacetic ester with sodium ethoxide in ethanol and an alkyl bromide gives yields of 70–80% with *n*-alkyl bromides,[1] but secondary alkyl bromides and bromides with a branch in the chain at the β-position (*i. e.*, isobutyl) generally give less than a 30% yield[2] of mono-substituted acetoacetic ester. Moreover, the further alkylation in the usual way of a mono-α-substituted acetoacetic ester with an *n*-alkyl bromide generally gives less than a 40% yield of disubstituted acetoacetic ester.[3]

Theoretical considerations indicated that the yields in the less favorable cases could be improved by the use of an alkoxide of greater proton-affinity than sodium ethoxide. Potassium *t*-amyloxide is a conveniently available base which is stronger than sodium ethoxide,[4] and was selected for investigation.

Table I gives the results obtained. The course of the reaction was followed by titration of aliquots with acid, and the approximate times were determined at the temperature of the refluxing solutions for one-half of the base to react.

Comparison of the data in Table I with similar data using sodium ethoxide[1,5,6] shows that potassium *t*-amyloxide in *t*-amyl alcohol and sodium ethoxide in ethanol are of about equal effectiveness for the alkylation of ethyl acetoacetate with primary, straight-chain bromides. However, potassium *t*-amyloxide gives considerably better yields of ethyl α-isopropylacetoacetate, ethyl α-isobutylacetoacetate, ethyl α,α-diethylacetoacetate and ethyl α,α-dibutylacetoacetate than can be obtained by use of sodium ethoxide in ethanol.[2,7,3]

(1) For the usual method of alkylation, see: Gilman, Blatt, "Organic Syntheses," Coll. Vol. I, John Wiley and Sons, New York, N. Y., 1941, p. 248.

(2) In the present investigation ethyl isopropylacetoacetate and ethyl isobutylacetoacetate were obtained in 20–25% yields by the method described in (1).

(3) Hess and Bappert, *Ann.*, **441**, 151 (1925), obtained a 38% yield of α,α-di-*n*-butylacetoacetic ester under certain conditions. Under other conditions the product was almost exclusively ethyl di-*n*-butylacetate. Compare also Billon, *Ann. chim.*, **7**, 355 (1927).

TABLE I

RESULTS OF ALKYLATIONS USING KO—C(CH$_3$)$_2$—C$_2$H$_5$ IN HO—C(CH$_3$)$_2$—C$_2$H$_5$

R (R =)	R′Br (R′ =)	Reaction half-time (minutes)	Yield of CH$_3$C(=O)—C(R)(R′)—C(=O)—OEt (per cent)	Boiling range °C.	Mm.	Ref.
H	Ethyl	10	80	96–98	26	5
H	*n*-Butyl	15	73	110–114	14–15	1
H	Isoamyl	20	72	120–123	15–16	6
H	Isobutyl	100	61	99–103	13–14	9
H	Isopropyl	200	50	200–203	748	10
Ethyl	Ethyl	10	75	96–99	13–14	7
n-Butyl	*n*-Butyl	15	70	143–147	18–19	3

The superiority[8] of potassium *t*-amyloxide over sodium ethoxide in ethanol is considered to be due mainly to two factors: (1) the stronger base causes less shift of the following equilibrium to the right (reverse Claisen condensation[11])

$$CH_3COCRR'CO_2C_2H_5 + HOR'' \underset{}{\overset{KOR''}{\rightleftharpoons}} CH_3CO_2R'' + HCRR'CO_2C_2H_5$$

and (2), the stronger base makes available a higher concentration of the desired metallic enolates of acetoacetic esters by shifting the following equilibrium further to the right.

$$CH_3COCHR'CO_2C_2H_5 + KOR'' \rightleftharpoons (CH_3COR'CO_2C_2H_5)K + HOR''$$

A slow rate of alkylation (as with isopropyl and isobutyl bromides) permits greater reversal of the Claisen condensation by necessitating a prolonged refluxing of acetoacetic esters with alcohol and alkoxide. The α,α-disubstituted acetoacetic esters are especially susceptible to cleavage by sodium ethoxide in ethanol and this side reaction is very troublesome when the usual alkylation procedure is followed.[3] Since it has been shown that a strong base favors the Claisen condensation[11b] (and hence should oppose reversal of the reaction), the higher yields obtained by use of the stronger base are probably mainly due to this factor.

The second factor is probably not significant in the alkylation of ethyl acetoacetate, since this compound is a sufficiently strong acid[12] to be converted almost completely into its enolate by means of sodium ethoxide. This factor may be of some importance, however, in the alkylation of more weakly acidic monosubstituted acetoacetic esters.

Experimental

The technical grade of *t*-amyl alcohol was refluxed for five hours with 2% of its weight of sodium, allowed to stand overnight, decanted through a plug of glass wool and distilled rapidly until the boiling point reached about 106°. The distillate was refluxed for four hours with 1% its weight of sodium and distilled. The fraction boiling at 100–100.8° (747 mm.) was collected as pure *t*-amyl alcohol. This amounted to about 73% of the starting material, and had d^{20}_4 0.809.

Ethyl acetoacetate was purified by fractionation through a 20-cm. column packed with glass helices. The fraction boiling at 83–85° (24 mm.) was used.

The alkyl bromides were thoroughly extracted with concentrated sulfuric acid, washed with bicarbonate solution, dried (calcium chloride) and fractionated.

Experiments were made using from 0.1 to 1.0 gram-atom of potassium. The most convenient amount was about 0.3 gram-atom, and the general procedure was as follows: Potassium (11.7 g., 0.3 gram-atom) was dissolved with stirring at reflux temperature in *t*-amyl alcohol (170 ml.). When larger amounts of potassium were added all at once, external cooling of the flask was usually necessary to prevent too violent refluxing. The solution was cooled (inert atmosphere) to room temperature, ethyl acetoacetate (42.9 g., 0.33 mole) was added and the solution stirred for about two minutes. The alkyl bromide (0.33 mole) was then added and the solution was refluxed and stirred until 90–100% of the base had reacted (usually about three hours).

The reaction mixture was diluted with water (about 100 ml.) and acidified with acetic acid (litmus). The organic layer was separated and distilled at atmospheric pressure until the boiling point reached 110°. The cooled residue was filtered and the filtrate was fractionated through a column packed with glass helices, and 10 to 20 cm. in length, depending upon the boiling point of the product. The columns were equipped with heaters to prevent excessive flooding. Ethyl ethylacetoacetate was further purified before fractionation by extracting it with aqueous sodium bisulfite (20%) to remove excess ethyl acetoacetate.

The procedure was the same for the alkylation of α-substituted acetoacetic esters, except that equivalent amounts of potassium and ester were used. A 10% excess of alkyl bromide was used in all cases.

The rate at which the alkali disappeared was determined as follows: After addition of the alkyl halide, 1.0-ml. aliquots were removed from time to time and added to ethanol (15 ml.) containing "Nitrazine"[13] indicator solution (2

(8) Other improved methods of alkylation that have been suggested involve the use of non-hydroxylic solvents: Wallingford, THIS JOURNAL, **64**, 580 (1942); Elderfield, *J. Org. Chem.*, **4**, 370 (1939); **6**, 57 (1941).

[a] Apparently a new compound. Analyzed by method of Veibel, *Bull. soc. chim.*, **41**, 1410 (1917). Calculated for $C_{12}H_{25}ON_3$: $^1/_3$N, 6.16. Found: $^1/_3$N, 6.11.

drops). The solution was titrated with 0.100 *N* hydrochloric acid until the blue color changed to yellow. Since aliquots taken toward the end of the reaction required small volumes of titrating solution, water was added so that approximately equal volumes of ethanol and water were present at the end-points of all titrations.

The structure of alkylation products was confirmed by ketonic hydrolysis. The mono-substituted acetoacetic esters were hydrolyzed with aqueous sodium hydroxide (5%). The esters were first stirred with the alkali (1.5 moles to 1 of ester) for four hours at room temperature, after which the mixture was refluxed for about six hours. The ketones were removed from the cooled solution by ether extraction, the extracts were dried, the solvent was removed and the residue was fractionally distilled. The α,α-disubstituted acetoacetic esters were very resistant to hydrolysis. The following procedure, of many that were tried,[14] gave the best results: a solution of ethyl α,α-dibutylacetoacetate (26 g., 0.107 mole) in methanol (100 ml.) and water (20 ml.) containing potassium hydroxide (8 g., 0.14 mole) was refluxed for four hours. Additional potassium hydroxide (8 g.) and water (10 ml.) were added and the refluxing was continued for eight hours longer. The mixture was distilled from a water-bath, and when 105 ml. of distillate had been removed the residue was transferred to a separatory funnel. Water (25 ml.) was added and the mixture was thoroughly shaken; three layers separated. The lower layer was potassium carbonate solution; the middle layer yielded α-butylcaproic acid (3.7 g.) on acidification; and fractionation of the upper layer gave α,α-dibutylacetone (11.6 g.). The results of the ketonic hydrolyses are summarized in Table II.

(14) The method of Connor and Adkins (THIS JOURNAL, **54**, 3420 (1932)) could not be tried because the equipment was not available. α,α-Dibutylacetoacetic ester was recovered unchanged after it was stirred for six hours at 150–170° with 85% phosphoric acid (Dehn and Jackson, THIS JOURNAL, **55**, 4284 (1933)). Attempts to induce an ester interchange by refluxing α,α-dibutylacetoacetic ester with formic or acetic acid and zinc chloride were unsuccessful.

Summary

1. A procedure is described for the alkylation of acetoacetic esters, by action of potassium *t*-amyloxide in *t*-amyl alcohol and alkyl bromides.

2. The method was found to be advantageous for the preparation of certain α,α-disubstituted acetoacetic esters.

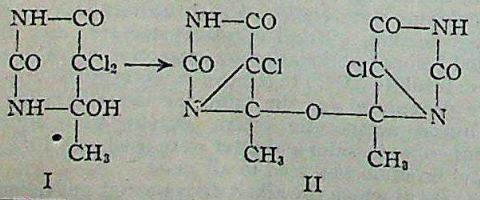
Reactions Characterizing the Oxide of 6-Methyl-6-oxy-5-chloro-1,5-bicyclouracil[1]

BY TREAT B. JOHNSON[2]

The formula adopted to interpret the constitution of the 1,5-bicyclouracil derivative, under discussion in this paper, is expressed graphically in no. II. This cyclo-pyrimidine is produced in excellent yield by digestion of 5,5-dichloro-6-hydroxy-6-methylhydrouracil (I) with concentrated hydrochloric acid.[3]



I II

The specific reactions pertaining to this first representative of a new type of pyrimidine compound, which the author is prepared to discuss at this time, are reported below under the two headings of (a) Reduction and (b) Oxidation Reactions, respectively.

Reduction Reactions

The 1,5-bicyclouracil derivative (II) loses its characteristic bicyclo structure on reduction and reverts to the constitution of a true uracil derivative. Interaction with stannous chloride and hydrochloric acid leads to the quantitative formation of 5-chloro-6-methyluracil, while warming with hydriodic acid and red phosphorus removes

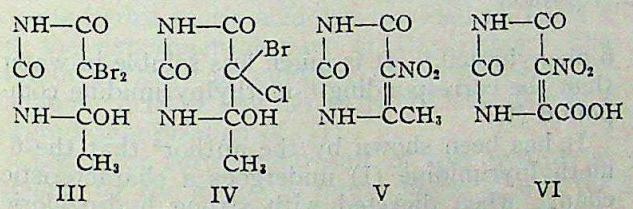
all halogen from the bicyclo pyrimidine (II) with regeneration of 6-methyluracil. No other reduction products have been identified.[3]

Oxidation Reactions

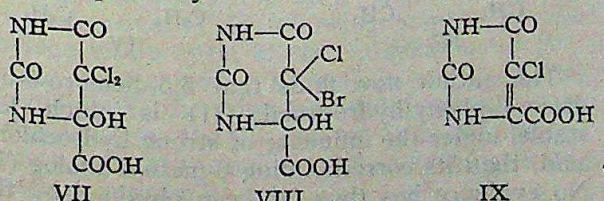
This section is confined to a discussion of the action of three different oxidizing reagents on the 1,5-bicyclouracil compound (II) namely: (a) superoxol and concentrated hydrochloric acid, (b) bromine water, and (c) concentrated nitric acid. Unexpected and characteristic reaction changes were disclosed as a result of this study.

The behavior of 6-methyluracil toward these three oxidising reagents is well known. Hydrogen peroxide in the presence of hydrochloric acid, and bromine water react quantitatively at ordinary temperature to give 5,5-dichloro-6-hydroxy-6-methylhydrouracil (I),[3,4] and 5,5-dibromo-6-hydroxy-6-methylhydrouracil[5] (III), respectively. With bromine water 5-chloro-6-methyluracil yields 5 - bromo - 5 - chloro - 6 - hydroxy - 6 - methylhydrouracil[5] (IV). In neither case is the methyl group of the respective uracil molecule converted by oxidation to a carboxyl group. Nitric acid is known to react with 6-methyluracil smoothly with formation of 5-nitro-6-methyluracil cil (V), but at elevated temperatures oxidation takes place yielding 5-nitro-6-uracil-carboxylic acid[6] (VI).



III IV V VI

This comparison of differences in chemical behavior on interaction of the 6-methyluracil molecule with these three oxidizing reagents is instructive and interesting, when we consider the action of these same reagents on the 1,5-bicyclouracil derivative (II). In this case the author finds that the 6-methyl group in (II) is oxidized easily by all three reagents with destruction of the bicyclo structure and formation of 5,5-dichloroxyhydroorotic acid (VII), 5-chlor-5-bromoxyhydroorotic acid (VIII) and 5-chloroorotic acid (IX), respectively.



VII VIII IX

5,5-Dichloroxyhydroorotic acid (VII) is reduced quantitatively to 5-chloroorotic acid (IX) by means of hydriodic acid and red phosphorus. It is of special interest to note here that this same hydropyrimidine derivative (VII) is not formed by the action of superoxol and hydrochloric acid directly on orotic acid.[7] The end-product resulting under such experimental conditions is 5-chloroorotic acid (IX).[8]

Experimental Part

The Action of Superoxol and Concentrated Hydrochloric Acid on the Oxide of 6-Methyl-6-oxy-5-chloro-1,5-bicyclouracil. (II)

Formation of 5,5-Dichloroxyhydroorotic Acid (VII).—Five-tenths gram of the finely pulverized pyrimidine compound (II) was exposed to the action of an oxidizing mixture containing 5 ml. of superoxol and concentrated hydrochloric acid, respectively. After standing for five to six days at ordinary temperature a clear liquid was obtained with 0.2 g. of colorless prismatic crystals in suspension. These prisms melted sharply at 182° with violent effervescence. After recrystallization from boiling water it still melted at the same temperature, 182–183° with effervescence. The compound was dried for analysis at 100–110°. *Anal.* Calcd. for 5,5-dichloroxyhydroorotic acid (VII), $C_5H_4O_5N_2Cl_2$: C, 24.69; H, 1.65; N, 11.50. Calcd. for 5,5-dichloro-6-hydroxy-6-methylhydrouracil (I), $C_5H_6O_3N_2Cl_2$: C, 28.12; H, 2.81; N, 13.1. Found: (I) C, 24.67; H, 1.88; N, 11.0. (II) C, 24.55; H, 1.90; N, 11.41.

Reduction of 5,5-Dichloroxyhydroorotic Acid (VII) to 5-Chloroorotic Acid (IX).[9]—Two grams of this pyrimidine (VII) and 0.5 g. of red phosphorus were suspended in 2 ml. of hydriodic acid (sp. gr. 1.5) diluted with an equal volume of water, and the mixture digested at its boiling point for fifteen to twenty minutes. The solution was then diluted with 5 ml. of hot water, filtered and finally evaporated at 100° to a sirupy consistency and cooled.

On adding cold water a colorless crystalline substance separated, which was difficultly soluble in boiling water. When heated in a capillary tube it turned brown at about 255°, shriveled and decomposed with effervescence at 294–296°. This decomposition point varies depending upon the rate of heating. The substance contained chlorine, and did not respond to the characteristic Wheeler and Johnson color test for uracil.[10] This same pyrimidine is formed by the direct action of superoxol and hydrochloric acid on orotic acid.[8] *Anal.* Calcd. for $C_5H_3O_4N_2Cl$: N, 14.68. Found: N, 14.60, 14.62.

The Action of Concentrated Nitric Acid on the Oxide of 6-Methyl-6-oxy-5-chloro-1,5-bicyclouracil (II). Formation of 5-Chloroorotic Acid (IX).—Five-tenths gram of this bicyclo pyrimidine was partially dissolved in 10 ml. of cold, concentrated nitric acid, and the mixture allowed to stand in a stoppered flask at ordinary temperature; red fumes were evolved slowly during a period of six days. After allowing to stand in the laboratory for nearly two weeks, a crystalline deposit of 0.15 g. was filtered off which did not melt or decompose below 280°. This was purified by recrystallization from boiling water and separated in the form of prismatic crystals. These shriveled and turned brown on heating finally decomposing with effervescence when heated above 285°. The compound contained chlorine and was dried for analysis at 100–110°. *Anal.* Calcd. for 5-chloroorotic acid (IX), $C_5H_3O_4N_2Cl$: N, 14.68. Found: N, 14.55, 14.59.

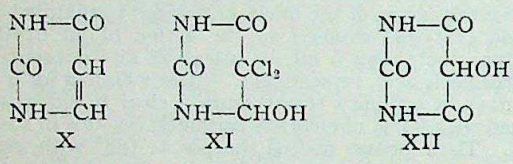
Formation of 5-Chloro-5-bromoxyhydroorotic Acid (VIII).—This acid is formed in excellent yield by the action of bromine water at ordinary temperature on the oxide of 6-methyl-6-oxy-5-chloro-1,5-bicyclouracil (II). The pyrimidine is moderately soluble in hot water and crystallizes in the form of prismatic crystals melting at 192–193°. It was dried for analysis at 100–110°. *Anal.* Calcd. for $C_5H_4O_5N_2BrCl$: N, 9.63. Found: N, 9.63.

The Conversion of 5,5-Dihalogenated-6-hydroxyhydroorotic Acids to Dialuric Acid.—The two new hydroorotic acid derivatives, namely: 5,5-dichloroxyhydroorotic acid (VII) and 5-chloro-5-bromoxyhydroorotic acid (VIII) bear the same structural relationship to orotic acid as 5,5-dichloroxyhydrouracil (XI) does to the uracil molecule (X).

The author now finds that these two hydropyrimidines (VII) and (VIII) cannot be distinguished from 5,5-dichlorhydrouracil (XI) by application of the standard



X XI XII

Wheeler and Johnson color reaction for uracil.[10] By application of their well-known technique the 6-carboxyl groups in the two pyrimidines (VII) and (VIII) are removed by the action of barium hydroxide yielding at once dialuric acid (XII), and its characteristic purple-colored barium salt.

These are the first pyrimidines of the halogenated 6-hydroxyhydrouracil type, so far discovered, which have responded to this characteristic color reaction reported by Wheeler and Johnson as a specific color test for uracil and cytosine.[10]

Summary

1. The oxide of 6-methyl-6-oxy-5-chloro-1,5-bicylouracil is converted smoothly by reduction to a true uracil derivative.

2. The chemical action of three different oxidizing reagents has thus far been studied namely: superoxol and hydrochloric acid, bromine water and nitric acid.

3. The methyl group of this 1,5-bicyclopyrimidine compound is oxidized to carboxyl by the action of all three reagents, with regeneration of the normal pyrimidine structure, yielding characteristic derivatives of hydroorotic acid.

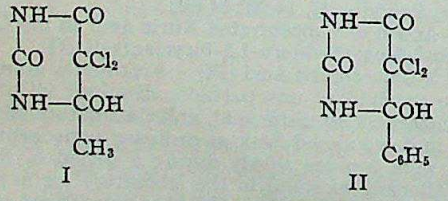
The Acid Hydrolysis of a 6-Aryl-5,5-dichloroxyhydrouracil[1]

BY TREAT B. JOHNSON[2]

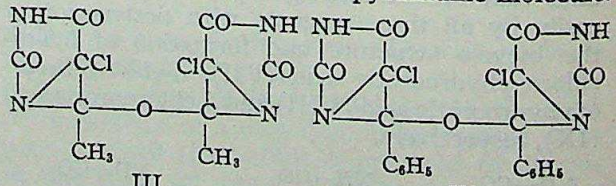
In the light of the results obtained during the previous experimentation on acid hydrolysis of 5,5-dichloro-5-hydroxy-6-methylhydrouracil[3] (I), it became of increased interest to the author to undertake a similar study with the simplest aromatic representative of this heterocyclic pyrimidine series, namely, 5,5-dichloro-6-hydroxy-6-phenylhydrouracil (II). Very little is known about the chemistry of such aromatic pyrimidine compounds as represented by (II).



I II

Judging from the experience of the author in other fields of pyrimidine research, it might be predicted that the study of such aryl derivatives as (II) would disclose further evidence in support of reaction mechanisms that have previously been postulated[3] regarding positions 1-, 5- and 6- in this type of hydrouracil compound. The pyrimidine (II) is easily prepared, without substitution of chlorine in the 6-phenyl group, by the action of superoxol and concentrated hydrochloric acid on 6-phenyluracil.[4] It is much less soluble in water than the corresponding 6-methylpyrimidine compound (I).

It has been shown by the author[3] that the 6-methylpyrimidine (I) undergoes a characteristic change when digested with strong hydrochloric acid yielding the first representative of a new type of pyrimidine compound to which has been assigned the constitution of the oxide of 6-methyl-6-oxy-5-chloro-1,5-bicyclouracil (III). In fact, the 1,5-bicyclouracil structure expressed in this formula (III) is favored by the oxide structure functioning in position 6- of the pyrimidine molecule.



III IV

The author now finds that 5,5-dichloro-6-hydroxy-6-phenylhydrouracil (II) is much less stable, under the influence of strong hydrochloric acid, than its corresponding 6-methyl-analog (I). No evidence has thus far been obtained by the author of the formation of a condensed 1,5-bicyclouracil compound (IV) by digestion of (II) with this mineral acid.

TABLE I

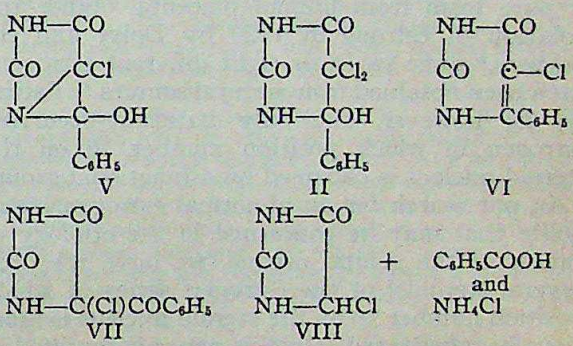
ACID HYDROLYSIS OF 5,5-DICHLORO-6-HYDROXY-6-PHENYLHYDROURACIL (II)

Reactant, g.	Hydrochloric acid, cc.	Digestion period, hr.	Reaction products	Analyses, $C_{10}H_8O_2N_2Cl_2$ Calcd.	Found
The hydropyrimidine (II), 1	100 of concd. acid	2 at 100°	Reactant recovered = 0.75 g., NH_4Cl identified	C, 43.66	43.9
				H, 2.91	3.17
				N, 10.18	10.09
1	100	6 at 100°	Reactant completely dextroyed. Benzoic acid and NH_4Cl identified		
1	100	4 at 100°	Recovered 0.4 g. benzoic acid and 4 mg. of reactant m. p. 209–210°. 5-Chloro-6-phenyluracil identified m. p. 260–261°. Also NH_4Cl	N, 10.18	9.95
1	100	4 at 100°	Recovered 0.5 g. of benzoic acid, and 3.5 mg. of reactant. NH_4Cl identified		

While aryl derivatives of uracil-like 6-phenyluracil and 5-chloro-6-phenyluracil, for example, can be heated with strong hydrochloric acid without degradation of the pyrimidine cycle, the hydrouracil derivative (II) suffers complete destruction of the pyrimidine ring by such treatment with formation of benzoic acid and ammonium chloride. The only pyrimidine degradation product identified after the hydrolysis was a few milligrams of 5-chloro-6-phenyluracil (VI). The results of four hydrolysis experiments obtained after two, four and six hours of digestion with strong hydrochloric acid are recorded in Table I of the experimental part of this paper. The author obtained no evidence of the formation of cinnamic acid or any derivative of this acid as a degradation product of (II).

The most surprising result of this hydrolytic change by the action of hydrochloric acid is the quantitative conversion of (II) to benzoic acid. To explain this molecular transformation of the pyrimidine (II), the author has presupposed the possibility of formation of different intermediate compounds, but he concludes at present, that the formation of a 1,5-bicyclouracil derivative (V) is probably the first intermediate product of hydrolytic change. According to this interpretation of reaction we are dealing with an hypothetical **ethylene-imide** cycle, which would be predicted to be unstable due to the influence of a free hydroxyl group in position 6- of (V) and (II), and to revert in acid solution to the hypothetical hydantoin derivative (VII) following scission of the **ethylene-imide** cycle in the 1,6-position of (V). In the corresponding hydrolysis study of the pyrimidine (I) the **ethylene-imide** ring structure is stabilized by the absence of hydroxyl due to the formation of the oxide or ether structure functioning in position 6- of (III).

This intermediate, hydantoin derivative (VII) would be predicted from our present knowledge of the chemistry of such heterocyclic compounds to undergo degradation easily, by hydrolysis with strong hydrochloric acid, leading to complete destruction of the hydantoin ring and production of benzoic acid and ammonium chloride. The hydantoin expressed by formula (VIII) has not, thus far, been isolated as a product of reaction. The study of the behavior on acid hydrolysis of aryl and alkyl substituted pyrimidine compounds of types (I) and (II) will be continued by the author.



Experimental Part

Formation of 5,5-Dichloro-6-hydroxy-6-phenylhydrouracil from 6-Phenyluracil.—Two grams of finely pulverized 6-phenyluracil[4] was stirred into a cold mixture of 30 cc. of superoxol and concentrated hydrochloric acid, respectively. The pyrimidine did not dissolve at any stage of the operation, and was allowed to stand for fully twenty-four hours when the colorless reaction product was filtered off and purified by recrystallization from hot water. It separated on cooling in the form of flat prisms melting at 209–210° with violent effervescence. The compound contained chlorine, and was dried at 100–110° before analysis.

Anal. Calcd. for $C_{10}H_8O_3N_2Cl_2$: N, 10.18. Calcd. for $C_{10}H_7O_2N_2Cl$: N, 12.58. Found: N, 9.75, 9.86.

In a second experiment 3.5 g. of 6-phenyluracil was triturated with a mixture of 50 cc. of superoxol and 50 cc. of concentrated hydrochloric acid for twenty-four hours. We obtained 4.0 g. of a colorless product melting at 195–196° with decomposition. After recrystallization from hot water this product melted at 209–210° with violent effervescence.

Reduction of 5,5-Dichloro-6-hydroxy-6-phenylhydrouracil (II). Formation of 5-Chloro-6-phenyluracil (VI).—One gram of the hydrouracil derivative mixed with 10 cc. of hydriodic acid (sp. gr. 1.5) and 0.5 g. of red phosphorus was heated to 100°, and the mixture diluted with 20 cc. of water. This was then digested for fifteen minutes at the boiling point and finally cooled. Following filtration, the phosphorus residues were triturated with dilute sodium hydroxide and filtered giving a clear alkaline solution. Acidifica-

tion with hydrochloric acid gave an immediate precipitate of 6-phenyl-5-chlorouracil melting at 260–261° to a clear oil. The compound contained chlorine, and was dried for analysis at 100–110°.

Anal. Calcd. for $C_{10}H_7O_2N_2Cl$: N, 12.58. Found: N, 12.32.

Summary

1. 5,5-Dichloro-6-hydroxy-6-phenylhydrouracil (II) is formed in good yield by the combined action of superoxol and hydrochloric acid on 6-phenyluracil.

2. This hydrouracil compound is characterized by its behavior when digested with concentrated hydrochloric acid. This treatment leads to complete destruction of the pyrimidine ring with formation of benzoic acid and ammonium chloride.

3. A reaction mechanism has been proposed to explain this unexpected decomposition of (II) by action of hydrochloric acid.

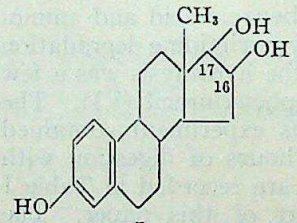
16-Substituted Steroids. I. Isoestriol-A

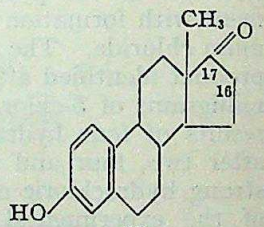
BY MAX N. HUFFMAN[1] AND HUGH H. DARBY

In 1930 Marrian[2] in England and Doisy[3] in America succeeded in isolating from human pregnancy urine the estrogen which is now known as estriol or theelol. Browne,[4] working in Collip's laboratory, subsequently obtained this hormone in pure form from human placenta. Since the isolation of estrone in 1929 by Doisy and coworkers,[5] some seven or eight different estrogens have been obtained from natural sources. Estriol (I) is, however, the only naturally-occurring estrogen in which position number 16 on the steroid nucleus is occupied by a functional group.

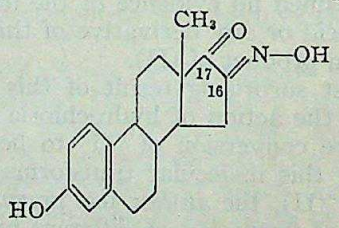
In our search for an abnormal estrogen metabolite that may be concerned in the etiology of cancer of the genital organs, we have prepared several steroids[6] of the estrogen series in which position number 16 on the steroid nucleus is functionally substituted. In this paper is reported in detail the preparation of an epimer of theelol. It is to be noted that there exists the theoretical possibility for four stereoisomeric estriols, considering only the spatial arrangements of the carbinols at positions 16 and 17 on the estrane skeleton. On the reduction of estrone (II) (which is ketonic at position 17) to the secondary alcohol stage, two isomeric estradiols are possible. Both these estradiols are known.[7] Similarly, the reduction of 16-ketoestrone (an α-diketone) should give rise to four isomeric estriols. Previously only one estriol was known—the naturally occurring theelol. The isomer prepared by us has been designated isoestriol-A in view of the fact that the geometric arrangement of the two carbinols at positions 16 and 17 has not as yet been determined. It is our goal to prepare the remaining two isomers in order that all four compounds of the series Δ1,3,5-estratrientriol-3,16,17 be on hand for experimentation on tumor production.



I



II



III

Isoestriol-A was prepared from estrone by a five step synthesis involving benzoylation of estrone, formation of the 16-oximino derivative, saponification of the ester, reductive hydrolysis of the oximino group, and, finally, hydrogenation of the ketol (or ketols).

Litvan and Robinson[8] in 1938 first prepared the 16-oximino derivative of a steroid when they submitted estrone methyl ether to reaction with isoamyl nitrite in a medium of *t*-butyl alcohol and potassium *t*-butoxide. We followed their procedure with modifications but were forced to employ an ester of estrone in order that the free phenol might be easily recovered. Estrone benzoate was chosen in the hope that with it, under the conditions of our reaction, saponification would occur much less readily than nitrosation. Such was very likely the situation, for, after saponification 16-oximinoestrone (III) was obtained in 80% yield.

Recently Stodola, Kendall and McKenzie[9] found that the mild reduction of 16-oximinodehydroisoandrosterone using zinc and aqueous acetic acid yielded only a small amount (less than 5%) of the expected amine, the bulk of the compound having been changed to a mixture of isomeric α-ketols. Our experience with the zinc–acetic acid reduction of 16-oximinoestrone was similar, as we rocovered a nitrogen-free material in over 90% yield. The exact composition of this material is not known, but certainly the preponderating component is an α-ketol. On further reduction of the α-ketolic material with hydrogen and Adams catalyst a triol (m.p. 267–269°)[10] was obtained which on admixture with authentic theelol (m.p. 271°) showed a depression of some 10°. Furthermore, the new triol gave a triacetate melting at 152° and a monomethyl ether melting at 141–142°, as contrasted against the analogous derivatives[11] of theelol which melt at 127 and 159°, respectively. The values[11] listed in the literature for the optical rotation of estriol vary from +57 to +66°, while that of isoestriol-A was found to be +88°. Isoestriol-A is also less soluble in ethanol than naturally-occurring estriol.

Experimental

Benzoylation of Estrone.[11]—Estrone (II) was benzoylated by the Schotten–Baumann method. For each gram of estrone, 570 cc. of 0.5 *N* potassium hydroxide and 10 cc. of benzoyl chloride were employed.

16-Oximinoestrone (16-Isonitrosoestrone) (III).—Potassium metal (1.0 g.) was dissolved in 40 cc. of *t*-butyl alcohol and 766 mg. of powdered estrone benzoate (m. p. 215–216°) added. The mixture was stirred for five hours to dissolve the ester and then 0.8 cc. of freshly-prepared isoamyl nitrite pipetted into the solution, which at once turned red in color. After the red solution had been stirred for four hours, another 0.8-cc. portion of isoamyl nitrite was added, and the stirring continued for an additional eight hours. The whole procedure was conducted at room temperature under an atmosphere of dry nitrogen.

The reaction mixture was transferred to a separatory funnel containing a solution of 10 g. of glycine in 150 cc. of water, and the whole shaken with ethyl ether until solution of all components was effected. After separation, the ether was extracted once with water and then with 0.5 *N* potassium hydroxide. In order to ensure complete saponification, the yellow potassium hydroxide layer was allowed to remain at room temperature for four hours. It was then extracted twice with ether, acidified with concentrated hydrochloric acid, and placed at 0°. A bulky white precipitate soon formed. After standing overnight, the precipitate filtered easily, and it was submitted to copious washing with water. On drying in the desiccator over calcium chloride, 495 mg. (81% yield)[12] of α-oximino ketone melting at 210–211° was obtained. On recrystallization from aqueous methanol, the 16-oximinoestrone crystallized in small tufts of fine, practically colorless needles which melted at 214–215° with decomposition.

Anal. Calcd. for $C_{18}H_{21}O_3N$: N, 4.68. Found: 4.59.

16-Oximinoestrone is a typical α-oximino ketone[13] in that its solution is colorless in ether but yellow in alkali.

Reduction of 16-Oximinoestrone with Zinc and Acetic Acid.—16-Oximinoestrone (397 mg.) was dissolved in 12.0 cc. of glacial acetic acid and 0.5 cc. of water. Zinc dust (1.0 g.) was added and the mixture swirled in a water-bath at 40–45°. The α-oximino ketone soon dissolved to give a yellow solution with a greenish fluorescence. Water[14] (11.5 cc.) was then added and the solution heated under reflux in an oil-bath held at a temperature of 120–125°. At first the color of the solution deepened to an intense green but this gradually disappeared, and at the end of 1.5 hours only a slight color remained. The hot solution was then decanted from the zinc into a separatory funnel containing an ice-cold aqueous solution of 9.0 g. of sodium hydroxide. A further rinsing of the zinc was performed with 5.0 cc. of hot acetic acid and the latter combined with the previous decantation. The mixture was shaken out with ethyl ether, the ether separated and washed successively with 1.0 *N* hydrochloric acid, aqueous bicarbonate, and water. Evaporation of the ether yielded a crystalline, almost colorless residue which on recrystallization from aqueous methanol with the use of charcoal gave 320 mg. The principal constituent in this product is an α-ketol which will be described in a subsequent publication.

Isoestriol-A.—The 320 mg. of α-ketolic product from the zinc–acetic acid reduction of 16-oximinoestrone was dissolved in 150 cc. of 0.5 *N* sodium hydroxide and 600 mg. of Adams catalyst added. After being shaken for twenty-four hours under hydrogen, the solution was filtered from the platinum and the latter washed with 0.5 *N* sodium hydroxide. The alkaline filtrate was acidified and extracted with ethyl ether. After being washed with aqueous bicarbonate and then with water, the ether was distilled off. In order to remove any possible unreduced ketone, the ether residue was treated with carboxymethoxylamine by a procedure previously published.[15] The non-ketonic fraction was recrystallized twice from acetone to yield 110 mg. of white microscopic crystals melting at 267–269°. This melting point remained the same after treatment with charcoal and successive recrystallizations from acetone, methanol and ethanol. A mixed melting point taken with authentic theelol[16] showed a depression of about 10 degrees. $[\alpha]^{29.5}D$ +88° (0.227% solution in 95% ethanol).

Anal. Calcd. for $C_{18}H_{24}O_3$: C, 74.97; H, 8.39. Found: C, 74.88; H, 8.40.

Isoestriol-A Methyl Ether.—Isoestriol-A (35 mg.) was dissolved in 20 cc. of 0.5 *N* sodium hydroxide and 0.5 cc. of redistilled dimethyl sulfate added. After being shaken for one and one-half hours the reaction mixture was left at room temperature overnight. The white precipitate was then filtered, washed several times with 0.5 *N* sodium hydroxide, and finally with water. After being dried in the desiccator the product was dissolved in methanol, treated with charcoal, and recrystallized from aqueous methanol at 0°. The yield was 12 mg. of white microscopic crystals melting at 141–142°. For analysis the ether was dried to constant weight *in vacuo* over phosphorus pentoxide at 80°.

Anal. Calcd. for $C_{19}H_{26}O_3$: C, 75.46; H, 8.67. Found: C, 75.23; H, 8.72.

Isoestriol-A Triacetate.—To 42 mg. of Isoestriol-A, 3 cc. of acetic anhydride and 3 cc. of pyridine were added. The solution was heated for three hours on the steam-bath, cooled and diluted with 50 cc. of cold water. Well-formed

(9) Stodola, Kendall and McKenzie, *J. Org. Chem.*, **6**, 841 (1941).

(10) All melting points in this paper are uncorrected.

(11) Doisy, in "Sex and Internal Secretions," Williams and Wilkins Co., Baltimore, p. 866 (1939).

(12) This reaction has been carried out several times, and the yield is usually around 80%. Once, however, we obtained a 96% yield of pure product.

(13) Meyer and Jacobson, "Lehrbuch der Organischen Chemie," Veit & Co., Leipzig, Sec. Ed., I, Part 2, p. 829 (1913).

(14) After conducting several zinc–acetic acid reductions on 16-oximinoestrone by the procedure of Stodola, Kendall and McKenzie, we decided that it was advantageous to use a more dilute solution of acid and to reflux longer if necessary, since, by this alteration, less fluorescing by-product seemed to be formed.

crystals came out at once; the mixture was left at 0° overnight, filtered, and the crystals washed with water and dried in the desiccator over calcium chloride and potassium hydroxide. On recrystallization from methanol at 0°, long slender needles were slowly deposited; yield, 24 mg. melting at 152°.

Anal. Calcd. for $C_{24}H_{30}O_6$: C, 69.54; H, 7.30. Found: C, 69.13; H, 7.51.

Solubility of Isoestriol-A.—No direct solubility measurements were made; however, in attempting to prepare a solution for polarimetry it was found impossible to dissolve 23.66 mg. of the triol in 3.00 ml. of 95% ethanol at room temperature. The solubility of theelol in 95% ethanol has been found to be 1.20 g. (10°) and 1.65 g. (30°) in 100 g. of solvent.[17] It was further observed that isoestriol-A dissolves in 0.5 *N* sodium hydroxide much more readily than does theelol.

Ultraviolet Absorption Spectrum.—Ultraviolet absorption spectra of isoestriol-A and of theelol were obtained by use of the Hilger medium spectrograph. The two curves were identical, each with the other, and with that of theelol previously published by Callow.[18] This finding was anticipated, since isomers of this nature are not expected to show differences in ultraviolet absorption spectra.

Acknowledgment.—The authors wish to thank Miss Georgiana Becker for technical assistance and to express their appreciation to Mr. William Saschek for the micro-analyses reported in this paper. The authors are very grateful to Mr. Floyd H. Eggert, U. S. Standard Products Company, for the generous gift of crude estrone. To Professor Hans T. Clarke, who furnished the facilities for this research and who was a constant counselor throughout, they are deeply indebted.

Summary

1. 16-Oximinoestrone has been prepared from estrone benzoate.

2. Using 16-oximinoestrone as an intermediate, an estriol isomeric with theelol has been synthesized. Like theelol, the new estriol is a Δ1,3,5-estratrientriol-3,16,17.

The Use of Certain Phenyl Esters in the Reformatsky Reaction[1]

BY MELVIN S. BLOOM AND CHARLES R. HAUSER

The Reformatsky reaction using ethyl esters instead of aldehydes or ketones as the carbonyl component has not generally been very satisfactory.[2] Since phenyl esters have a more reactive carbonyl group than the corresponding ethyl esters (judging from their relative rates of alkaline hydrolysis)[3] it seemed possible that phenyl esters might serve satisfactorily as the carbonyl component in the Reformatsky reaction. This has been realized in certain cases but not in others.

It has been found that, although ethyl benzoate fails, phenyl benzoate undergoes satisfactorily the Reformatsky reaction with ethyl α-bromoisobutyrate to form ethyl benzoyldimethylacetate.

$$C_6H_5CO_2C_6H_5 + BrC(CH_3)_2CO_2C_2H_5 \xrightarrow{Zn} C_6H_5COC(CH_3)_2CO_2C_2H_5 + C_6H_5OZnBr$$

The yield (52%) of the β-keto ester obtained by this method is essentially the same as that obtained by the benzoylation of ethyl isobutyrate in the presence of the triphenylmethide ion.[4]

Phenyl esters are satisfactory as the carbonyl component in the Reformatsky reaction apparently only when neither the phenyl ester nor the bromoester has α-hydrogens. With 4-phenylphenyl acetate and ethyl α-bromoisobutyrate, ethyl α,α-dimethylacetoacetate was obtained in only low yield (11%), while with phenyl benzoate and ethyl α-bromoacetate or with 4-phenylphenyl propionate and ethyl α-bromoacetate, only very low yields of the respective β-keto esters appeared to be formed. Since most of the zinc was used up in these experiments, the low yields in these cases appears to be due to the predominance of side or subsequent reactions, which, among others, may involve the self-condensation of the phenyl ester (when it has an α-hydrogen) and the enolization of the β-keto ester formed from bromoesters having α-hydrogens. Both of these reactions could probably be effected by the organozinc halide which is presumably the intermediate in the Reformatsky reaction.[2]

Experimental

Ethyl Benzoyldimethylacetate.—In a 500-cc. three-necked flask fitted with a mechanical stirrer, a separatory funnel, and a reflux condenser protected with a calcium chloride tube was placed 16.4 g. (0.25 mole) of zinc foil which had been sandpapered and cut into small strips. A mixture of 48.8 g. (0.25 mole) of ethyl α-bromoisobutyrate (b. p. 49–51° (10 mm.)), 49.6 g. (0.25 mole) of phenyl benzoate (m. p. 68–68.5°), 100 cc. of dry benzene, and 150 cc. of dry toluene was placed in the separatory funnel. About 50 cc. of this solution was added to the zinc and the flask was heated to 150° in an oil-bath until the reaction started. The mixture was then stirred and the rest of the solution introduced at such a rate that gentle refluxing occurred, about thirty minutes being required. Refluxing and stirring were continued for an additional three hours. The flask was cooled in an ice-bath and its contents poured into ice-cold 10% sulfuric acid with vigorous stirring. The acid layer was separated and the benzene–toluene layer was washed with water. The combined wash water and

the acid layer was extracted with ether, and the combined ether and benzene–toluene solution was dried over anhydrous sodium sulfate followed by Drierite. The solution was distilled up to 140° and the residue was fractionated at 9 mm., collecting fractions at 72–130° and at 130–145°. To the residue was added the fraction boiling at 72–130° (9 mm.), and the mixture distilled, the material boiling at 129–149° (9 mm.) being collected and combined with the fraction boiling at 130–145 (9 mm.). Redistillation yielded 28.5 g. (52%) of ethyl benzoyldimethylacetate boiling at 132–135° (9 mm.). Some phenyl benzoate was recovered in the residues.

With hydroxylamine hydrochloride, the β-keto ester gave 3-phenyl-4-dimethylisoxazolone-5 (m. p. 69–70°)[5] in 90% yield. On ketonic hydrolysis by the acetic-sulfuric acid method,[6] the β-keto ester gave a 77% yield of phenyl isopropyl ketone (102–103° (15 mm.)); m. p. of 2,4-dinitrophenylhydrazone, 162–163°.[7]

In the Reformatsky reaction described above, in which approximately 80% of the zinc was used up, the zinc tended to become coated with a precipitate in the course of the reaction, and the yield was satisfactory only when the reaction mixture was stirred vigorously using zinc foil. With 20–30 mesh zinc 30% of the zinc was used up, giving an 18% yield of the β-keto ester. When magnesium turnings were used instead of zinc only an 18% yield of the β-keto ester was obtained even though practically all of the magnesium was used up.

In an experiment in which ethyl benzoate was used instead of phenyl benzoate, less than 10% of the zinc reacted, and the reaction was not further studied.

Other Reactions.—The following reactions were carried out essentially as described for the preparation of ethyl benzoyldimethylacetate.

Ethyl α-bromoisobutyrate with 4-phenylphenyl acetate[8] (m. p. 87–88°) gave an 11% yield of ethyl α,α-dimethylacetoacetate, b. p. 75–76° (14 mm.). When phenyl acetate was used instead of 4-phenylphenyl acetate, the β-keto ester could not be freed from the unreacted phenyl acetate. Ketonic cleavage by the acetic-sulfuric acid method,[6] gave a small amount of methyl isopropyl ketone, b. p. 93–95°; m. p. of 2,4-dinitrophenylhydrazone of the ketone, 118°.[9]

Ethyl bromoacetate with phenyl benzoate yielded a small fraction boiling at 141–143° (6 mm.) which apparently contained, in addition to phenyl benzoate, at least a trace of ethyl benzoylacetate since it gave the red enol test and the green copper salt.[10]

Ethyl bromoacetate with 4-phenylphenyl propionate[11] (m. p. 92.0–92.5°) yielded a small fraction of product boiling over a large range, giving the red enol test and the copper salt,[12] (m. p. 143–144°) of ethyl propionylacetate.

Summary

1. Phenyl benzoate has been found to undergo the Reformatsky reaction with ethyl α-bromoisobutyrate to form ethyl benzoyldimethylacetate in good yield.

2. Phenyl esters appear to be satisfactory as the carbonyl component for the Reformatsky reaction only when neither the phenyl ester nor the bromoester has α-hydrogens.

DURHAM, N. C. RECEIVED OCTOBER 18, 1943

NOTES

2,3,4-Triacetyl-α-methylglucopyranoside-6-nitrate and 3,4,6-Triacetyl-β-methylglucopyranoside-2-nitrate

BY E. K. GLADDING[1] AND C. B. PURVES

Although these two compounds were synthesized, apparently for the first time, by conventional methods as an incident in a larger research, it seems advisable to make a brief, separate record of their preparation and their properties.

The nitration of 2,3,4-triacetyl-6-trityl-α-methylglucoside[2] produced a crystalline residue consisting of triphenylmethyl carbinol and the desired 6-nitrate in equimolecular amount.[3] A fractional crystallization, carried out exactly as specified below, resulted in a 79% yield of pure 2,3,4-triacetyl-α-methylglucoside-6-nitrate, which occurred as well formed prisms having m. p. 112–113° (cor.). No wandering of acetyl groups occurred during the nitration because the same nitrate was obtained by heating 2,3,4-triacetyl - 6 - iodo - 6 - desoxy - α - methylglucopyranoside[4] with excess silver nitrate in acetonitrile. Conversely, the 6-iodo compound was produced in 91% yield by heating the nitrate with excess sodium iodide dissolved in acetonylacetone.[5] The specific rotation of the nitrate in 1.11% chloroform solution was $[\alpha]^{20}D$ 132°, and this value, in conjunction with that of −14.3° found for triacetyl-β-methylglucopyranoside-6-nitrate,[6] leads to a molecular rotation difference of 53,400. The fact that this difference is very close to that of 53,900, accepted for tetraacetyl α- and β-methylglucoside[7] supports the conclusion that the two isomeric nitrates differ only in the configuration of the glycosidic carbon atom,

The experimental portion describes one or two manipulative improvements in the standard synthesis of 3,4,6-triacetyl-β-methylglucopyranoside.[8,9] Nitration of the latter gave a triacetyl methylglucoside nitrate in an over-all yield of about 15% from glucose pentaacetate. The nitrate occurred as small prisms, m. p. 117–118° (cor.) and with a specific rotation of $[\alpha]^{25}D$ −1° in 3.69% chloroform solution. Since acyl wandering is unlikely during nitration, and was not observed during several similar substitutions,[8,9] the nitrate group was assigned to the second position in the triacetyl-β-methylglucoside molecule.

Experimental

2,3,4-Triacetyl-α-methylglucoside-6-nitrate.—Commercial α-methylglucopyranoside, 50 g., was condensed with triphenylmethyl chloride,[2] and the product was acetylated prior to isolation.[10] Although the purified triacetyl-6-trityl derivative, 81 g., analyzed correctly and had the accepted rotation of $[\alpha]^{20}D$ 137° in pyridine,[11] it melted at 143–145° (cor.) instead of at 136°.[2,11] A solution of 15 g. of the 6-trityl derivative in 75 cc. of chloroform was mixed, at 3 to 5°, with 6 g. of phosphorus pentoxide previously dissolved in 75 cc. of nitric acid.[12] This nitric acid was prepared by distilling a mixture of concentrated sulfuric and nitric acids (1:1) in an all-glass apparatus and was miscible without turbidity with chloroform. After being kept at 3 to 5° for ten to fifteen minutes, the nitration mixture was poured, with stirring, into 750 cc. of cracked ice and water. The chloroform layer was separated, washed with dilute sodium bicarbonate solution and with water, and dried over anhydrous sodium sulfate. Evaporation under reduced pressure left a solid, crystalline residue consisting of triphenylmethyl carbinol and the desired nitrate. This mixture was completely, or almost completely, dissolved in 75 cc. of warm, glacial acetic acid, and exactly 50 cc. of water was added, drop by drop with continuous shaking, in order to precipitate the carbinol. After the mixture had stood at room temperature for several hours, 6.1 g., or 88% of the carbinol was removed by filtration and the 6-nitrate was then precipitated by slowly adding 150 cc. of water to the mother liquor. An easy recrystallization from 50 cc. of hot benzene and 100 cc. of ligroin left 7.7 g. of practically pure material, which was recrystallized once more from methanol.

Anal. Calcd. for a triacetyl methylglucoside mononitrate, $C_{13}H_{19}O_{11}N$: C, 42.7; H, 5.2; N, 3.84. Found: C, 42.8, 42.8; H, 5.2, 5.1; N, 4.12, 4.15.

3,4,6-Triacetyl-β-methylglucoside-2-nitrate.—The trichloroacetyl group was removed from 20 g. of pure, recrystallized 2-trichloroacetyl-3,4,6-triacetyl glucopyranosyl chloride[8] by solution at 0° in 350 cc. of dry ether previously saturated with dry ammonia gas.[8] The crystalline aggregates of crude triacetyl glucosyl chloride that promptly separated were broken up by occasional shaking. They were then washed with ether, 25 cc., and benzene, 50 cc., and were suspended without previous drying in 160 cc. of dry benzene. This procedure retained the highly swollen, flocculent condition of the crystals and resulted in a semi-permanent benzene suspension that gave reliable yields in the next operation. Suspensions of previously dried crystals gave erratic results. A slow stream of dry ammonia gas was passed through this suspension at room temperature for eight hours and benzene was occasionally added to replace that lost by evaporation. A rapid stream of gas greatly delayed the reaction because a quick evaporation of benzene chilled the mixture. Although it was easy to purify the crude 3,4,6-triacetyl anhydroglucose<1,5><1,2>, 11.8 g., that was produced,[8,9] for present purposes it was sufficient to dissolve the sirup in 200 cc. of dry methanol. A nearly quantitative yield, 12 g., of 3,4,6-triacetyl-β-methylglucoside was isolated on the following day. Trituration of the crude product with 20 cc. of cold ether left 8.9 g., m. p. 93–94° (uncor.), whose specific rotation of 18.8° in methanol[9] showed that it was pure enough for nitration. Recrystallization from absolute alcohol was slow and difficult but better results were obtained with an alcohol–petroleum ether mixture. Yields, melting points and rotations given for all intermediates in the synthesis were confirmed.[8,9]

A solution of 5 g. of triacetyl methylglucoside in 50 cc. of chloroform was nitrated with 50 cc. of chloroform-soluble nitric acid and 6 g. of phosphorus pentoxide in the way already described. The crude product, 4.5 g. or 76% of calcd., crystallized readily and was recrystallized from 25 cc. of hot methanol. The physical properties given in the Introduction for 3,4,6-triacetyl-β-methylglucoside-2-nitrate were not changed by further recrystallization.

Anal. Calcd. for $C_{13}H_{19}O_{11}N$: C, 42.7; H, 5.2; N, 3.84. Found: C, 42.6, 42.5; H, 5.2, 5.7; N, 3.90, 3.87.

The Alkylation of *o*- and *p*-Xylene

BY DOROTHY NIGHTINGALE AND J. R. JANES[1]

Our experiences with various catalysts for the alkylation of *m*-xylene[2] indicated that it would be worth while to study their efficiency with *o*- and *p*-xylene, especially since one of these catalysts, boron trifluoride, is less likely to promote migration or rearrangement of alkyl groups already on the ring. *t*-Butyl compounds were selected as alkylating agents since they are more reactive than their isomers and the *t*-butyl radical does not undergo rearrangement.

o-Xylene alkylated readily with *t*-butyl chloride and anhydrous ferric chloride and with *t*-butyl alcohol and boron trifluoride to form 1,2-dimethyl-4-*t*-butylbenzene in good yield.

As might be expected *p*-xylene did not alkylate as readily as the *o*- and *m*-xylenes. It did not alkylate at all with *t*-butyl alcohol and 80% sulfuric acid, *t*-butyl chloride and ferric chloride, or isobutylene and ferric chloride. With boron trifluoride and *t*-butyl alcohol, the product distilled over a 45° range and no one compound could be isolated from the mixture. Toluene alkylated readily with isobutylene and ferric chloride so the failure of *p*-xylene to alkylate was not due to the reagents.

Experimental

Alkylation of *o*-Xylene with Ferric Chloride and *t*-Butyl Chloride.—*t*-Butyl chloride (25 g.) was added during one hour and with stirring to 150 g. of *o*-xylene and 12.5 g. of anhydrous ferric chloride in a one-liter round-bottom

three-necked flask equipped with a reflux condenser and motor stirrer. The temperature was maintained at −3 to 10° during the total reaction time of seven hours. The mixture was decomposed by pouring into 100 cc. of hydrochloric acid and 100 g. of cracked ice. The upper layer was extracted with petroleum ether (28–38°), washed and dried.

After removal of the solvent and excess *o*-xylene, the product (74 g.) distilled at 83–85° (3 mm.). Fractionation of this material yielded 30.5 g. (70%) of 1,2-dimethyl-4-*t*-butylbenzene, $n^{25}D$ 1.4970.

Anal. Calcd. for $C_{12}H_{18}$: C, 88.89; H, 11.11. Found: C, 88.83; H, 11.45.

Oxidation of 1,2-Dimethyl-4-*t*-butylbenzene.—The hydrocarbon (5 g.) was dissolved in 40 cc. of pyridine in a 3-necked conical flask and water added until the solution became slightly turbid. The flask was heated to 80° in a water-bath. Potassium permanganate (15 g.) was added with stirring during one hour and the mixture stirred an additional six hours. The manganese dioxide was separated by filtration. The filtrate was acidified with concentrated hydrochloric acid and the acid collected on a filter. Crystallization from dilute alcohol yielded 2 g. of white needles, m. p. 140–141°, the melting point recorded in the literature for 2-methyl-4-*t*-butylbenzoic acid.[3,4]

Anal. Calcd. for $C_{12}H_{16}O_2$: C, 75.00; H, 8.33; n. e., 197. Found: C, 74.60; H, 8.44; n. e., 197.

Alkylation of *o*-Xylene and Boron Trifluoride and *t*-Butyl Alcohol.—*o*-Xylene (102 g.) and 19 g. of *t*-butyl alcohol were placed in a 500-cc. three-necked conical flask equipped with a motor stirrer, gas inlet and outlet tubes for the boron trifluoride. The boron trifluoride (14 g.) was added according to the procedure previously described.[2] The product was worked up in the usual manner; yield of 1,2-dimethyl-4-*t*-butylbenzene 34.5 g., b. p. 76–81° (3 mm.), $n^{26}D$ 1.4970.

The acid obtained by oxidation of this hydrocarbon melted at 139–140° (n. e., 198) and did not depress the melting point of the acid described above.

Pyrazine–Water Azeotrope

BY HARRY F. PFANN[1]

In the course of an investigation involving the purification of pyrazine by fractional distillation, it was observed that an azeotrope was formed with water. This was found to distil at 95.5° (uncor.) at 760 mm., to have a refractive index $n^{25}D$ 1.4510, density of 1.06 at 25°, and a composition of 60% pyrazine—40% water. The mole ratio of 1:3.38 approaches the 1:3.31 ratio for the pyridine–water azeotrope, for which the boiling point is variously given as 92.6–94.0°.[2,3,4] The refractive index of pyrazine–water solutions appears to be a linear function of weight concentration. The pyrazine taken for this work had a melting range of 50–52° and boiling range 114–115°. Values in the literature[5,6] range from m. p. 47–54° and b. p. 111–118°.

The minimum boiling mixture was obtained from solutions containing an excess of either pyrazine or water. Essentially dry pyrazine resulted from fractionation of mixtures containing more than 60% pyrazine, the water being removed as the azeotrope. No azeotrope was observed with methyl or ethyl alcohols.

Carbon–Carbon Cleavage in the Hydrogenolysis by Raney Nickel Catalyst of Ethylenedithiol and its Ethers

BY H. R. SNYDER AND GEORGE W. CANNON

In the determination of the structure of ω,ω'-bimethionine $[HO_2CCH(NH_2)CH_2CH_2SCH_2CH_2SCH_2CH_2CH(NH_2)CO_2H]$ the *bis*-phenylhydantoin obtained from the substance was subjected to hydrogenolysis by Raney nickel catalyst.[1] This treatment converts a monosulfide (RSR′) into the two molecules RH and R′H,[2] and accordingly was expected to convert the *bis*-phenylhydantoin into two molecules of *dl*-3-phenyl-5-ethylhydantoin and one molecule of ethane. The first of these products was isolated in good yields.[1] However, analysis of the gas produced during the hydrogenolysis has shown that not only ethane but also methane is formed. The occurrence of these two hydrocarbons indicates that the hydrogenolysis of ethers of 1,2-dithiols may take two courses.

$$RSCH_2CH_2SR \begin{cases} \rightarrow 2RH + CH_3CH_3 & (a) \\ \rightarrow 2RH + 2CH_4 & (b) \end{cases}$$

To determine whether carbon–carbon cleavage may be expected of other similar substances ethylenedithiol and certain of its ethers have been subjected to the hydrogenolysis. The hydrogenolyses were run as described by Mozingo, Wolf, Harris and Folkers[2] and the evolved gases were passed through a tower containing 20% aqueous sodium hydroxide into a liquid-air trap. At the end of each reaction the collection tube was connected momentarily to a vacuum pump while still immersed in liquid air, and the residual liquid was allowed to vaporize into gas sample tubes. The gas then was analyzed by standard methods.[3] The results are shown in the table.

HYDROGENOLYSIS OF ETHYLENEDITHIOL AND CERTAIN OF ITS ETHERS

R in $RSCH_2CH_2SR$	Composition of hydrocarbon fraction of gas evolved, % Methane	Ethane
$HO_2CCH(NH_2)CH_2CH_2$—	34	66
$CON(C_6H_5)COCHCH_2CH_2$— (NH)	44	56
$HOCH_2CH_2$—	0	100
C_6H_5—	23	77
H	14	86

In all five instances ethane was the major product, but in only one was it the sole product. Thus it is evident that carbon–carbon cleavage (reaction b) may occur as an important side reaction in the hydrogenolysis of derivatives of ethylenedithiol, but it is not yet possible to evaluate the structural factors which influence the two reactions (a and b).

URBANA, ILLINOIS RECEIVED NOVEMBER 15, 1943

Reaction of Diazomethane with α-Tetralone

BY R. B. THOMPSON[1a]

The ring expansion of cyclic ketones with diazomethane[1b] should be of considerable interest when applied to α-tetralone, since this system, stabilized by a fused ring, might permit preparation of more highly unsaturated compounds.

Although Burger and Mosettig reported that[2] α-tetralone did not react with diazomethane in ether, O. Pauli[3] found that the alcohol–sodium carbonate method gave a slow reaction yielding chiefly a mixture of ethylene oxides plus a ketonic fraction too small to identify.

The following experiments were carried out to investigate this reaction further: to 1 mole (146 g.) of α-tetralone, b. p. 87–88° (0.7 mm.) and $n^{20}D$ 1.5660, were added 130 cc. of absolute alcohol and 1.5 g. of finely powdered sodium carbonate and the temperature adjusted to 10–15°. Nitrosomethylurethan (246 g.) was added with stirring over a period of twenty-six to twenty-eight days, during which gas was regularly evolved.

After filtering, the low-boiling alcohol, water and methyl ethyl carbonate were distilled. Careful fractionation of the remainder gave 80–85% of unchanged α-tetralone, 7–8% of non-ketonic material, b. p. 93–96° (0.7 mm.) and 6–7% of a higher ketone, b. p. 103–106° (0.7 mm.).

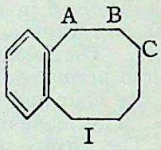
The ketone was crystallized by hydrolyzing the semicarbazone, which could not be obtained in a pure condition for analysis. The ketone then recrystallized from methyl alcohol melted at 73–75° and possessed a camphor-like odor.

Anal. Calcd. for $C_{12}H_{14}O$: C, 82.7; H, 8.1. Found: C, 82.5; H, 8.4.

The ketone gave an oxime that after recrystallization from ethyl alcohol melted at 164–165°. In one instance an oxime melting at 89–90° was obtained.

Anal. Calcd. for $C_{12}H_{15}NO$: C, 76.1; H, 8.0. Found: (165°) C, 76.4; H, 8.3; (90°) C, 75.9; H, 7.7.

These analytical data indicated that two methylene groups had been added to α-tetralone. Since diazomethane reacts with other cyclic ketones to give ring expansion, it is believed that this reaction has occurred here. Therefore, three structural formulas are possible, namely, those having the keto group at I-A, -B, or -C.



I

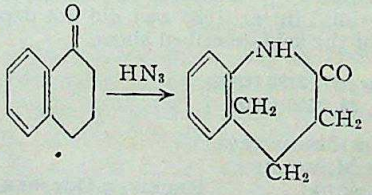
The structure has not been rigidly proved, but there is considerable evidence to show that it is IB.

Fry and Fieser[4] have prepared IC. It melts at 49–50° and gives an oxime melting at 112.5–114° while the ketone from the present experiment melts at 73–74° and gives an oxime melting at 165°.

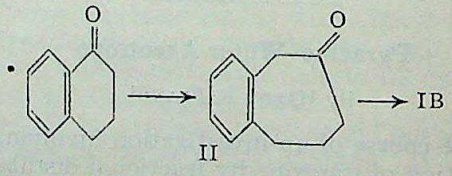
The following evidence tends to reject formula 1A. Mosettig and Jovanovic[5] found that diazomethane reacts with acetophenone to insert a methylene group next to the benzene ring.

$$C_6H_5COCH_3 \longrightarrow C_6H_5CH_2COCH_3$$

Briggs and DeAth[6] obtained the same results in the reaction of hydrazoic acid (the ammonia analog of diazomethane) with α-tetralone.



Since the reaction probably goes



II

it is easy to see why efforts to isolate II failed. Thus, α-tetralone, having the ketone group in the α-position, is relatively unreactive, but II, with a β-keto group, has an enhanced activity and will react as rapidly as formed. The final product IB is still a β-ketone but has lost most of its activity through resistance of the eight-membered ring to further expansion.[1b] Presumably, therefore, any higher ketones are present in quantities too small to be isolated from the mixture.

COMMUNICATION TO THE EDITOR

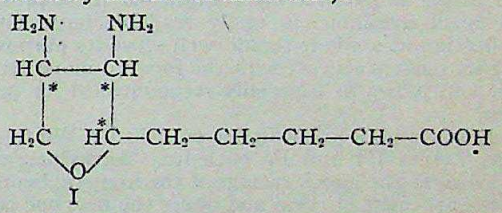
THE SYNTHESIS OF TWO STEREOISOMERIC 3,4-DIAMINO-2-TETRAHYDROFURAN-VALERIC ACIDS

Sir:

Recently[1] a convenient procedure has been described for the preparation of 3,4-dicarboxy-2-furan-valeric acid. These studies have been continued in order to develop synthetic procedures for the preparation of biotin analogs. The purpose of the present communication is to report the synthesis of two stereoisomeric 3,4-diamino-2-tetrahydrofuran-valeric acids.

3,4-Dicarbethoxy-2-furanpentanol was prepared from 2-furanpentanol[2] (α-naphthyl-urethan m. p. 58–59°; calcd.: C, 74.27; H, 6.55; N, 4.33. Found: C, 73.97; H, 6.46; N, 4.41) and diethylacetylene dicarboxylate by the procedure outlined in the aforesaid publication. This material was subjected to high pressure hydrogenation and the reduction products were treated with hydrazine to yield two crystalline hydrazides, $C_{11}H_{22}O_4N_4$, m. p. 208–211° (calcd. C, 48.16; H, 8.08; N, 20.41. Found: C, 48.15; H, 7.85; N, 20.18) and m. p. 177–180° (Found: C, 48.01; H, 7.95; N, 20.27). These two dihydrazides of the stereoisomeric 3,4-dicarboxy-2-tetrahydrofuranpentanols were degraded by the Curtius method to the corresponding 3,4-diaminocarbethoxy-2-tetrahydrofuranpentanols, $C_{15}H_{28}O_6N_2$, m. p. 110–113° (calcd.: C, 54.21; H, 8.49; N, 8.42. Found: C, 53.92; H, 8.09; N, 8.57) and m. p. 128–130° (Found: C, 53.84; H, 8.19; N, 8.64). The primary alcohol group at the end of the aliphatic side chain was then converted to a carboxyl group by oxidation with chromic acid in glacial acetic acid and the resulting 3,4-diaminocarbethoxy-2-tetrahydrofuran-valeric acids (m. p. 118–124° and 157–159°, respectively) were hydrolyzed with concentrated barium hydroxide to the corresponding 3,4-diamino-2-tetrahydrofuran-valeric acids. In order to characterize these compounds by means of sharply melting derivatives, the dibenzoyl methyl esters, m. p. 183–186° (calcd. C, 67.89; H, 6.64; N, 6.60. Found: C, 67.87; H, 6.38; N, 6.62) and m. p. 171–172° (Found: C, 67.62; H, 6.36; N, 6.68), respectively, were prepared, the higher melting isomer being derived from the higher melting hydrazide.

The molecule of 3,4-diamino-4-tetrahydrofuran-valeric acid I contains 3 asymmetric carbon atoms (denoted by means of asterisks).



I

and may exist in eight optically active forms. Four racemic mixtures therefore may be expected, two of which contain the amino groups in the *cis* and two which contain the amino groups in the *trans* configuration. The above-described diamino-carboxylic acids undoubtedly represent two of the four possible racemic forms; further work in this connection is at present under way in this Laboratory.

NEW BOOKS

The Chemical Background for Engine Research. Editors, R. E. BURK, Director of Research, The Standard Oil Company, Cleveland, Ohio, and OLIVER GRUMMITT, Morley Chemistry Laboratory, Western Reserve University, Cleveland, Ohio. (Frontiers in Chemistry. Volume II.) Interscience Publishers, Inc., 215 Fourth Avenue, New York, N. Y., 1943. vii + 297 pp. Illustrated. 15.5 × 23.5 cm. Price, $3.50.

"Prominent scientists report on recent investigations and interpretations of combustion processes and lubrication":—this brief advertisement which appears on the front jacket page of the volume expresses its contents much better than does the overly ambitious title. Actually, the work is a group of lectures on particular topics by six leading authorities; it is the second successful course of this type given by Western Reserve University in a commendable effort to present both the student and the mature chemist with an intelligible—but by no means superficial—view of current knowledge in the field.

Of the six chapters, "A Survey of Combustion Research," by Ernest F. Fiock, presents a brief but excellent historical review and description of modern methods of studying flame travel. "Chemical Thermodynamics of Hydrocarbons," by Frederick D. Rossini, gives the calculation and best values of the entropy, heat and free energy of formation, and isomerization equilibria. "Synthetic Methods for Hydrocarbons," by Frank C. Whitmore, contains a survey of the typical laboratory Grignard reactions used, and a brief mention of some of the industrial methods of synthesis. "Kinetics of Flame and Combustion," by Guenther von Elbe, is restricted to the slow oxidation and self-ignition of hydrogen and the paraffin-

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

hydrocarbons. "The Experimental Side of Combustion Research in Engines," by Bernard Lewis, explains the devices used to measure flame travel, pressure, and temperature in the automobile (Otto-cycle) engine, and reviews present knowledge of knocking combustion. Finally, "Some Physicochemical Aspects of Lubrication," by Otto Beeck, is a comprehensive survey covering engine ring sticking and bearing corrosion, oil oxidation and detergency studies, and boundary lubrication theory and testing.

As is perhaps inevitable in a collection of separate papers such as this, there are some conspicuous omissions. For example, the Diesel engine receives only a page and a half; safety fuels and their ignition are not mentioned nor are fuels of the non-hydrocarbon type; the effects of supercharging and of charge dilution (as by exhaust gas or by water injection) might have been noted; the chemical aspects of work on spark plugs, valves, and bearings is not described, despite its practical importance. Numerous other examples could be adduced but would only serve to illustrate further the obvious fact that the field as a whole is far too large to be completely covered in one small volume.

As a matter of fact, the authors are to be congratulated on having made a judicious selection of important topics and significant details from the mass of information available to them, and on having compressed these into the limited space available, in easily readable form withal. The collection as a whole should well serve its purpose of keeping its readers abreast with the forward movement of science, and it can be especially recommended for school libraries.

The reviewer noticed but few errors. In Dr. Whitmore's chapter, Tables III and IV both list "2-ethylpentane"; Table IV gives the knock ratings of the isomeric heptanes but lists only eight of them and omits the best one of all, triptane; the omission, like others in the book, may have been intentional, although the quality of triptane is surely no military secret.

The volume is printed in large type on high-quality paper, and contains numerous photographic illustrations including some excellent pictures of flame travel. A praiseworthy innovation is the inclusion of two pages giving photographs of the six authors and short biographical sketches about each of them.

HAROLD A. BEATTY

The Adsorption of Gases and Vapors. Volume I. Physical Adsorption. By STEPHEN BRUNAUER, Chemist, Bureau of Plant Industry, United States Department of Agriculture. Princeton University Press, Princeton, New Jersey, 1943. vii + 511 pp. 169 figs. 16.5 × 23.5 cm. Price, $7.50.

This is a very interesting and worth-while contribution to the literature of adsorption. The author has dealt with a great mass of heterogeneous and sometimes contradictory material, and has been markedly successful in achieving an orderly and logical presentation. A general description of the main phenomena and the methods of investigating them is followed by more detailed developments of particular topics such as the shape of the adsorption isotherms, the surface of the adsorbent, and the kinetics of the process. A certain amount of repetition is inevitable, but the net effect is satisfactory.

The author discusses a great many different theories connected with one or another aspect of the subject. Holding definite views of his own, he does not allow them to obtrude themselves unduly into his presentation and evaluation of the work of others. In fact, if fault must be found, it would be rather on the opposite grounds that the various theories are presented as put forth by their authors without sufficient analytical criticism by the author. However, the reviewer is not inclined to reproach the author for this. If the net impression after a forced march through the considerable bulk of this book is that of a mass of theories most of which are limited to the explanation of a few facts and many of which are mutually incompatible, the reasons are to be found in the complexities and difficulties inherent in the subject itself. The careful reader will likely be stimulated to try what he can do to improve the situation.

JOURNAL OF THE AMERICAN CHEMICAL SOCIETY

Published monthly by the American Chemical Society at Easton, Penna.

Editorial Office: Chemical Laboratory of Harvard University, 12 Oxford St., Cambridge 38, Mass.

Assistant to the Editor (Proof and Make-up): Allen D. Bliss, Department of Chemistry, Simmons College, 300 The Fenway, Boston 15, Mass.

Business Office: American Chemical Society, 1155 16th St., N.W., Washington 6, D. C.

Advertising Office: American Chemical Society, 332 West 42nd St., New York 18, N. Y.

The American Chemical Society and the Editors of the *Journal of the American Chemical Society* assume no responsibility for the statements and opinions advanced by contributors to THIS JOURNAL.

Remittances and orders for subscriptions and for single copies, notices of changes of address and new professional connections, and claims for missing numbers should be sent to the American Chemical Society, 1155 16th Street, N.W., Washington 6, D. C. Changes of address for the *Journal of the American Chemical Society* must be received on or before the 18th of the preceding month.

Claims for missing numbers will not be allowed (1) if received more than sixty days from date of issue (owing to the hazards of war-time delivery, no claims can be honored from subscribers outside of North America), (2) if loss was due to failure of notice of change of address to be received before the date specified in the preceding paragraph, or (3) if the reason for the claim is "missing from files."

Annual subscription—$8.50 to non-members, $3.00 to members. Postage to countries not in the Pan American Union, $1.50; Canadian postage, $0.50. Single copies—current issues $0.75, back numbers $0.80; special rates to members.

The American Chemical Society also publishes *Chemical Abstracts*, *Industrial and Engineering Chemistry* (Industrial and Analytical Editions), and *Chemical and Engineering News*. Rates on request.

NOTICE TO AUTHORS OF PAPERS

Manuscripts for THIS JOURNAL should be submitted to the Editor ready for publication, typewritten (double space), with 2–3 cm. margins, on a good quality, durable paper, preferably of 8.5″ × 11″ size. In addition to the original typewritten copy, one or more carbon copies should be submitted so that the time required for examination by the Editorial Board may thus be considerably shortened. Care should be taken that all pages in a manuscript, including tables (but not the diagrams) be numbered consecutively. In preparing manuscripts authors are requested to observe, for reasons of economy, the utmost conciseness consistent with clarity of presentation. The manuscripts should be addressed to specialists in their particular field rather than to the general reader. Extensive reviews of the literature cannot be accepted. When well-known or previously published procedures have been followed in the experimental work they should only be designated or referred to.

Form of Presentation.—There should be one or more introductory paragraphs setting forth the occasion, significance and main objectives of the investigation and the method of attack. This should be followed by the experimental results and a discussion of them, either *seriatim* or at their conclusion. Finally, there should be a brief summary of the main achievements of the investigation. Sometimes, particularly when the subject matter is involved and there are many details which, though essential for a successful repetition of the experiments, are unnecessary for the main account of the investigation, these details can with advantage be relegated to an appendix or supplement, just preceding the Summary. In intermediate cases it is often advisable to retain a single, straightforward presentation but to intercalate sections in fine print giving the experimental details of procedure. This has the great advantage of keeping the experimental details close to the more general statements based upon them and yet at the same time permitting the reader if he wishes to pass over this section without inconvenience.

It will be of great assistance to the Editor's Office if the style, arrangement and orthography of the manuscripts are made to conform to the usages of the JOURNAL as exemplified in its recent issues and as set forth in the following paragraphs.

Center headings should be employed sparingly; side headings should be indented and run into the text to which they apply, using period and dash. References to the literature and all footnotes regardless of their nature (except those in tables) should be numbered in one consecutive series, repetition of notes being avoided by using simply the superscript number corresponding to the original reference. They should follow immediately in separate lines the line of text containing the text words to which they refer, and may be set off by short rules above and below. The items in the references to the literature should conform to the uniform usages of the Journal as regards order and punctuation, and to the abbreviations as given by *Chemical Abstracts* in its "List of Periodicals Abstracted." The names of all simple compounds rather than their formulas should be used whenever they occur in the text. Periods of time (unless fractional) should be written in words and quantities of material in Arabic numerals, unless occurring at the beginning of a sentence. Letters used to represent quantities in mathematical expressions should be underscored to indicate that they are to be printed in italics, and Greek or other unusual characters should be written plainly or should be explained by annotations. Simple fractional expressions should be written with a slant line rather than in the conventional manner, so that only a single line of type is required. All subscripts and superscripts should be carefully made and placed (the degree sign ° or a small o should not be used to represent zero). For economy, except in unusual circumstances the abbreviations %, °A., cm., cc., ml., g., Å., m. p., f. p., b. p., cal., kcal., expt. and Fig., should be used rather than the words.

Figures and graphs should be carefully prepared line drawings on plain white drawing paper, blue drawing cloth or coördinate paper printed in blue only. The

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

originals are preferable, but clear, well-prepared photographic prints or photostats are acceptable. Illustrations are most conveniently handled when made in the conventional 8.5″ × 11″ manuscript size; if they are of necessity larger, and therefore liable to damage in mailing, duplicate rough sketches or photographic prints of smaller size should be furnished for dispatch to the Referees. Diagrams should be designed to occupy a single column width and should therefore be tall rather than wide. Particular attention should be given to the correct proportions of the various parts of the figure, especially the experimental points, and if any letters, numbers, or legends must be placed on the diagram to their proportions also. In graphs the frame and actual curves should be ruled and inked more heavily than the coördinate lines, and these latter should not be too close together. Experimental points should always be given and should be indicated not by crosses but by circles or other symbols carefully drawn with drafting instruments. Where feasible it is often helpful to have the diameter of the circles indicate the precision of the measurements. The numbers and legends on coördinate axes are set up in type by the printer; the author, therefore, should place them in pencil outside the axes. The numbers and titles of figures should be placed below the diagrams, or on the back, or collected on a separate sheet. Small photographic prints should be mounted on cardboard and any composite series of photographic prints should be mounted in the order and arrangement desired. Each piece of illustration copy should be marked on the margin or back with the name of the author and brief title of the article (for identification purposes).

Tables.—Tables should not be used indiscriminately as they are much more expensive, line for line, than running text. If reasonably possible, they should be designed to occupy fully a single column (3 inches), which will take 50–75 characters and spaces. Tables occupying the full width can be used, but they are undesirable for the same reasons advanced with regard to page wide figures; their preparation should follow the same principles as for those of single width. Care should be taken to avoid any arrangement which unduly increases the depth of a table, and column heads should be made as small as possible, using abbreviations liberally. Lines of data should not be numbered nor run numbers given unless these numbers are needed for reference in the text. Columns should not be used to contain only one or two entries, nor should the same entry be repeated numerous times consecutively, since these cases may be taken care of more economically in footnotes, or by entries following the title of the table. Data should not be included in one column which are deducible easily by simple arithmetic from data in another column. Tables should be interspersed in the manuscript as near as possible to the places where they are referred to in the text, and need not be placed alone on separate sheets.

Formulas and Equations.—Empirical and structural formulas and mathematical and chemical equations should be arranged to fill adequately the width of a single column. This will often require a continuation of the equation in additional lines, and although this is a disadvantage it is in general preferable to intrusion into the adjoining column. Subscripts and superscripts, especially the latter, should be written with care and the conventional fractional arrangements should not be used in exponents. Organic structural formulas should be arranged to fill the space economically, and arrows should be used horizontally or vertically, not diagonally, wherever possible.

Notes do not differ fundamentally from Articles. They describe fragmentary or less complete studies and hence particular attention must be given to brevity and conciseness of presentation. Summaries are not included. They are collected in a special section near the end of each number of the Journal.

New Compounds.—This department is for brief accounts of new substances which do not appear of sufficient importance to justify separate publication and cannot be described appropriately as part of any other Article or Note. These accounts should report the preparation of the new compound succinctly, yet fully enough so that the operations can be duplicated. Significant properties, formulas and analytical data to establish the identity and purity of the substance should be given. Material appearing in this classification will not be accepted for subsequent publication.

Communications to the Editor are designed to afford prompt, brief, preliminary publication in our Journal of new and significant observations or discoveries. Their total length may in no case exceed 500 words or the equivalent. They will be given as rapid editorial consideration as possible, but at best it will usually be out of the question to include them in a given issue of the Journal if they arrive at the Editor's office later than the 20th of the preceding month. Communications like other contributions should be self-sustaining; that is, they should present experimental or other evidence adequate to establish the *prima facie* credibility of the results or conclusions stated or to permit their appraisal by an expert in the field although because of the 500-word limit a complete presentation cannot usually be expected. These requirements make Communications on many subjects impracticable, particularly those of an involved or theoretical nature.

Communications differ from ordinary Articles or Notes in that their publication does not prevent the re-publication of their subject matter in a later, more complete article in the Journal. In view of this special provision and their expedited publication, it is clear that the contribution made by the Communication should be of special interest or timeliness; mere abstracts of forthcoming articles cannot be accepted. Proof and reprint order will be sent to authors whenever possible, but as this cannot always be done, a memorandum as to the reprints desired should accompany the manuscript.

Microfilm Supplements.—By arrangement with Science Service material supplementary to articles in THIS JOURNAL, such for instance as extensive tables, graphs or calculations, can be distributed at small cost as American Documentation Institute Documents in the form of microfilms with images 25 mm. high on standard 35-mm. film or photoprints 6 × 8 inches legible to the unaided eye. Such material must, however, have been submitted to the Editor of the Journal and must have been approved by him for publication. Attention will then be called to these documents by means of footnotes at appropriate points in the text of the article concerned.

[CONTRIBUTION FROM THE RESEARCH LABORATORY, UNITED STATES STEEL CORPORATION]

The Adsorption of Gases on Smooth Surfaces of Steel[1]

BY MARION H. ARMBRUSTER AND J. B. AUSTIN

This paper reports the results of measurements of the adsorption of hydrogen, argon, neon, nitrogen, carbon monoxide and carbon dioxide at pressures up to 0.1 cm. and at 20, −78, −183 and −195° on three surfaces of cold-rolled steel of the same nominal composition. The sorption on each surface was determined first after degreasing and degassing and subsequently on the identical surface after reduction in carefully purified hydrogen. In some cases it was necessary to condition the surface many times before adsorption was reproducible within the experimental error.

Apparatus and Materials.—The apparatus is described in an earlier paper.[2] The fixed temperatures were: (1) that of a mixture of solid carbon dioxide and alcohol (−78°); (2) the boiling point of oxygen (−183°); and (3) the boiling point of nitrogen (−195°). All temperatures were checked by means of a copper–constantan thermocouple immersed in the bath. Proper corrections, as described in the earlier paper, were made for the difference in temperature between the several parts of the system, a correction which also took account of the effect of thermal diffusion.

Argon, neon, nitrogen and carbon dioxide of the Air Reduction Company's "spectroscopically pure" grade were obtained in glass flasks which were sealed to the gas manifold of the adsorption system before being opened.

Carbon monoxide, prepared by the reaction of formic acid with sulfuric acid, was freed of carbon dioxide by passage through a solution of potassium hydroxide and was then dried over phosphorus pentoxide.

Hydrogen used in the measurement of sorption was of the Air Reduction Company's "spectroscopically pure" grade; that used for reducing the surface was tank hydrogen, freed from traces of water vapor and oxygen by passage through sulfuric acid, then successively over calcium chloride, hot platinized asbestos, activated alumina and phosphorus pentoxide.

Steel Surfaces.—These were all cold-rolled flat wire whose chemical composition is given in Table I. Sample 1 (no. 25261), the surface used in our measurements of the sorption of ethyl iodide,[3] was a bundle of strips 0.08 mm. in thickness, 110 mm. in length and 19 mm. in width; it weighed 357.1 g. The total surface area, determined by measuring the dimensions of each strip, was 11130 sq. cm. Examination of a polished section under the microscope showed that this sample contained an unusually large number of non-metallic inclusions which appeared on the surface as small ellipsoids elongated in the direction of rolling; there were also a number of spheroidized carbide particles. The portion of the surface covered by each of the several phases, as estimated by cutting up photomicrographs and weighing the bits of paper representing each phase, was: inclusions about 5%, carbides about 30%, and iron about 65%.

TABLE I

CHEMICAL COMPOSITION OF THE STEELS

Sample	C	Mn	S	P	Si
1	0.39	0.70	0.049	0.016	0.128
2	.31	.58	.024	.011	.115
3	.12	.47	.041	.016	.003

Sample 2 (no. 25277) was a similar bundle of strips 0.07 mm. in thickness; it weighed 308.4 g. The total area was again 11130 sq. cm. This sample contained very few non-metallic inclusions; the carbides, which were spheroidized, covered about 25% of the surface, the rest of which was iron.

Sample 3 (no. 25278), was a bundle of strips 0.04 mm. thick; it weighed 366.7 g. The total measured area was 24680 sq. cm. or 2.22 times that of the other samples. This sample contained few inclusions, which covered not more than 2% of the surface; the carbides, which were spheroidized, covered about 15% of the surface, the remainder of which was iron.

Orientation of Grains.—Photomicrographs showed that initially the grains of each sample were elongated in the direction of rolling, the elongation being greatest on Sample 3 which had been rolled thinner than the others. The X-ray pole figure of each sample showed, as expected, a marked preferred orientation of the grains with the (100) planes in the rolling plane. Examination of a strip from each sample after the sorption measurements had been completed showed that the grains had become equiaxed but that preferred orientation persisted.

Treatment of Surfaces.—Before use, each piece of metal was degreased with absolute alcohol and anhydrous

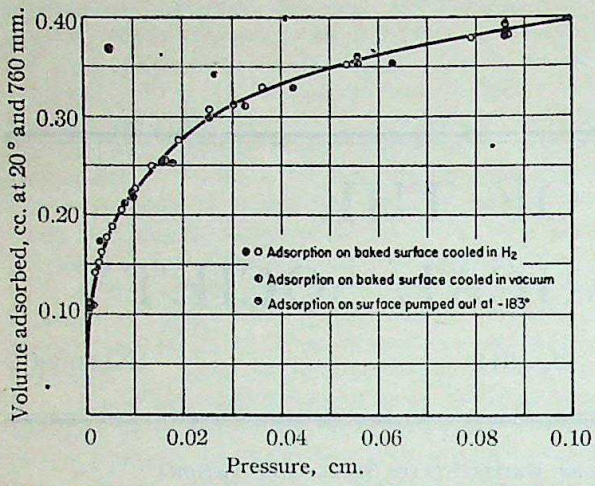

Fig. 1.—Sorption of argon at −183° on reduced surface of Sample 1: ●, surface outgassed and cooled in hydrogen, measurements made by increasing pressure; ○, surface outgassed, cooled in hydrogen (decreasing pressure); ◐, sample outgassed and cooled in vacuum (increasing pressure); ◓, surface pumped out at temperature (increasing pressure).

ether, care being taken to avoid touching the strips with the fingers. The first set of measurements was made on the degreased surface after it had been baked for two hours at 300° at a pressure of less than 10^{-6} mm. In the first few runs on each surface the results were not satisfactorily reproducible, the amount of adsorption increasing slightly on successive runs, but this increase became successively smaller and was negligible after about 20 measurements so that the volume of gas sorbed at a given pressure was reproducible within 5%. Although the magnitude of the adsorption of a specific gas changed during this initial period, the relative adsorption of different gases remained substantially the same, indicating that the increasing adsorption was due to an effective increase in surface area rather than to a change in the nature of the surface. Since tests using longer time of baking or higher temperature failed to show any significant deviation from the results obtained by baking for two hours at 300°, this latter procedure was adopted as standard. In the first set of measurements no attempt was made to reduce the invisible "oxide" always present on iron which has been exposed to oxygen, hence, the degreased and outgassed surface is referred to as "unreduced."

A second set of measurements was made after the surface had been reduced at 450° in a stream of purified tank hydrogen introduced at the bottom of the adsorption bulb, the surface being freshly reduced before each run. The period of reduction ranged in general from twenty-four to forty-eight hours, although in a few cases it was as much as sixty hours. After reduction of the surface the hydrogen inlet tube was sealed off and the sample was given the standard degassing treatment at 300° which yielded a surface, apparently free of oxide, on which adsorption was satisfactorily reproducible. The absence of an oxide film on the reduced surface was demonstrated by an accident which occurred during one of the runs. In replenishing the liquid air around one of the traps, the trap cracked and mercury was blown into the adsorption bulb, where it wet the iron wherever there was contact, a reaction which is observed only when an iron surface is substantially oxide-free. There was a tendency for the amount of adsorption on the reduced surface to decrease slightly on successive runs, the change being relatively the same for all gases, indicating a slight decrease in effective surface area. This change usually became negligible after a number of check runs had been made. The purified hydrogen used in reducing the surface tends to decarburize as well as to deoxidize, but the rate of decarburization with the carefully dried gas employed is so small that no significant loss of carbon from the surface was observed.

The adsorbent was cooled either in vacuum or in hydrogen, which direct measurement shows is not measurably sorbed on a smooth surface of steel in the temperature range studied. Direct comparison showed that the amount of adsorption was independent of the method of cooling, as is evident from Fig. 1 which shows the sorption of argon on the reduced surface of Sample 1 as determined by different procedures. Since cooling was most rapid in hydrogen, this gas was used in most runs. The trap between the adsorption train and the diffusion pump was immersed in liquid air from about half way through the baking period to the end of a run. A number of check runs, up to as many as 25, were made for each combination of gas, surface and temperature.

Procedure.—After the surface of the sample had been suitably prepared and brought to equilibrium at the temperature of test, adsorption was determined by admitting successive increments of gas; this is the procedure of building up to the pressure in steps described in our earlier paper.[4] The pressure was then diminished by steps to determine the amount of gas desorbed as the pressure decreased. A difference between the results on adsorption and on desorption at a given pressure was taken to indicate the existence of some irreversible sorption which was checked by measuring the adsorption a second time after the system had been pumped down to a pressure of less than 10^{-6} mm. at the temperature of test. A typical example of the agreement obtained when the adsorption was completely reversible[5] is shown in Fig. 1.

Results

Neither neon nor hydrogen was measurably sorbed on any of the surfaces within the temperature range investigated. Likewise none of the gases investigated was measurably sorbed at room temperature (20°). The sorption of the several gases on the three reduced surfaces at −78, −183 and −195° is shown by typical isotherms in Figs. 2, 3 and 4; representative iso-

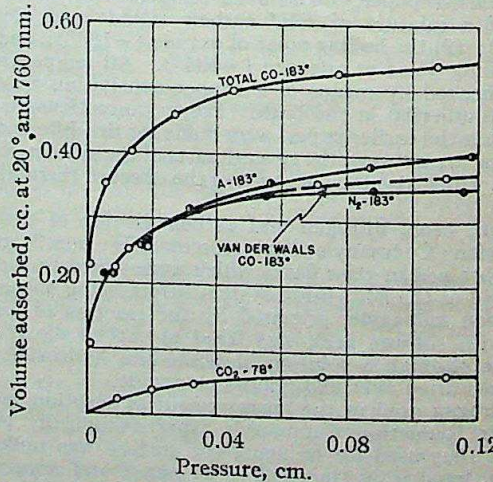

Fig. 2.—Adsorption isotherms for the several gases on reduced surface of Sample 1.

(4) Armbruster and Austin, THIS JOURNAL, 61, 1117 (1939).

(5) The term reversible adsorption is used to describe that part of the total sorption which can be removed by evacuation at temperature. It is used without any connotation as to the forces involved and implies nothing more than the observation that the sorbed gas can be removed by reducing the pressure to the order of 10^{-6} mm. at the temperature of test. Adsorption which cannot be removed by evacuation at temperature is designated as irreversible.

coverage of the surface by a close-packed monolayer as derived from the corresponding value of v_s, the nominal or geometric area of the surface, and the cross-section[6] of the adsorbed molecule are given in Table III.

(6) The apparent coverage is calculated from the relation: $v_s \times 2.5 \times 10^{19} \times$ cross section per molecule/geometric area of surface. The exact value to be taken for the cross-sectional area is not as yet well established; in fact, data reported by Harkins and Jura (*J. Chem. Physics*, 11 431 (1943)) suggest that it may not be constant for all surfaces. We have selected the areas used by Langmuir, namely, A 12.9, N_2 15.2, CO 15.2, CO_2 16.4 sq. Å. which lie between the two sets calculated by Brunauer, Emmett and Teller from the density of the respective liquid and solid phases. They are believed to be a reasonable compromise and in any case are sufficiently accurate for the present purpose.

Adsorption on a freshly outgassed surface, either reduced or unreduced, was always slow when the sample had cooled in vacuum; more specifically, there was initially a fairly rapid adsorption which slowed down markedly as equilibrium was approached. On the other hand, when an outgassed sample had cooled in hydrogen or argon, or when the surface had merely been pumped out at temperature, sorption was practically instantaneous. This suggests that the slow adsorption on a surface cooled in vacuum may have been due to failure to attain temperature equilibrium, yet holding in vacuum at temperature for as long as fifty hours did not suffice to make the sorption instantaneous.

Discussion

Sorption of Neon and Hydrogen.—The sorption of these gases was less than the error of measurement, that is, less than 3×10^{-4} cc., which corresponds to less than 1% of the surface covered.

Adsorption at −183° on Unreduced Surfaces.—The characteristics of the unreduced surface were studied most extensively on Sample 1, measurements on the other samples being made chiefly to confirm certain specific observations on the first. The unreduced surfaces were without question covered with a thin film of oxygen or oxide, as is demonstrated directly by the observation that the sorption of oxygen on the unreduced surface was always less than that on a reduced surface by an amount equivalent to a film about three molecules thick. The behavior of these surfaces must therefore be interpreted in terms of the presence of this film.

The most significant result obtained for this type of surface is that at −183° some of the sorbed nitrogen, argon or carbon monoxide is held so strongly that it cannot be removed by reducing the pressure at temperature, in marked contrast to the behavior of a reduced surface on which the sorption of argon and nitrogen is entirely reversible. Moreover, the percentage of the total gas which is thus strongly held is in every case substantially the same, as is illustrated by the data in Table II, which indicate that about one-seventh of the total amount adsorbed was not removed by reducing the pressure to 10^{-6} mm.

TABLE II

Difference between amount of gas sorbed at −183° on a baked out surface and that on a surface pumped out at temperature, expressed as a percentage of the former.

Gas	Sample 1	Sample 3
N_2	14.5	11.0
A	16.1	..
CO	11.8	..

The exact nature of this strong adsorption is not clear; but the instantaneous rate of sorption and the improbability that argon is held to the surface by anything other than physical forces indicates that it is basically van der Waals adsorption. It might be a process of the sort described by Beebe and Dowden,[7] who found that at low temperature nitrogen and certain other gases are instantaneously adsorbed on chromic oxide by what appears to be van der Waals adsorption, but later go over to another type of sorption for which the heat effect is much greater; against this view, however, is the fact that they did not find such an effect with argon. An alternative view is that this gas is held in cracks and fissures in the surface, since van der Waals forces are much stronger in such crevices than on a plane surface; yet it seems unlikely that the volume of gas thus sorbed would be so nearly the same for different gases or on different surfaces. A third possibility is that because of the structure of the film there are on the surface certain sites which are virtual depressions in which a sorbed molecule can come in very close contact with a number of oxygen atoms so that the strength of the van der Waals attraction is greatly increased. We incline to this last view because a similar strong adsorption of nitrogen and argon has already been observed on mica[8] in which case the sorbed molecules appeared to be held in positions vacated by potassium ions during cleavage; moreover, if these sites are a result of the structure of the film, the constant fraction of the surface so covered is easily explained.

Adsorption at −78° on Unreduced Surfaces.—Carbon dioxide was measurably sorbed on the unreduced surface of Sample 1, the only surface on which measurements were made. The rate of sorption was virtually instantaneous and the isotherm for a surface pumped out at temperature agreed with that for a baked surface, indicating that carbon dioxide is physically sorbed on this surface.

Carbon monoxide was not measurably sorbed on any of the unreduced surfaces at this temperature.

Adsorption at −78° on Reduced Surfaces.—Carbon dioxide was measurably sorbed on all three samples, the amount being from one-fourth to one-half that of nitrogen on the same surface at −183°. The rate of sorption was instantaneous and on Samples 1 and 3 the isotherm for a surface evacuated at temperature agreed with that for a baked out surface, indicating that the adsorption is entirely physical. On Sample 2, however, adsorption on a pumped surface was slightly less than on a baked surface (Fig. 3), indicating some chemisorption. In view of the observation of Emmett and Brunauer,[9] that on a promoted iron catalyst at −78° carbon dioxide is chemisorbed on the alkali promoter but not on iron, it is likely that this chemisorption on the smooth surface occurs on some non-metallic phase.

The amount of carbon monoxide sorbed at −78° differed widely, ranging from none on

[a] 1 cc. = 41.6 micromoles = 2.5×10^{19} molecules. [b] The observations for Sample 3 have been divided by 2.2 to reduce them to the same geometric surface area as for the other samples.

Sample 1 to something approaching a complete layer on Sample 3, as estimated by comparison of the values of v_s (Table III) with that for nitrogen sorbed at −183°. The gas was adsorbed instantaneously but could not be desorbed by pumping at temperature. Brunauer and Emmett report that a complete layer of carbon monoxide is chemisorbed at −78° on iron catalysts, a result confirmed, insofar as strength of binding is concerned, by the calorimetric measurements of Beebe and Stevens.[10] On this basis one would expect a similar layer to be sorbed on a smooth surface, as it was on Sample 3, though not on the other two surfaces. Again the explanation for this difference is uncertain. Brunauer[11] has stated, however, that in his experiments if the iron surface was strongly sintered, not only did the quantity of chemisorbed carbon monoxide decrease but also the binding of the adsorbed gas to the iron was weakened as is evident from the fact that it was possible to pump off a part of the carbon monoxide at −78° from a strongly sintered catalyst. These observations, together with the fact that the surface of Sample 1, on which there was no measurable adsorption, had been baked out a great many times, whereas that of Sample 3, on which a complete layer of carbon monoxide was sorbed, had been baked out only a few times, suggest that the different behavior of the several samples was due to an effective difference in the smoothness of the surface. Thus, if the reduction of the oxide film were to leave a relatively rough skin on the iron which then sintered during subsequent bakings, there might be variations of the sort described by Brunauer.

It should be noted that on Sample 3, all the carbon monoxide was chemisorbed at −78° whereas at −183° only a small fraction of it was chemisorbed, a result in accord with the observation of Beebe and Stevens,[10] that the heat of adsorption is greater at −78° than at −183°.

Adsorption at −183 and −195° on Reduced Surfaces.—Since most of the isotherms are represented reasonably well, especially at the higher pressures, by the Langmuir equation, the results for −183 and −195° are most conveniently discussed in terms of the limiting volume sorbed (v_s), as derived by means of this equation. The value of this limiting volume is given in Table III along with the ratio of this value to that for nitrogen at −183°, which in effect reduces the observations to a common effective surface area.

This ratio for carbon monoxide (total) at −183° is approximately constant; moreover, the fraction of the surface covered by chemisorbed carbon monoxide is substantially constant and is roughly 0.4 times the coverage by nitrogen. This is less than half that reported by Emmett and Brunauer,[12] who observed a complete layer of chemisorbed carbon monoxide as well as a complete layer of van der Waals adsorption. The reason for this difference is not clear.

Specific Surface Area.—The coverage, shown in Table III, indicates that the layer of sorbed gas does not exceed one molecule in thickness, and the close agreement in coverage by the several gases at the same temperature is presumptive, though not conclusive, evidence that the monolayer covers substantially the whole surface. Emmett and his colleagues[13] have had considerable success in estimating the surface area of a powder from the observed adsorption of nitrogen or argon at low temperature by assuming that the volume, corresponding to the point at which the isotherm ceases to be concave to the pressure axis and becomes substantially linear (the point they call B, which corresponds to v_m calculated by means of their equation for multimolecular adsorption) represents the volume of gas required for complete coverage by a close-packed monolayer. Since, as is shown later, our isotherms are very probably of the same type as theirs, the coverage by nitrogen and argon, as derived from the value of v_s, should likewise represent the completion of a monolayer on the cold-rolled steel. Investigations of adsorption on the smooth surface of other metals, notably silver and platinum,[14] have demonstrated, however, that under certain conditions substantial saturation of the surface may be achieved by a monolayer in which the effective cross-sectional area of the sorbed molecules is much greater than that commonly assumed, which indicates that the Emmett–Brunauer–Teller method may not always be reliable when applied to a smooth metallic surface; this makes necessary some reservation on the above conclusions.

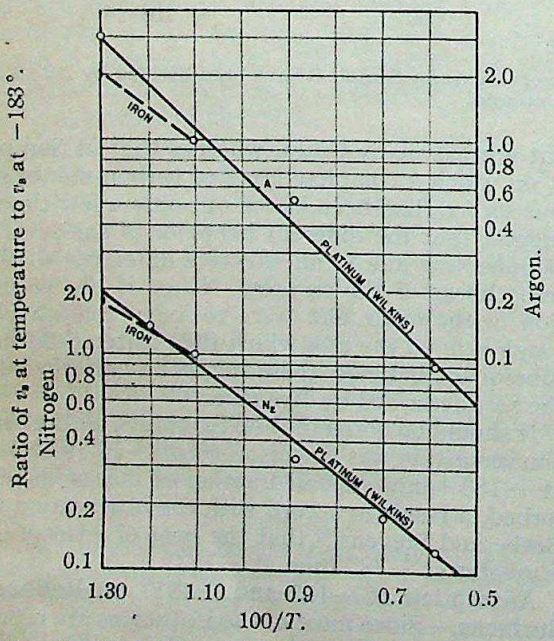

Fig. 7.—Variation with temperature of the limiting volume (v_s), as derived by means of the Langmuir equation, plotted as the ratio v_s at temperature to v_s at −183°. Solid lines and circles represent Wilkins' data for nitrogen and argon on smooth platinum; dashed lines, our data for smooth iron.

On the basis that the limiting volume (v_s) corresponds to the completion of a relatively close-packed monolayer, the specific surface of the steel, relative to the geometric area of the strips, is approximately 1.5 for Sample 1, 3 to 4 for Sample 2 and about 1 to 1.5 for Sample 3, which indicates that these surfaces are remarkably flat.

Variation of v_s with Temperature.—The value of v_s increases markedly with decreasing temperature, as is common in systems of this type. Although the exact form of the variation cannot be determined from observations at only two temperatures, it appears to be consistent with that reported by Wilkins for the sorption of argon and nitrogen on platinum foil. He found that for the range −100 to −195° v_s is satisfactorily represented by the relation

$$v_s = v_0 e^{\beta/T} \qquad (1)$$

where v_0 and β are constants. His more extensive data are plotted along with ours in Fig. 7 in which, to eliminate the effect of the difference in surface area and to permit direct comparison of the two sets of observations, log (v_t/v_{-183}) is plotted against $1/T$. The agreement between the two sets of data is as close as could be expected, indicating that in this temperature range the variation of v_s for nitrogen and argon is substantially the same on both platinum and iron foil.

Heat of adsorption can be calculated by means of an analog of the Clausius–Clapeyron equation or by means of an equation developed by Brunauer, Emmett and Teller.[15] The former method, based upon the adsorption isostere, is commonly assumed to give the heat of sorption corresponding to a given volume of gas sorbed; the second method, which requires but a single isotherm, yields the average heat of sorption in the less active portion of the first layer. In several instances the results of application of these two methods to our data differ significantly; moreover, the heat calculated by means of the Clausius–Clapeyron equation in a number of cases increases as the fraction of the surface covered increases, a result which is hardly acceptable in view of the great body of evidence, including di-

rect calorimetric measurement, that on iron the heat of adsorption decreases with increasing coverage. For example, the heat of adsorption for nitrogen on the reduced surface of Sample 2 as derived by means of the Clausius–Clapeyron equation varies from 1370 cal. per mole at 200 cu. mm. sorbed to 2800 cal. at 600 cu. mm.; the corresponding heat calculated by means of the Brunauer–Emmett–Teller relation is 2750 cal. at −195° and 3160 cal. at −183°. The values derived by means of the Clausius–Clapeyron equation are, therefore, significantly lower in the range of small fraction of the surface covered, which is, however, just the range in which they should be higher. These discrepancies led us to suspect that the heat of sorption derived by means of the Clausius–Clapeyron equation may not be reliable under all circumstances and resulted in a critical examination of its accuracy and precision as compared to those of the Brunauer–Emmett–Teller method.

For monomolecular adsorption, the Brunauer–Emmett–Teller relation is

$$p/v = \frac{p_0}{v_m c} + \frac{p}{v_m} \qquad (2)$$

where v is the volume sorbed at pressure p, v_m is the volume of gas required to complete a close-packed monolayer, p_0 is the saturation pressure of the liquid adsorbate at the given temperature, and c is a quantity defined by the relation

$$c = fe^{-(\Delta H_a - \Delta H_L)/RT} \qquad (3)$$

where ΔH_a is the average heat of adsorption, ΔH_L is the heat of liquefaction of the gas and f is a coefficient whose value is close to unity.

The most convenient form of this relation for ordinary use, and the one best fitted to show the accuracy and precision of the calculation, is

$$\Delta H_a = A - 2.303\ RT \log v_m I \qquad (4)$$

in which v_m and I are, respectively, the numerical value of the reciprocal of the slope and the intercept derived from the linear plot of p/v against p, and

$$A = \Delta H_L + 2.303\ RT \log p_0 \qquad (5)$$

Inspection of equation (4) shows that the use of this method tends greatly to reduce the effect of any observational error. The only term containing a factor derived from the adsorption data is log $(v_m I)$, whose value is commonly smaller, and frequently is very much smaller, than that of A, so that this term is in essence merely a correction to A, whose value can in most cases be determined with considerable accuracy. Furthermore, the value of this correction is, because of the logarithmic form of the term, relatively insensitive to an error in the value of v_m or I. For example, if the value of the product $(v_m I)$ is in error by a factor of 2, the change in the logarithm is only 0.301 unit, corresponding to an error of (4.57 T × 0.301) calories in the heat effect; for T = 100°K., this is about 150 calories.

The analog of the Clausius–Clapeyron equation is

$$\left(\frac{\partial \ln p}{\partial (1/T)}\right)_v = \frac{\Delta H_a}{R} \qquad (6)$$

in which p is the pressure required at absolute temperature T to cause the sorption of volume v.

Its accuracy appears to be open to serious question. The limitations of the Clausius–Clapeyron equation when applied to vaporization are well recognized but no corresponding evaluation of equation (6) as applied to adsorption appears to have been reported, although we have not exhaustively searched the early literature. On the other hand, the use of the equation has been criticized on several different grounds. The primary objection is a practical one, namely, that if the isotherms indicate saturation of the surface at the higher pressures, as they do in monomolecular adsorption, and if the maximum volume sorbed increases with decreasing temperature, as it commonly does, then the isostere can be constructed for a limited range of volume only.

Wilkins,[16] from statistical calculations, has concluded that equation (6) should be used not at constant volume but at constant concentration on the surface, that is, at constant fraction of the surface covered, a procedure which removes the primary difficulty in constructing the isostere. Wilkins has shown further that, if equation (1) is valid, then the heat of adsorption calculated by means of equation (6) is in error by the amount $R\beta$,[17] where R is the gas constant.

Since it is clear that the use of equation (6) may yield a result significantly in error, it is instructive to compare it with the Brunauer–Emmett–Teller equation, which may be written

$$p = p_0 e^{-\Delta H_a - \Delta H_L/RT} \left(\frac{v}{v_m - v}\right) \qquad (7)$$

whence

$$\left(\frac{\partial \ln p}{\partial(1/T)}\right)_v = \left(\frac{\partial \ln p_0}{\partial(1/T)}\right)_v + \frac{\Delta H_a}{R} - \frac{\Delta H_L}{R} - \left(\frac{\partial \ln (v_m - v)}{\partial(1/T)}\right)_v \qquad (8)$$

but

$$\left(\frac{\partial \ln p_0}{\partial(1/T)}\right) = \frac{\Delta H_L}{R} \qquad (9)$$

hence

$$\Delta H_a = R\left[\left(\frac{\partial \ln p}{\partial(1/T)}\right)_v + \left(\frac{\partial \ln (v_m - v)}{\partial(1/T)}\right)_v\right] \qquad (10)$$

On this basis, the ordinary analog of the Clausius–Clapeyron equation yields a value of ΔH_a which is in error by the amount $R(\partial \ln (v_m - v)/\partial(1/T))_v$. Under optimum conditions, as for example a very small variation of v_m with temperature, this error is negligible, but under less favorable circumstances it may be appreciable.

If v_m can be represented as a function of $(1/T)$,

(16) Wilkins, *Proc. Roy. Soc.* (London), **A164**, 496 (1938).

(17) Wilkins' paper gives this difference as β, but this is clearly a typographical error and should be $R\beta$.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

equation (10) can be simplified. Thus, on the basis of Wilkins' suggestion that $v_m = v_0 e^{\beta/T}$

$$\left(\frac{\partial \ln (v_m - v)}{\partial(1/T)}\right)_v = \frac{\beta v_0 e^{\beta/T}}{v_0 e^{\beta/T} - v} = \frac{\beta v_m}{v_m - v} \qquad (11)$$

For $v \ll v_m$, this correction reduces to β, whence

$$\Delta H_a = R\left(\frac{\partial \ln p}{\partial(1/T)}\right) + R\beta \qquad (12)$$

which is the same relation as was obtained by Wilkins.

Equation (10) is clearly limited in use to the range of v in which the isostere can be constructed, a restriction which, however, is inherent in any calculation based on constant volume. This difficulty can be avoided, as suggested by Wilkins, by the use of constant concentration, a procedure which gives the true heat of adsorption. Thus, if the ratio v/v_m be represented by θ, equation (7) leads to the relation

$$\left(\frac{\partial \ln p}{\partial(1/T)}\right)_\theta = \frac{d \ln p_0}{d(1/T)} + \frac{\Delta H_a}{R} - \frac{\Delta H_L}{R} \qquad (13)$$

whence

$$\Delta H_a = R\left(\frac{\partial \ln p}{\partial(1/T)}\right)_\theta \qquad (14)$$

In contrast to the Brunauer–Emmett–Teller method, in which the adsorption data yield a relatively small correction to be applied to a quantity which is known precisely, the Clausius–Clapeyron relation and its several modifications tend to magnify experimental error and are, in consequence, less likely to give satisfactory results. In view of this conclusion, we report only the average heat as derived by the method of Brunauer, Emmett and Teller.

The average heat of reversible adsorption of the several gases is given in Table IV, which includes for comparison the heat of liquefaction of each gas at its normal boiling point. In each case the heat effect is 2 to 3 times the heat of liquefaction which indicates that the sorbed molecules are held to the surface by fairly strong physical forces. These data show further that, except for the sorption of carbon dioxide at −78°, the heat is substantially the same for all the gases on all the surfaces; moreover, these heats are virtually identical with those for the sorption of the same gases at the same temperature on smooth surfaces of silver or platinum, as is illustrated in Table V. They are, however, significantly higher than the heat effect of 2170 ± 70 cal. reported by Brunauer, Emmett and Teller[18] for the sorption of both argon and nitrogen at −183° on porous iron catalysts. A similar difference in the heat of adsorption of oxygen on silver at −183° has already been described.[19]

TABLE IV

AVERAGE HEAT OF REVERSIBLE ABSORPTION (ΔH_a) OF THE SEVERAL GASES ON SMOOTH IRON AS DERIVED BY MEANS OF THE EQUATION OF BRUNAUER, EMMETT AND TELLER

[a] Derived from data of Armbruster. [b] Derived from data of Wilkins.

The difference between the heat effect on the two kinds of iron surface appears, moreover, to be characteristic of the physical condition of the surface rather than of its chemical nature; since Brunauer, Emmett and Teller found that the heat of sorption of nitrogen at −183° on twelve different catalysts, including iron, copper, silica gel, and chromic oxide is always 2170 ± 70 cal., whereas the data in Table V indicate that on a smooth metallic surface, whether it be iron, silver, or platinum, the heat is always close to 3000 cal. Moreover, since both argon and nitrogen have the same heat of sorption on the same surface, it is concluded that at a given temperature the heat of sorption is chiefly a function of the physical state of the surface and relatively independent of the chemical nature of either adsorbent or adsorbate.

The difference between the heat of adsorption on smooth iron and that on an iron catalyst provides a possible explanation for the seemingly different form of the isotherm for the two kinds of surface, and makes it possible to show that the isotherm for sorption on a smooth surface, though apparently of the saturation type, is probably of the sigmoid type characteristic of sorption on a catalyst. Thus the Brunauer–Emmett–Teller relation for multimolecular adsorption may be written

$$v/v_m = \frac{p/p_0 \Big/ \left(1 - \frac{p}{p_0}\right)}{\left(\frac{1}{c} + \frac{c-1}{c}\frac{p}{p_0}\right)} \qquad (15)$$

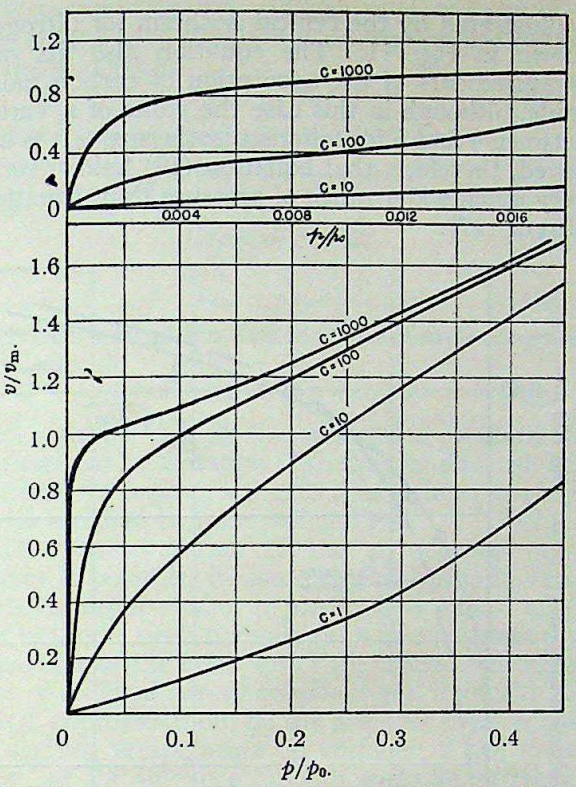

Fig. 8.—Variation of ratio v/v_m with p/p_0 for different values of c as derived by means of the equation of Emmett, Brunauer and Teller.

where the symbols have the significance explained earlier. Since the difference $\Delta H_a - \Delta H_L$ enters exponentially into the quantity c, this quantity, hence, the shape of the isotherm, is very sensitive to a change in ΔH_a, as is illustrated in Fig. 8 which shows v/v_m plotted against p/p_0 for different values of c. As c increases, v/v_m approaches unity at a much lower value of p/p_0, and tends to remain virtually constant at unity over an appreciable range of p/p_0, as is illustrated in the upper part of Fig. 8 which shows the low-pressure portion of the several curves on a greatly enlarged scale. For sorption on iron catalysts at −183°, the value of c is between 10 and 100, whereas for the smooth surface it is well over 1000 (see Table IV). On this basis, the isotherms in Figs. 2 to 6 are probably of the same type as those described by Brunauer, Emmett and Teller, and had our measurements been carried to a higher pressure, the isotherms would have become convex to the pressure axis.

Form of Isotherms.—The isotherms in Figs. 2 to 6 are of the form apparently typical of sorption at a relatively low pressure on a smooth metallic surface, which has generally been considered by investigators in this specific field to be of the saturation type. There is reason to doubt the justification for this classification, as has been pointed out earlier, yet it is instructive to consider our results from the standpoint of two common adsorption equations

$$v = ap^{1/n} \quad (16)$$

$$v = \frac{av_s p}{1 + ap} \quad (17)$$

where v is the volume of gas sorbed at pressure p, v_s is the maximum volume of gas sorbed at apparent saturation of the surface, and a and n are constants.

The first of these is the parabolic isotherm, variously and inaccurately called the classic, Freundlich or exponential isotherm, in which the value of n is almost always positive and greater than unity. Applied to our data, it fits very well over the low pressure range, as is illustrated in Fig. 9 by typical data for nitrogen plotted on double logarithmic coördinates to yield a straight line. These data yield a straight line over the 200 fold pressure range 0.0001 to 0.020 cm.; moreover, the several lines are substantially parallel, with a slope corresponding to a value of n of about 4. A similar plot of the data for argon yields an analogous set of parallel straight lines with a slope corresponding to a value of n of about 3. The equation fails, as it must, as the surface approaches saturation.

Equation (7) is the relation originally derived by Langmuir,[20] which yields a straight line when the ratio p/v is plotted against p. When this test is applied to our results, the equation holds over a considerable range of pressure, yet there are marked deviations in the low pressure range as is well illustrated by the typical isotherms for nitrogen shown in Fig. 10. These deviations are all of the same kind—the volume adsorbed at a given pressure in the low range being greater than that calculated by extrapolation of the data in the high

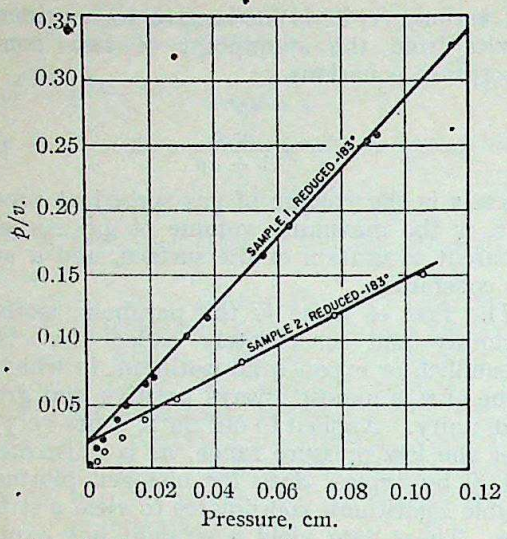

Fig. 10.—Isotherm at −183° for nitrogen adsorbed on reduced surface of Samples 1 and 2 plotted as p/v against p.

pressure range. Such deviations, which seem to be quite common, have been discussed at some length by Barrer,[21] who cites a number of examples in addition to those in his own measurements of adsorption of gases in graphite; similar behavior has been noted by Wilkins in his studies of adsorption on platinum foil.[22] These deviations from the Langmuir equation occur in the range of low pressure, precisely that in which the parabolic isotherm fits, which suggests that a combination of the two equations might hold over the whole range. Such a combination can be made in two ways

$$v = \frac{av_s p^{1/n}}{1 + ap^{1/n}} \qquad (18)$$

$$v = v_s \sqrt[n]{\frac{ap}{1 + ap}} \qquad (19)$$

each of which reduces to the form of equation (16) for low pressures, that is, when the product ap becomes small compared to unity, and to the form of equation (17) when ap is very large compared to unity.

The first equation (18), is analogous to Langmuir's expression for adsorption of a gas which occupies n elementary spaces. It fails, however, to yield a satisfactory fit for our measurements. Equation (19) is a generalized form of the equation

$$v = \sqrt{\frac{k_1 k_2 p}{1 + k_1 p}} \qquad (20)$$

proposed by Zeise which describes the adsorption of gases and vapors on glass,[23] and the adsorption of hydrogen on nickel.[24] Our results do not conform to equation (20) but the data for argon and nitrogen are represented satisfactorily by equation (19), if n is taken as 3 and 4, respectively, as is illustrated by the typical isotherm for nitrogen shown in Fig. 11. The equation also fits our measurements of the adsorption of carbon monoxide, although in this case the value of n varies between 4 and 5 for different isotherms. It is believed, therefore, that equation (19) holds over a very much wider range of pressure than equation (16) or (17).

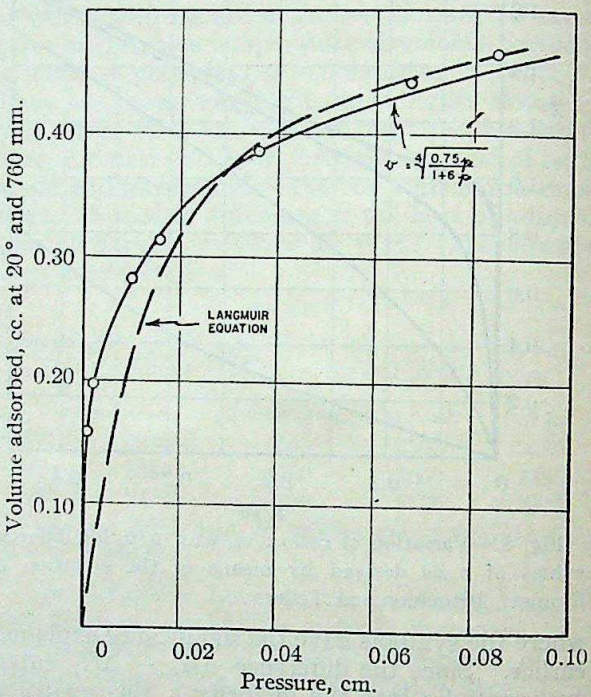

Fig. 11.—Adsorption of nitrogen on reduced surface of Sample 3. Circles represent the observations; the dashed line is derived by means of the Langmuir equation, fitted to the data over the higher range of pressure; the solid line represents equation (19) fitted to the observations.

Significance of Exponent n.—The exponent n in these several equations can be demonstrated to be a measure of the departure of the behavior of the sorbed film from that of an ideal two-dimensional gas. Thus, Innes and Rowley[25] have shown that, if the adsorption equation is known, the equation of state of the sorbed gas can be calculated by a modified form of the Gibbs adsorption equation, specifically

$$m_1 \frac{\mathrm{d}(RT \ln p_1)}{\mathrm{d}m_1} = A_s \frac{\mathrm{d}F}{\mathrm{d}m_1} \qquad (21)$$

in which F is the spreading force (more strictly the two dimensional pressure exerted against a theoretical barrier) of the film, A_s is the total surface area, and m_1 is the number of moles of gas sorbed at pressure p_1. By means of this relation they have also demonstrated that if the adsorption isotherm is linear, that is, if $v = ap$ (or $n = 1$), the sorbed film is an ideal two-dimensional gas, in which case the equation of state may be written $FA = kT$, where A is the cross-sectional area occupied by a single molecule and k is the

Boltzmann constant. If instead of a linear isotherm, one uses equation (16), expressed in terms of moles, that is

$$p_1 = bm_1^n \quad (22)$$

where b is a constant, then

$$\mathrm{d} \ln p_1/\mathrm{d}m_1 = n/m_1 \quad (23)$$

and

$$A_s \mathrm{d}F/\mathrm{d}m_1 = nRT \quad (24)$$

or

$$FA_s = nm_1RT \quad (25)$$

Expressing equation (25) in terms of area occupied per molecule

$$FA = nkT \text{ [26]} \quad (26)$$

which shows that if the adsorption isotherm is represented by equation (16), the two-dimensional pressure for a given value of A is n times as great as for an ideal two-dimensional gas.

This interpretation of the significance of n makes it possible, in some special cases, to estimate the value of n, or to predict how it may vary. For example, since the value of n characterizes the departure of the behavior of the sorbed film from that of an ideal two-dimensional gas, it should, as a first approximation, be the same for a given gas at a given temperature on surfaces of the same type, as for instance smooth metallic surfaces. This conclusion is supported by Wilkins'[27] data for the sorption of argon and nitrogen at low pressures on platinum foil at −183° which fit equation (16) satisfactorily and which at the same temperature yield a value of n of approximately 3 and 4, respectively, in agreement with the value of n derived from our measurements on the sorption of these gases on smooth iron. Moreover, since the deviation from ideality in the sorbed film should decrease as the temperature is increased, the value of n should for all systems approach unity at the higher temperatures; stated in other terms, deviation from the Langmuir equation should be most marked for a gas or vapor which deviates widely from ideal behavior and should, therefore, become more evident as the temperature of the system is decreased toward the critical temperature of the adsorbate. That this is in fact the case is amply confirmed by evidence available in the literature. To mention but two examples, Wilkins' measurements on the sorption of argon on platinum[27] show that the lower the temperature, the greater the deviation from the Langmuir isotherm, and Titoff's[28] measurements of the sorption of vapors on charcoal show clearly that the value of n approaches unity at the higher temperature, Table VI.

On the basis of this interpretation of the significance of n, it is possible to derive equation (19) by a reasonable modification of the postulates which Langmuir used to derive equation (17). Specifically, he assumed: (1) that the rate of condensation of atoms on the surface is equal $\alpha\mu\theta$, where μ is the number of molecules striking the surface in unit time, θ is the fraction of the surface still uncovered; and (2) that the rate of evaporation of adsorbed molecules is equal to $\nu\theta_1$, where ν is the rate of evaporation when the surface is covered by a complete monolayer and θ_1 is the fraction of the surface covered. The fact that at low pressures, that is, when θ is small, the observed adsorption is greater than that derived by extrapolation of the data at higher pressures indicates that the Langmuir postulates yield a rate of condensation which is too small, or a rate of evaporation which is too large, or, more probably, both. The general validity of the postulate that the rate of evaporation is a linear function of θ_1 is extremely doubtful in view of Becker's measurements of the rate of evaporation of cesium atoms from tungsten, which show that the rate varies exponentially[29] with θ_1; hence, if ν is the rate where $\theta_1 = 1$, the rate when $\theta_1 = 0.5$ should be much less than the value of $0.5\ \nu$ calculated on the basis of the Langmuir postulate, and this is in the direction of the observed deviations.

TABLE VI

Values of the exponent n in the parabolic isotherm for the sorption of different gases on charcoal at different temperatures (derived from the data of Titoff).

Temp., °C.	Gas N_2	Gas CO_2	Gas NH
151.5	1.0	1.1	...
80	1.1	1.4	1.3
30	1.1	2.0	1.7
0	1.2	2.7	3.3
−79	2.2	11.6	...

In place of Langmuir's postulate that the rate of evaporation varies linearly with θ_1, it is assumed, as a second approximation, that the rate varies as θ_1^n, where n is the exponent in equation (19), that is, the rate is assumed to be a function not only of the fraction of the surface covered but also of the strength of the intermolecular forces within the film. On this basis, if ν be the rate of evaporation where $\theta_1 = 1$, the rate for a lesser coverage is $\nu\theta_1^n$, a variation which for $n = 1$, that is, for an ideal two-dimensional film, reduces to the linear variation assumed by Langmuir, but which, for a value of n greater than unity, approximates the type of variation observed experimentally by Becker.

The rate of condensation is taken as proportional to the rate at which molecules strike the surface and to the fraction of those impinging which condense. The rate at which molecules strike the surface is proportional to the pressure and it is assumed that the fraction which condenses varies with the fraction of the surface covered and with the value of n, specifically, it is taken as proportional to $(1 - \theta_1^n)$, on which basis the rate of condensation is equal to $\alpha p(1 - \theta_1^n)$ where α is a proportionality constant. This result is admittedly somewhat arbitrary but never-

(26) If A is expressed in sq. Å. and F in dynes/cm. $FA = 1.372\ nT$.

theless meets two of the ends desired: namely, for a film which is an ideal two-dimensional gas, that is, one for which $n = 1$, this rate reduces to $\alpha p\theta$, where θ is the fraction of the surface not covered, which is the rate of condensation postulated by Langmuir; for a value of n greater than unity this variation is in accord with the general principle that the rate of condensation is initially high but falls off rapidly with increasing fraction of the surface covered.

Since at equilibrium the rate of condensation must equal the rate of evaporation

$$\alpha p(1 - \theta_1^n) = \nu\theta_1^n \qquad (27)$$

whence

$$\theta_1 = \frac{v}{v_s} = \sqrt[n]{\frac{\alpha p/\nu}{1 + \alpha p\nu}} \qquad (28)$$

which is identical with equation (19).

Force–Area Curves.—Two methods, both based on Gibbs' adsorption equation, have been considered for deriving the force-area curve of a sorbed film from the adsorption isotherms. The first, that of Innes and Rowley,[30] depends upon the relation

$$FA = v_1RT + RT\int_{p/v \text{ as } v \to 0}^{p_1/v_1} v\,d\ln(p/v) \qquad (29)$$

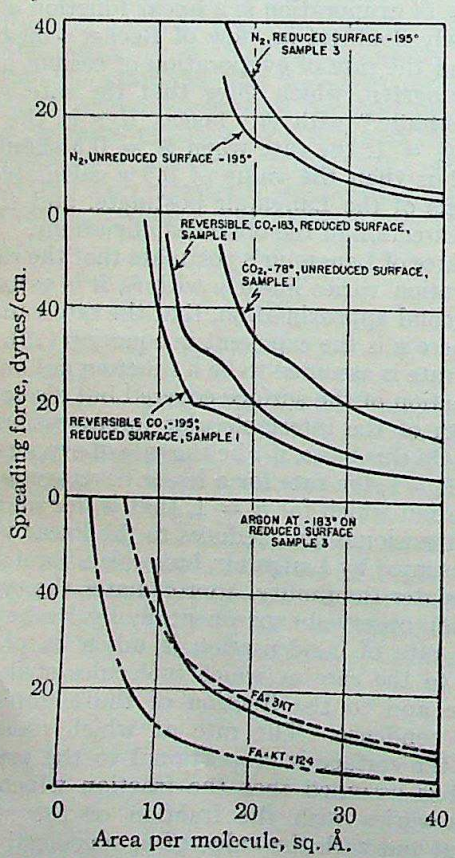

Fig. 12.—Force–area curves for sorbed films derived by the method of Innes and Rowley: (a) argon at −183° on reduced surface of Sample 3; (b) CO and CO_2 on Sample 1; N_2 at −195° on Sample 3.

(30) Innes and Rowley, *J. Phys. Chem.*, **45**, 158 (1941).

in which F is the surface pressure in dyne/cm., A is the area of the absorbing surface and v and v_1 are, respectively, the volume of gas adsorbed at pressure p and p_1. The integration can be carried out mathematically if the variation of v with p can be represented satisfactorily, or it can be carried out graphically, which is in general more convenient. The second method was devised by Palmer[31] on the assumption that the logarithm of φ, the adsorption potential, varies linearly with the volume sorbed, a postulate which in many instances is valid over a fairly wide range of pressure.

These two methods yield significantly different results, as has been pointed out in an earlier paper.[32] The cause of this difference is not certain but is probably the extrapolation to $v = 0$ which must be made with either method and, on this basis, the Innes and Rowley method is to be preferred. For the Palmer method assumes that $\log \varphi$ is linear with v down to $v = 0$, which cannot be so if the behavior of the sorbed film is to approach that of an ideal film, as it should. Moreover, it has already been demonstrated that if the isotherm is represented by equation (19) the force–area curve should lie above that for the ideal two-dimensional gas. For these several reasons we report here only force–area curves derived by the method of Innes and Rowley.

Typical force–area curves are shown in Fig. 12, the lowest section of which shows the curve for argon sorbed at −183° on a reduced surface of Sample 3. These data were selected because the specific surface of this sample appears to be very nearly unity and because the isotherm is closely represented, over most of the range studied, by the relation $v = ap^{1/3}$. It is evident that over the whole range the curve derived by means of equation (29) lies close to that representing the equation $FA = 3\,kt$, as it should, on the basis of equation (26). The curve is also smooth over the whole range of measurement. Similar smooth curves were obtained for the sorption of argon or nitrogen on all the reduced surfaces at both −183 and −195°, another example being the curve for nitrogen sorbed at −195° on a reduced surface of Sample 3, shown in the top section of Fig. 12.

In a number of instances, however, the force–area curve was not smooth but showed a plateau, as is illustrated by several typical curves shown in the middle and upper sections of Fig. 12. These curves are derived from a curve of $\ln(p/v)$ *vs.* v based on the experimental observations, not on the smooth isotherms shown in Figs. 2 to 6. These curves are entirely analogous to those for an insoluble liquid film on water,[33] and indicate the existence of phase transformations in the sorbed film. The two curves in the middle sec-

tion of Fig. 12 for carbon monoxide sorbed at −183 and −195° also show that with increasing temperature the plateau appears at a higher surface pressure and at a slightly lower value of A, as is usually observed for a monomolecular film on water.

These plateaus appear only when some molecules are held to the surface very strongly, either by physical or chemical forces; for instance, in the physical sorption of carbon monoxide, the surface already has on it some molecules which are chemisorbed. Another illustration is given in the top section of Fig. 12, which shows the sorption of nitrogen at −195° on the unreduced and reduced surface of Sample 3. The curve for the reduced surface, in which adsorption is completely reversible, is smooth whereas the curve for the unreduced surface, from which some nitrogen molecules cannot be removed by pumping at temperature, shows a plateau, which suggests that the molecules which are strongly held are attached to definite sites whereas those which can be desorbed by reducing the pressure are not. As the concentration of mobile molecules increases their mobility is diminished because of the interference by what is equivalent to a lattice of rigidly held molecules so that the film condenses to a less fluid structure and undergoes a phase transformation.

Summary

The adsorption on cold-rolled steel of argon, neon, hydrogen, nitrogen, carbon monoxide and carbon dioxide has been determined at 20, −78, −183 and −195° and at pressures up to 0.1 cm. Measurements were made first on a degreased and outgassed surface and subsequently on the same surface after reduction by hydrogen. In some cases the surface had to be conditioned a number of times before adsorption was reproducible within the error of measurement. Neither hydrogen nor neon was measurably adsorbed on either surface within the range of temperature or pressure investigated. A monomolecular layer of physically-held nitrogen, argon or carbon monoxide was sorbed on the unreduced surface at −183° but in each case approximately 15% of the total volume of gas sorbed was held so strongly that it could not be desorbed by reducing the pressure at temperature. A similar monolayer of physically-held nitrogen and argon was adsorbed on the reduced surface but could be entirely desorbed by evacuation of the system at temperature. On this same surface a complete monolayer of physically-held carbon monoxide was adsorbed along with a partial layer of chemisorbed molecules.

The isotherms appear to be of the saturation type but it is believed that they are in fact merely the low pressure section of an isotherm of the sigmoid type characteristic of adsorption on iron catalysts.

The ordinary analog of the Clausius–Clapeyron equation does not in principle yield a correct value for the heat of adsorption. The Emmett–Brunauer–Teller equation appears to be preferable. The heat of adsorption calculated by this method is, for all the physically-held sorption, approximately 3000 cal./mole. The heat of adsorption is influenced more by the physical nature of the surface than by the chemical nature of the gas.

The isotherms are represented in the low pressure range by the parabolic or Freundlich, equation and in the high pressure range by the Langmuir relation. A combination of these equations

$$v = v_\infty \sqrt[n]{\frac{ap}{1 + ap}}$$

represents most of our results over the whole range of pressure. The exponent n is interpreted as a measure of the departure of the behavior of sorbed film from that of an ideal two-dimensional gas. The value of n decreases with increasing temperature; when it is unity, the film is ideal and the isotherm equation reduces to the Langmuir relation.

Force–area curves for the sorbed films show that when some of the gas is held to the surface very strongly phase-transformations similar to those occurring in monomolecular films on water may take place.

The surface of cold-rolled steel is remarkably flat, the specific surface being not more than 4 times the geometric area of the steel.

The Photolysis of Hydroxylamine[1]

BY R. NELSON SMITH[1a] AND PHILIP A. LEIGHTON[1b]

The photolyses of ammonia, hydrazine, water and hydrogen peroxide have been studied with care, and while many questions yet remain concerning the mechanisms of these reactions, the experimental evidence suggests that amino or hydroxyl radicals are produced as intermediates in all of them, and that the secondary processes consist largely of reactions of these radicals. The work here reported indicates that this is true also of hydroxylamine, and provides added support for some of the specific reactions of amino and hydroxyl radicals which have already been postulated.

Materials.—Hydroxylamine was prepared by the method of Hurd and Brownstein.[2] After removing all traces of solvent retained from the preparation, the solid hydroxylamine was purified by sublimation *in vacuo*. The hydroxylamine reservoir was kept evacuated and at dry-ice temperature at all times except when withdrawing samples. The melting range of one sample thus prepared was determined to be 31.8–32.8°, in good agreement with reported data.

The ammonia used was stored over sodium to remove water. All traces of air were removed by alternately warming the ammonia to atmospheric pressure and then freezing the ammonia with liquid air and evacuating.

Oxygen and hydrogen samples were taken from commercial tanks in a manner which prevented contamination by air. The purity of new samples was always determined by combustion before use in analysis, and if impurities were present, a different sample was collected.

The hydrogen peroxide used at one point was prepared by concentrating a 30% commercial aqueous solution from about 30 cc. to 3 cc. by distillation *in vacuo* at room temperature. The purity of this product was estimated to be well over 90%.

Ultraviolet Absorption Spectrum of Hydroxylamine.—The literature reveals no spectrochemical data for hydroxylamine other than the results of the determination of the infrared spectrum of aqueous solutions[3] and the infrared and Raman spectra of solid hydroxylamine hydrochloride and its aqueous solutions.[3,4]

To determine its ultraviolet absorption spectrum, a 150-cm. focal length quartz prism spectrograph and an Allen–Franklin type hydrogen discharge tube[5] were employed. A slit width of 0.001″ was used. The absorption cell was made of fused silica, 3.5 cm. in diameter and 134.7 cm. long. It was connected to a hydroxylamine reservoir and a diamyl phthalate differential manometer by interchangeable ground joints. The entire absorption system was capable of being highly evacuated. Eastman Kodak Co. No. 33 photographic plates coated with a thin film of transil oil were used for recording the light transmitted. After each exposure, the absorption tube and reservoir (at dry-ice temperature) were evacuated. If such a procedure was not followed, the diffuse ammonia bands and the characteristic bands and fine structure of nitric oxide at 2269, 2260 and 2154 Å. appeared. These products apparently arise from the thermal decomposition of hydroxylamine, especially after long standing at the higher hydroxylamine pressures.

Figure 1 shows a microphotometer tracing of spectrograms taken at different hydroxylamine pressures. It is evident that in this region only continuous absorption is observed. For the length of cell used here, "complete" absorption sets in at about 2140 Å., at 3.02 mm. and about 2015 Å. at 0.15 mm., but at the higher pressure some absorption takes place at wave lengths as long as 2350 Å. It is evident that the measurements were taken to the limit of the transmission of silica. Photographic plate characteristics were not obtained, and hence absorption coefficients have not been calculated.

Apparatus and Method.—The reaction system is shown in Fig. 2. The fused silica reaction cell, M, was connected to the rest of the system by a silica-to-Pyrex graded seal. The cell was cylindrical in shape, 10 cm. long and 3.0 cm. in diameter, with plane windows at either end. The hydroxylamine reservoir was at R. The amount of hydroxylamine added to the system was measured on the wide-bore mercury manometer, J, by means of a cathetometer. T_1 was a small freeze-out trap where first liquid air and then dry-ice was used to effect a partial separation of the products. The products obtained in each fraction were collected in a gas cup at Z by means of the atmospheric Toepler pump, W. The system was evacuated between runs through f_6.

The light source consisted of a spark discharge between two rapidly rotating zinc disks with a 5 mm. gap which could be accurately maintained and reproduced. A potential difference of 11,000 volts was supplied. The variation in light intensity with this apparatus was never more than 1 or 2%. The effective wave lengths were chiefly the 2025, 2062, 2100 and 2138 Å. lines of zinc.

The crystal quartz lens, L, was arranged to give a convergent beam of ultraviolet light through M with the ultraviolet focus somewhere past N. The volume effectively illuminated was a conical section of average cross section 150 mm.^{2} and volume 15 cc. Proper shielding of the cell and leads from stray radiation was provided.

An ammonia actinometer was used to measure the amount of light absorbed by the hydroxylamine. The actinometer cell, N, was 11 mm. deep and of slightly larger diameter than the reaction cell. At first it was sealed directly to the rear window of M with de Khotinsky cement, but the cement reacted slowly with ammonia and for most of the runs a crystal quartz window sealed to N with paraffin was used. With this arrangement N was about 1 mm. from the rear window of M. In use, N was first evacuated through f_1 and f_6, then with f_6 closed and f_7 open the ammonia reservoir P was warmed and N filled to 600 mm. Hg pressure, which in a cell of 11 mm. depth may be taken as completely absorbing for the wave lengths concerned.

After irradiation, the undecomposed ammonia in N was frozen out in T_2 with liquid air. The hydrogen and nitrogen resulting from irradiation were passed through f_1, collected in a gas cup, and their volume measured with a microburet.

To calculate the number of quanta of light absorbed, let A be the volume (cu. mm., corrected to S. T. P.) of hydrogen and nitrogen produced in M when filled with ammonia at 600 mm., B the volume of hydrogen and nitrogen formed in N with M empty, and C the volume of hydrogen and nitrogen formed in N with hydroxylamine in M. Then, using Wijg's value[6] of 0.18 for Φ_{NH_3} at this pressure and recognizing the fact that the volume of hydrogen and nitrogen

Hydroxylamine pressure, mm.	0.00	0.15	0.38	0.76	1.51	4.02

7 Background; corresponding to complete absorption

formed is twice the volume of ammonia decomposed, the number of quanta absorbed by hydroxylamine is

$$q = \frac{6.02 \times 10^{23}}{2.24 \times 10^{7}} \times \frac{1}{2\Phi_{NH_3}} \times \left(1 - \frac{C}{B}\right)A = \frac{7.47 \times 10^{16}\,(B - C)A}{B}$$

Parameter A remained nearly constant over a long period of time and did not often have to be redetermined. B tended to decrease over a period of time, but not regularly, and it was necessary to determine it daily. The measurement of C was a part of each run.

Variations in light intensity were accomplished by reducing the intensity with varying thicknesses of 0.001″ cellophane. It was shown that the cellophane did not measurably change the spectral distribution of the light effective in the decomposition.

In carrying out a run, the system was first evacuated, and ammonia added to N to a pressure of 600 mm. The ammonia was then frozen in T_2 with liquid air and the hydroxylamine frozen in R with dry-ice while the entire system was re-evacuated. Then with f_1 and f_2 closed, T_2 and R were allowed to warm to room temperature. Hydroxylamine was allowed to sublime into M to the desired pressure as measured on J. This was done slowly to

minimize thermal decomposition. After filling, f_2 was closed and dry-ice restored around R. After irradiation liquid air was placed around T_1 and the products noncondensable at that temperature were transferred to a gas cup at Z. Liquid air was again placed around T_2 and with liquid air still around T_1, the hydrogen and nitrogen formed in the actinometer were removed from the system to a second gas cup. This volume was measured, but the gas was not retained for analysis. Material condensed in T_2 was vaporized and refrozen to remove trapped gas. Finally, with f_1 closed, dry-ice was placed around T_1 and the gases non-condensable at this temperature were removed to a third gas cup.

In the thermal runs, exactly the same procedure was followed except that no actinometric measurements were made. The times required for filling the cell were about fifteen, twenty-two and thirty minutes for pressures of 1, 2, and 3–4 mm., and for a given pressure the length of time required for filling the cell was very nearly the same for all runs, both thermal and photolytic.

Identification and Determination of Products.—The micro methods devised by Blacet, Leighton and coworkers[7] were used for identification and analysis of the gaseous reaction products. The fraction not condensed at liquid air temperature was found to consist of hydrogen and nitrogen, usually with small amounts of nitric oxide. The dry-ice fraction was found to consist only of nitrous oxide and ammonia. These mixtures were analyzed by methods which have been described separately.[8]

In addition to the above products, the formation of both water and hydrazine was qualitatively demonstrated. Water was detected by first removing the undecomposed hydroxylamine, then passing the remaining gas over magnesium metal at 300°. Hydrazine was identified by the method of Curtius and Schrader,[9] *viz.*, the reduction of auric ion in 9 *M* sulfuric acid. The test for hydrazine was much stronger when the photolysis was carried out in a flowing system, by distilling hydroxylamine from one flask to another through an illuminated section of silica tubing. Slight tests were obtained with samples of hydroxylamine which had stood a long time, indicating that some hydrazine may also be formed in the thermal decomposition.

Quantitative Results.—Table I shows the results of the investigation of the photolysis of hydroxylamine for varying pressures, light intensities, and exposure times. Temperatures were 27 ± 3°. Table II compares the thermal decomposition of hydroxylamine in Pyrex and silica vessels for different pressures, and at 27 ± 1°. The thermal decomposition products represent the amounts obtained in times closely approximating those used for photolyses at the same pressure. It is evident that the amount of thermal decomposition is seriously large at pressures above 1 mm. It was not reproducible from run to run, and on this account accurate corrections could not be made either on the basis of alternate light and dark runs in the same vessel or simultaneous light and dark runs in separate vessels. It is evident by comparison with the photolytic experiments that at all pressures the amount of hydrogen produced in the thermal decomposition is negligible

compared to the amount produced on irradiation. Hence the yield of hydrogen is useful as an index of the extent of photolysis, and the rate of hydrogen formation and the Φ_{H_2} have been calculated for all runs.

A lower limit for the amount of hydroxylamine decomposed by light can be obtained from the nitrogen content of the measured products corrected for the thermal contribution, a correction which can be closely approximated only at 1 mm. pressure. The values of Φ_{NH_2OH} in Table I were estimated in this way. The true values will be higher by the amount of nitrogen in other nitrogenous products, such as hydrazine, which were not measured.

The decrease in hydrogen–nitrogen ratio with increasing hydroxylamine pressure is due to the increase in thermal decomposition with pressure. Approximate corrections for the amount of thermal reaction indicate a hydrogen–nitrogen ratio of nearly unity for the photolysis alone.

Since nitric oxide comprises about 31% of the liquid air fraction of the thermal decomposition, but only a very small percentage of the same fraction of the combined thermal and photolytic products, it seems likely that nitric oxide is formed only in the thermal reaction.

Any quantitative statement regarding the amounts of nitrous oxide or ammonia formed in the photolysis is impossible because of the magnitude of the contribution of the thermal decomposition and its erratic character. Except for a 1-mm. pressure of hydroxylamine, one can say only that the dry-ice fraction obtained from a photolysis is on the average only slightly larger than the dry-ice fraction from the thermal reaction at the same pressure and that the ammonia–nitrous oxide ratio is about the same in both cases and increases markedly with pressure.

At constant light intensity and for a given period of irradiation, the observed rate of hydrogen formation increases with increasing hydroxylamine pressure. From the per cent. of light absorbed at each pressure it is possible to calculate the rate of hydrogen formation for equal amounts of light absorbed. When this is done it is found that the rate actually decreases with increasing pressure (Fig. 3).

At constant pressure and for equal amounts of incident light (obtained by properly adjusting the irradiation time), the rate of hydrogen formation increases very markedly with increasing light intensity. If one plots $I_a^{1/2}$ *vs.* the rate of hydrogen formation, a straight line is obtained (Fig. 4), while Φ_{H_2} increases with the $I_a^{1/2}$. I_a is the rate of light absorption, in einsteins/cc. sec.

The figures given in Table I for Φ_{NH_2OH} are based on the nitrogen content of the measured decomposition products, corrected for the thermal contribution. Due to the increase in thermal reaction with pressure the values could be closely estimated only at 1 mm., and since some hydrazine is known to be found, they are only a lower limit. Φ_{NH_2OH} also increases with increasing light intensity, and, as with Φ_{H_2}, the drop in Φ_{NH_2OH} with increasing exposure time may be attributed to absorption by products.

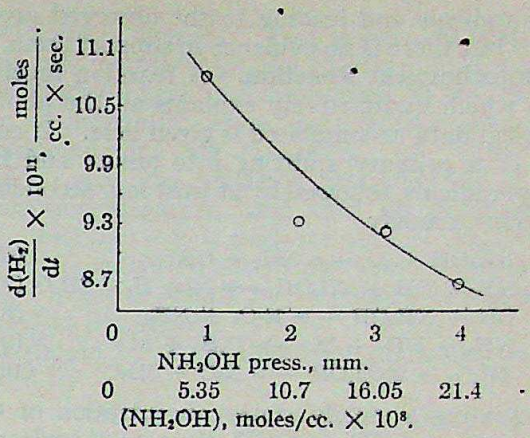

Fig. 3.—Rate of hydrogen formation at room temperature (27 ± 3°) *vs.* hydroxylamine pressure at constant light intensity and for a given amount of light absorbed. Points are experimental, but curve is calculated from the equation $\frac{d(H_2)}{dt} = \frac{5.74 \times 10^{-14}}{[2.3 \times 10^{-7} + (NH_2OH)]^{1/2}}$.

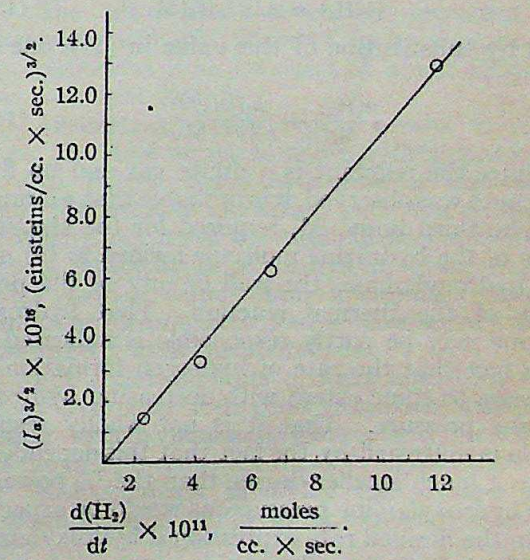

Fig. 4.—Rate of hydrogen formation *vs.* $(Ia)^{3/2}$, for hydroxylamine pressure of 1 mm. and equal amounts of light absorbed at each intensity.

Discussion

Thermal Reaction.—Little evidence is available upon which to base any mechanism for the thermal decomposition. It is evident that wall surfaces play an important part in the process. Hofmann and Kroll[10] postulated the formation of the mono- and diamides of nitrous acid as intermediates in the thermal decomposition of hydroxylamine hydrochloride in solutions and in the solid state. Reactions may be written involving

(10) Hofmann and Kroll, *Ber.*, **57**, 937 (1924).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

these radicals and leading to the observed products,[11] but there is no evidence to support them.

Photochemical Reaction.—A reaction mechanism which qualitatively explains all the photochemical data accumulated is given here. It consists of a primary splitting into amino and hydroxyl radicals, followed by at least four secondary reactions, namely

$$\phi I_a \quad NH_2OH + h\nu \longrightarrow NH_2 + OH \qquad (6)$$
$$k_1 \quad NH_2 + OH + NH_2OH \longrightarrow N_2 + H_2 + 2H_2O \qquad (7)$$
$$k_2 \quad OH + NH_2OH \longrightarrow H_2O_2 + NH_2 \qquad (8)$$
$$k_3 \quad NH_2 + NH_2 + M \longrightarrow N_2H_4 + M \qquad (9)$$
$$2H_2O_2 + 2NH_2OH \longrightarrow N_2O + 5H_2O \qquad (10)$$

Assuming a steady state concentration of the intermediates, NH_2 and OH, the rate of hydrogen formation becomes

$$d(H_2)/dt = k_1(NH_2)(OH)(NH_2OH) = k_1k_3(M)(NH_2)^3/k_2 \qquad (11)$$

The amino radical concentration may be obtained as the solution of the equation

$$(NH_2)^3 + \frac{k_2}{k_1}(NH_2)^2 - \frac{k_2\phi I_a}{k_1k_3(M)} = 0 \qquad (12)$$

The solution is greatly simplified if it is assumed that $k_2/k_1 \gg (NH_2)$ (*vide infra*). With this assumption

$$(NH_2) = \sqrt{\phi I_a/k_3(M)} \qquad (13)$$

and by substitution of this value in (11), one obtains

$$\frac{d(H_2)}{dt} = \frac{k_1(\phi I_a)^{3/2}}{k_2k_3^{1/2}(M)^{1/2}} \qquad (14)$$

Since the reactant is a dilute gas and no fluorescence was observed, it is probable that ϕ is unity.

The third body, M, required for the stabilization of the hydrazine molecule formed in (9) may be hydroxylamine, the wall or any of the products of the thermal reaction. That hydroxylamine may be partly responsible is indicated by the fact that the rate of hydrogen formation increases to some extent with decreasing hydroxylamine pressure. That it is not wholly responsible is suggested by the fact that this dependence is to a much smaller degree than the $^1/_2$ power of the hydroxylamine pressure, as would be expected from the derived rate expression if hydroxylamine replaced M. Considering the nature of amine radicals and of hydrazine itself, and the low pressures used in the experiments, it is conceivable that the walls play a role in the stabilization. Hence it should be possible to divide M into two parts, M = (W + N), where W represents the part played by the walls and N the concentration of hydroxylamine. If either W or N were greatly predominating, (M) would depend only on the one which predominated, but since it depends on both, W and N must be of the same order of magnitude. Figure 3 may be exactly reproduced by the equation

$$\frac{d(H_2)}{dt} = \frac{5.74 \times 10^{-14}}{[2.3 \times 10^{-7} + (NH_2OH)]^{1/2}} \qquad (15)$$

where (NH_2OH) is expressed in moles per cc., and the rate is expressed in moles per cc. per sec. The dependence of W on hydroxylamine pressure is neglected here because of the short pressure range (4 mm.) studied. Similarly, equation (14) may be modified to give

$$\frac{d(H_2)}{dt} = \frac{k_1(I_a)^{3/2}}{k_2k_3^{1/2}[2.3 \times 10^{-7} + (NH_2OH)]^{1/2}} \qquad (16)$$

also

$$\Phi_{H_2} = \frac{d(H_2)/dt}{I_a} = \frac{k_1(I_a)^{1/2}}{k_2k_3^{1/2}[2.3 \times 10^{-7} + (NH_2OH)]^{1/2}} \qquad (17)$$

It is evident from (17) that the slope of Φ_{H_2} *vs.* $(I_a)^{1/2}$ will yield some information regarding the rate constants. For a pressure of 1 mm., it is found that

$$\text{slope} = 1.19 \times 10^{-5} = k_2k_3^{1/2}(2.8 \times 10^{-7})^{1/2}/k_1$$

and

$$\frac{k_2}{k_1} = \frac{2.24 \times 10^{-2}}{k_3^{1/2}}$$

If k_3 is assumed to be of the same order of magnitude as rate constants for atomic recombination, *i. e.*, about 10^{15} (moles/cc.)$^{-2}$ sec.$^{-1}$, then $k_2/k_1 \sim 10^{-9}$.

Several arguments may be applied which lead one to the conclusion that the stationary amino radical concentration cannot be greater than 10^{-12} mole per cc. Now if $k_3 = 10^{15}$ and $(NH_2) < 10^{-12}$ mole per cc., then in equation (12) the cubic term, $(NH_2)^3$, is less than 1/1000 as large as $(k_2/k_1)(NH_2)^2$, and the original assumption in which the cubic term is neglected is valid.

If one assumes the pre-exponential factor values of 10^{14} (moles/cc.)$^{-1}$ sec.$^{-1}$ and 10^{15} (moles/cc.)$^{-2}$ sec.$^{-1}$ for the second and third order reactions (8) and (7), respectively, and if $k_2/k_1 = 10^{-9}$, it may be calculated from the Arrhenius equation that at 27° the activation energy of step (8) is about 11 kcal. greater than for step (7).

In addition to accounting for the observed products, it is seen that this mechanism accounts for the dependence of the rate of hydrogen formation on the 3/2 power of the light intensity. It is true that only a few cases have been reported in which increasing the light intensity leads to an increasing quantum yield, yet some of the most recent mechanisms proposed for the photolysis of ammonia[11a,12,13] yield ane xpression in which the

(11) Hofmann and Kroll's reactions are

$$NH_2OH + NH_2OH \longrightarrow NH_2NHOH + H_2O \qquad (1)$$
$$NH_2NHOH + NH_2OH \longrightarrow (NH_2)_2NOH + H_2O \qquad (2)$$

and to account for the majority of the observed products they suggested that the diamide acid decomposes to give nitrogen, ammonia and water. Further possibilities are

$$2NH_2NHOH \begin{cases} \nearrow N_2O + 2NH_3 + H_2O & (3) \\ \searrow N_2 + N_2H_4 + 2H_2O & (4) \end{cases}$$
$$2(NH_2)_2NOH \longrightarrow 2NO + 2NH_3 + N_2H_4 \qquad (5)$$

quantum yield of ammonia decomposition increases with the cube root of the light intensity. Mund, Brenard and Kaertkemeyer[12] have pointed out that experiments performed by them, by Wiig and by Ogg, Leighton and Bergstrom are in accord with this relation.

The requirement that hydrogen and nitrogen should be formed in approximately equal amounts is satisfied by step (7).

Step (10) was shown to take place by mixing hydrogen peroxide and hydroxylamine vapors. The dry-ice fraction resulting from this mixture was shown to contain only nitrous oxide. The quantities of nitrous oxide thus obtained were much larger than resulted at any time from the simple thermal decomposition of hydroxylamine. It is postulated that this reaction could account for the small amount of nitrous oxide observed in the photolysis. It is probable that the reaction is not fourth order as shown, but takes place in a series of simple bimolecular collisions, quite possibly involving the intermediates postulated in the thermal decomposition of hydroxylamine [equations (1) and (2)]. It is unlikely that hydrogen peroxide remains as a final product in the photolysis, but it is possible that some of it decomposes to form water and oxygen. This is not obviated by the fact that no oxygen was ever observed, since any formed in this manner would react with nitric oxide formed in the thermal decomposition to produce nitrogen dioxide. This in turn would either be frozen out or would react with ammonia formed in the thermal decomposition. Nitrous oxide, if it is formed directly in the photolysis, might appear as the result of reaction (10), while ammonia might result from the decomposition of hydrazine.

The requirement that Φ_{NH_2OH} should increase with increasing light intensity is also satisfied, and values of greater than 2 are permitted by the proposed mechanism. The decrease in Φ_{NH_3CH} with exposure time already has been partially explained.

Other possibilities for the primary step should be noted. The two most probable ones require breaking either an N–H bond or an O–H bond. All other possibilities require the breaking of more than one bond. It may be calculated that at least 67 kcal. would be necessary to break the N–O bond in step (6). This is some 40 kcal. less than that required for the O–H or N–H bonds. So though 67 kcal. is a lower limit to step (6), it is in all probability more likely from an energetic standpoint than are the other two. The fact that no structure whatever was observed in the absorption spectrum, and that no fluorescence could be observed, is evidence against the formation of an activated complex or excited hydroxylamine molecule which by secondary reactions is caused to decompose.

It should be noted that step (8) might be replaced by

$$NH_2 + NH_2OH \longrightarrow N_2H_4 + OH \qquad (18)$$

and (9) by

$$OH + OH + M \longrightarrow H_2O_2 + M \qquad (19)$$

Such a replacement in no way alters either the form of the rate expression for hydrogen formation or the amounts of hydrogen peroxide or hydrazine and their rate of formation. However, (9) seems more likely than (19) because there is some evidence that the latter does not readily take place.

Summary

1. The ultraviolet absorption spectrum of hydroxylamine vapor is found to be experimentally continuous from its onset at about 2350 Å. down to at least 2000 Å.

2. Absorption in this region results in photolysis, the chief products being hydrogen, nitrogen and water. Some hydrazine is also produced, the amount increasing in a flow system. The chief products of the thermal decomposition at room temperature are nitrogen, nitric oxide, nitrous oxide, water and ammonia. Small amounts of nitrous oxide and ammonia may also result directly from the photolysis.

3. For equal amounts of light absorbed, the rate of hydrogen formation decreases with increasing hydroxylamine pressure, and increases with the 3/2 power of the incident light intensity.

4. A mechanism involving amino and hydroxyl radicals is found to fit the experimental data.

The Solubility of Sodium Iodide in Sodium Hydroxide Solutions at 20°

BY RICHARD POMEROY AND H. DARWIN KIRSCHMAN

In a recent article[1] we have presented the results of a study of the solubility of potassium iodide in potassium hydroxide solutions at 20° over the range 0 to 14.35 *N* in alkali. The present paper extends the study to the iodide of sodium in solutions of sodium hydroxide from 0 to 15.21 *N*.

The results of our measurements are presented in Table I and Fig. 1.

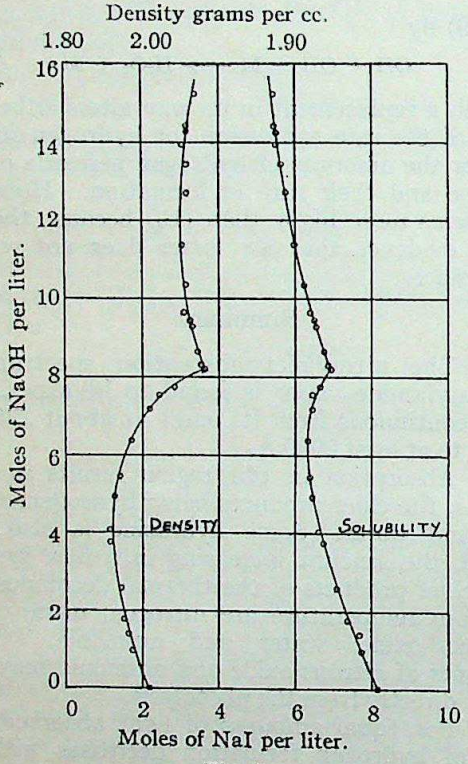

Fig. 1.

Experimental

Sodium iodide of C. P. grade was purified by recrystallization as the dihydrate. A highly concentrated solution of sodium hydroxide was prepared, filtered free from carbonate, and crystallized as the monohydrate by cooling. The bottle containing these crystals was warmed to produce a melt which was mixed with suitable amounts of water and sodium iodide crystals in the equilibrium bottles. These bottles were then immersed in a water-bath at 20° for from four to twelve days and shaken frequently. Portions were removed with pipets and diluted with water to suitable concentrations for analysis. The drainage error in the use of a pipet with these rather viscous solutions was corrected for by washing out and titrating the residual liquid in the pipet. The alkalinity was determined by titration with standard sulfuric acid solution using methyl orange indicator. The iodide content was determined gravimetrically as silver iodide. The density determination was made by weighing a 25-ml. sample of the saturated solution. These weighings were corrected for the buoyant effect of the air.

Equilibrium seemed to be somewhat more slowly attained than in the experiments with potassium iodide in potassium hydroxide but a few trials employing mechanical stirring of the mixture for several hours showed satisfactory agreement with other methods of saturation. The density and solubility curves show a discontinuity at a point corresponding to 8.20 *N* in sodium hydroxide and 6.92 *N* in sodium iodide. The solid phase in the mixtures with hydroxide concentrations above 8.20 was identified as anhydrous, cubic, sodium iodide.

The accuracy of results is estimated to be 1%.

Summary

The solubility of sodium iodide at 20° was determined in sodium hydroxide solutions from 0 to 15.21 *N* in alkali. The density and solubility curves show a discontinuity at a point correspond-

The Density and Transition Points of the *n*-Paraffin Hydrocarbons

BY WM. F. SEYER, RALPH F. PATTERSON[1] AND JOHN L. KEAYS[2]

The density and transition point of dicetyl ($C_{32}H_{66}$) formed the subject matter of a previous communication to this Journal.[3] Since then, all the even-numbered hydrocarbons, beginning with $C_{16}H_{34}$ and ending with $C_{34}H_{70}$, have been investigated, also $C_{29}H_{60}$ of the odd-numbered series.

Materials.—All of these hydrocarbons excepting $C_{16}H_{34}$ and $C_{29}H_{60}$ were synthesized in the laboratory. Samples of hexadecane were obtained from Messrs. Deanesly and Carelton of the Shell Oil Company, and Professor Parks of Stanford University. Both samples were from lots that had been carefully purified by the donors, but upon comparing the m. ps. of the two, it was found that the m. p. from the former had a slightly higher value than that from the latter. The m. p. of the best material was found to be 18.145 and its setting point 18.3.

The nonacosane was obtained from the Bureau of Standards through the efforts of Dr. B. J. Mair. It had an m. p. of 63.0° but as Piper and his co-workers[4] gave a value of 63.4–6° it was recrystallized until the m. p. rose to 63.5°.

The method employed for synthesizing the desired hydrocarbons depended upon the nature of the material available. Where alcohols served as a starting point the Kraft procedure was followed and where acids, the Peterson electrolytic method was utilized. After the usual preliminary purification the hydrocarbons were treated with sulfuric acid until no color formed upon the addition of the acid. To remove it, the hydrocarbons were washed with hot water. They were then dried and recrystallized from five to twenty times until a constant m. p. and t. p. were obtained.

Tetratriacontane, the highest member so far synthesized, was prepared by the electrolysis of the corresponding acid which in this case was stearic. Considerable difficulty was encountered in the purification of this compound. It could not be obtained completely colorless although it was drastically treated with sulfuric acid and recrystallized from glacial acetic acid over forty times. The reason for this failure may lie in the following statement of Oldham and Ubbelohde.[5] "Owing to the appreciable oxidation of certain liquid paraffins at 130°, it was advisable to hinder the circulation of air over the surface of the paraffin during the purification." It may be that this hydrocarbon was oxidized at the temperatures where purification was attempted.

Melting Points of the Normal Paraffin Hydrocarbons.—A knowledge of the melting points of the normal paraffin hydrocarbons was found to be essential for the present investigation. Piper,[4] *et al.*, claim that the transition point is a more reliable index of purity than the melting point.[4] This may be true for those hydrocarbons having more than twenty-six carbon atoms but for those below this in the series this cannot be so, because there is either no transition point or it is indistinct. As mentioned in the previous article, the melting points, even when done by the method outlined by Piper, *et al.*, were affected by the rate of heating and the personal equation, but experience showed that the setting point was not. It could be reproduced by any worker in the Laboratory to within 0.2 to 0.1° for any one sample by observing the temperature when the first crystal formed upon slow cooling (temperature dropping less than 0.5° per minute). Hence, the setting point has been used in this Laboratory for the purpose of establishing the purity of the compounds under investigation. The observed setting points along with the melting and transition points are given in Table II, where N denotes the number of carbon atoms in the chain.

Equations have been developed by Moullin,[6] Taskototos,[7] and Garner[8] for correlating the melting points with number of carbon atoms in the paraffin hydrocarbon chain. None of the equations was found to be satisfactory over the whole range of melting points. Moullin's equation, which is of the form $\log (N - 2) = a + bt$, could be made to fit the curve of melting point against carbon number, if one assumed discontinuities at about $N = 16$ and $N = 33$. N here represents the number of carbon atoms in the chain and a and b are constants. There is also up to $C_{16}H_{34}$ one curve for the odd numbers and one for the even numbers. Above this member, melting points of the odd and even numbered paraffins fall on the same straight line.

The values of the constants, a and b, obtained by the method of least squares for different sections of the curve are given in Table I. Members lower than C_6H_{14}, for both the odd and even numbered compounds, are not included, as the deviations of observed from calculated m. ps. are too great. The recorded m. p. of $C_{11}H_{24}$ is also out of line.

TABLE I

VALUES OF CONSTANTS *a* AND *b*

No. of carbon atoms range:		*a*	*b*
$C_6 \longrightarrow$	C_{16} (even)	1.051	0.00481
C_7	C_{15} (odd)	1.067	.00410
C_{16}	C_{34} (odd and even)	1.02	.0065
C_{33}	C_{70}	0.08	.0006

In correlating the melting points of the normal paraffin series with numbers of carbon atoms in the chain, it was attempted insofar as possible to select values obtained by one set of workers. For as has been mentioned above, the m. ps. obtained depend not only upon the purity of the product but also upon the m. p. technique. Further, workers interested in a set of values are sure to develop laboratory methods and gain experience much broader in scope that those who accidentally are led to make measurements only on one compound. Consequently, we have used the selected values of Deanesly and Carleton[9] for the range 6–18, and our own for the range 18–34.

For 40, 50, 60 and 70 we selected the melting point given by Carothers,[10] and for 36, 52, 62 and 64 those of Gascard.[11]

From the foregoing data, curves were constructed. Then by means of the smoothed curves a new set of values for the melting points of the paraffin hydrocarbons, up to $N = 70$, was computed as shown in Table II.

Experimental Procedure

The experimental procedure was in general the same as that used in the former measurements with dicetyl. For this, a special dilatometer had to be constructed with a funnel-like opening at the filling end, and to prevent the solid hydrocarbon from working its way upward through the mercury the bulb had to be inverted. However, the difficulties encountered in the measurements of those hydrocarbons lying within the range C_{16} to C_{26} were so great that additional information on the experimental method seemed advisable.

The dilatometer tube, after having been filled, was placed in the constant temperature bath and the capillary heights noted. These heights were plotted against temperature immediately as found. This was done for two reasons. The capillary height–temperature curves resemble, in shape, the density–temperature curve, and therefore, any discrepancy in this, when height was plotted against temperature, would show up at once. Further, the capillary height–density curve shows at a glance the temperature at which any transition points occur and thus indicate what regions must be investigated. The general method of obtaining these curves follows:

The general form of the curve obtained is shown in Fig. 1, where B represents the first transition point and C the second transition or melting point.

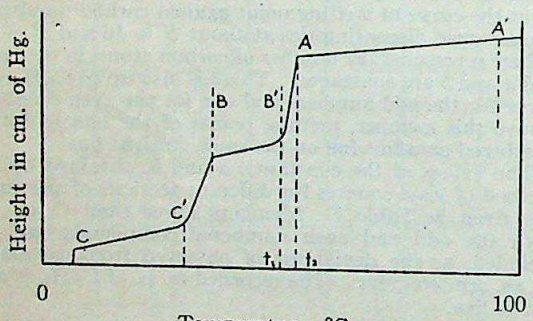

Fig. 1.

Readings were begun near 0°. The bath was kept at this temperature until a constant reading of the mercury level had been obtained. The temperature was then raised several degrees and held constant until equilibrium had been reached. The process was repeated at temperature intervals sufficiently close together to ensure a smooth and continuous curve. The curve given in Fig. 1 is an idealized form of the curve for all members of the aliphatic series greater than 18 and less than 44.

In the regions A–A′, B–B′, and C–C′, equilibrium was reached within a few minutes, but not so in the curve sections A′–B, and B′–C. As the regions of sharp transition were approached, the time required for the mercury level to reach a constant value increased rapidly. In the 0.1–0.2° interval between t_1 and t_2 (that is, at a temperature just below the setting point) it required from one to two weeks for equilibrium to be established. During this time it was necessary to control the temperature as closely as possible.

When the highest possible mercury level had been reached, the temperature was lowered by suitable increments, readings taken, and the values plotted in order to provide a check on the previous curve. It was found that on a descending temperature scale, the points A, B′, B or C′ for any given sample could be determined with an accuracy limited only by the rigidity of temperature control, the accuracy of temperature measurement, and the patience of the observer. In those regions where the densities were

linear functions of the temperature, determinations were made in about five-degree intervals. Elsewhere, the intervals were much smaller varying from 1 to 0.1°, depending upon rate of change of density in that particular region. The densities at the melting and transition points are given in Table II. Here n denotes the number of carbon atoms in the compound.

Discussion of Results

When the densities are plotted against the temperatures, a family of curves is obtained such as shown in Fig. 2. It is at once evident that the dilatometer method yields information which both amplifies and substantiates results arrived at by X-ray examinations of some of these hydrocarbons.

The straight, approximately parallel lines sloping to the right at the bottom of the figure represent the change in density with temperature of the various hydrocarbons in the liquid state. For this group of lines the following equation has been determined

$$d_t = 0.7615 + 0.00205n - 0.0006368t$$

where d_t is the density at $t°$, n the number of carbon atoms in the chain and t the temperature. Values of the density near the m. p. calculated by means of this equation agree to within less than 1% of those given in Beilstein. From the fact that the lines are straight and all have the same slope, one must conclude that the molecules in the liquid state under these conditions are parallel to one another, and that there is thus some degree of order or arrangement. This type of order has been given the name, "cybotaxis." It appears then that in the liquid state the behavior of the n hydrocarbon molecule, with respect to temperature, is the same whether it be even or odd numbered, or whether the chain be long or short. From the observations of Mueller,[12] it would appear safe to assume that hexagonal packing occurs in the liquid just above the m. p. as it does in the solid phase, just below the m. p. The difference between the two phases would then be only that in the liquid phase the molecules would be farther apart than in the solid and that the terminal groups would no longer be in one plane. While movement in the liquid could take place by the molecules sliding over one another in a direction parallel to their long axis, it is more likely that movement occurs by a rolling of the molecules over one another at right angles to the long chain axis. It is this type of motion which probably gives these long chain hydrocarbons their characterisic property as lubricants.

This orderly arrangement must, however, show signs of disappearing as the temperature approaches the b. p. A few preliminary measurements made with hexadecane indicated that a noticeable departure from linearity begins to occur at 100°. At a temperature then somewhere near the b. p. molecular agitation will become so great as to disturb the orderly arrangement and one would then expect the expansions per degree for the different hydrocarbons to differ from one another. Their differences should be a function of molecular weight or chain length. Hence, in the orderly liquid state, expansion must be largely at right angles to the long axis rather than in the chain itself or in the gaps between the terminal atoms between the molecules just as was found to be the case in the different solid phases.

Upon cooling the liquid, the setting point is reached. It is apparent that there is a slight increase in density at this point in going from C_{16} to C_{34}. At the s. p., crystallization begins, and there is a large change in density with a relatively small change in temperature as this process takes place. It would appear, at first sight, that no change in temperature should take place during this change in phase but experience shows this not to be the case. Considerable pains were taken to measure the density in this region by successively lowering the temperature through intervals of 0.1° over periods of time, amounting to several days. It is worth while to note that

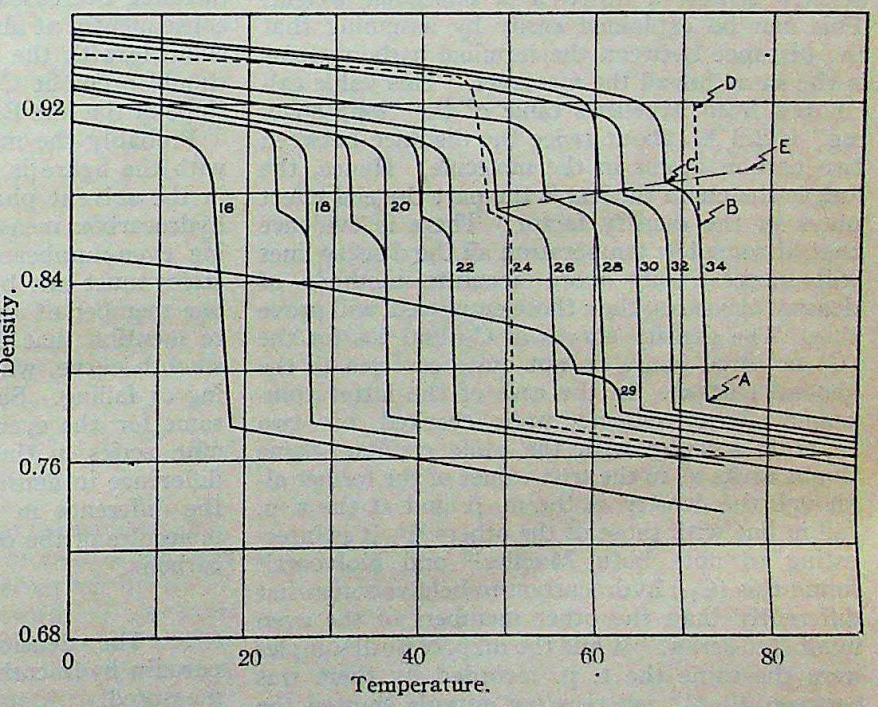

Fig. 2.

the slope of the lines from the s. p. (A) to the point (B) is practically the same for all the even numbered hydrocarbons, except C_{16} which shows no transition point. At the point (B), crystallization can be said to be completed and the rate of change of density with respect to temperature begins to fall off rapidly until the transition point (C) is reached. The solid phase existing in the region BC corresponds to Mueller's A modification with the "long spacing." In this case, X-ray work shows the molecule to be standing at right angles to the basal plane, the 001 plane. Here at the point (C), a new solid phase appears and the difference between this and the previous one, according to the above-mentioned investigator, and Piper, *et al.*,[4] is that the molecule in the crystal cell is now tilted with respect to the basal plane.

The similarity of the shapes of the curves in this solid phase is obvious. This suggests that the manner of crystal packing must be the same for all the even numbered *n*-hydrocarbons, and that expansion or contraction must be largely in a plane at right angles to the long chain axis. Unlike the liquid state, however, the density is now a function of molecular weight. This can be explained easily by assuming that the distance between the terminal carbon atoms is the same for all the members. This value calculated from Mueller's table of the "long spacing" is 2.6 Å., about twice the distance between two carbon atoms in the molecule. Hence, the longer the chain the less is the part the end effect plays in the density factor. There is evidence that at some low temperature all the density lines will merge. Only more accurate methods of density measures, than those employed, will prove this. The density curves of C_{24} and C_{30} for the (C) or tilted phase do not quite conform to the general pattern. In the case of the latter compound, measurements were checked on two separate samples with the same results. Some doubt exists as to the true values of the former although the density at the m. p. and at the t. p. fall in line with those of the others.[13] It is interesting to note both Mueller[12] and Kolvoort[14] found this (C_{24}) hydrocarbon to behave somewhat differently than the other members of the even numbered series. While the m. p. of both samples were the same the t. p. recorded by them was between 40–41° whereas our sample showed the expected value of 47.9. It appears that C_{24} forms a kind of boundary between the set of hydrocarbons to the left and the set to the right.

The difference between the two groups lay in their behavior with ascending or descending temperatures. In the case of the group to the right, comprising the members C_{26}, C_{28}, C_{30}, C_{32} and C_{34}, points on the curves could be retraced either upon heating or cooling. This condition also applied to C_{24}, but not for C_{22}, C_{20} and C_{18}. Points on the curve for C_{16}, which has no t. p., could also be checked, irrespective of whether the temperature was going up or down. Those hydrocarbons to the left of C_{24} showed no t. p. upon heating but only upon cooling. The curves obtained upon cooling were of the same form as all the other members of the series and were reproducible. Upon heating these compounds the C phase did not convert to the B but melted directly, and the curves drawn represent limiting conditions. Indications were noted which implied that if the heating were done slowly enough some of the B modifications might be formed before melting took place. Density points would then lie somewhere within the enclosed region as shown in the figure.

If the line AB is produced to the point D and the distance from this line to the t. p. is measured along the temperature axis, it will be seen that this distance decreases as we pass from C_{26} to C_{34}. This indicates that at some higher member in the series than C_{34} the transition point will again disappear. Measured from the figure this distance decreases 0.03° per carbon atom, and consequently at about C_{45} or C_{46} the t. p. should coincide with the m. p. Mueller states that this should occur at C_{44}. This is also shown by the slope of the line EC.

Probably the most striking fact in connection with the figure is the great difference in density in the solvent phase between C_{29}, the only odd hydrocarbon measured and that of its neighboring even-numbered members. While too much stress must not be laid on the behavior of this one member at this time, nevertheless it is well to mention that the density points all fell on a smooth curve, whether the temperature was rising or falling. Since the type of packing is the same for the even and odd members of the paraffin series in this molecular weight range, the difference in density must be ascribed largely to the difference in the gap distance between the molecules of the odd- and even-numbered hydrocarbons.

Summary

1. The densities of the even-numbered *n*-paraffin hydrocarbons from C_{16} to C_{34} have been measured.

2. The density measurements indicate that the structure in the liquid and solid states is the same for all members of the series.

3. The odd numbered hydrocarbon C_{29} has a solid phase much less dense than the neighboring even-numbered members.

4. The transition points of hydrocarbons C_{24} to C_{34} could be observed with either heating or cooling, while the transition points of C_{18}, C_{20} and C_{22} were observed only on cooling.

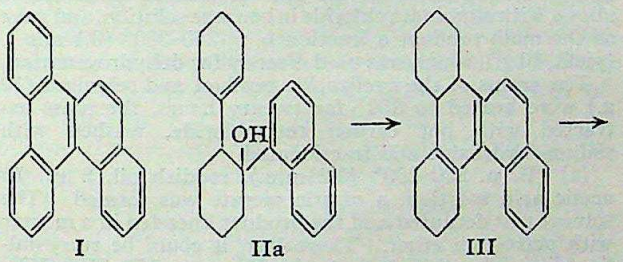
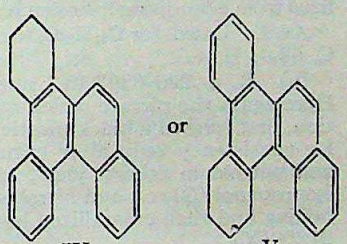
1,2,3,4-Dibenzphenanthrene and its Derivatives. II. Some New Synthetic Attempts[1]

BY FELIX BERGMANN AND H. EMILE ESCHINAZI

Amongst the several possible approaches to the synthesis of 1,2,3,4-dibenzphenanthrene (I) by cyclization, we have investigated more thoroughly the reaction of cyclohexenylcyclohexanone with α-naphthylmagnesium bromide, following the method of Rapson[2] for the synthesis of triphenylene. The carbinol II(a or b) could be cyclized by aluminum or stannic chloride in benzene rather than in carbon disulfide solution, but the reaction product, expected to correspond to III, was not homogeneous. This, however, is not surprising for a structure like III, which should be able to undergo a disproportionation. Dehydrogenation of III with selenium at 320–340° proceeded with extreme difficulty and yielded an oily product, which on the basis of the analytical results was considered to be one of the tetrahydro derivatives IV or V. No further aromatization



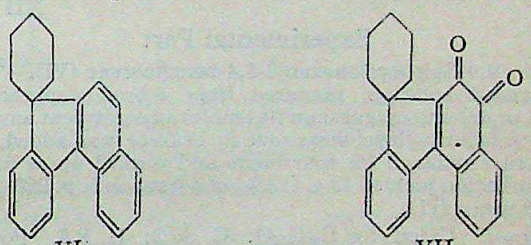
I IIa III



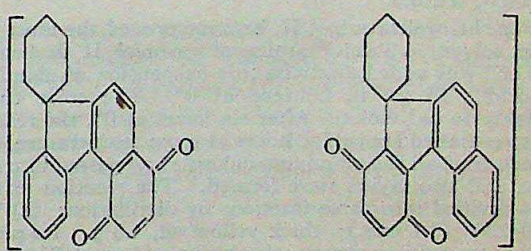
IV V

could be achieved by palladium asbestos at 350°. This resistance to complete aromatization was not understood, until it was observed by R. N. Jones,[3] that the ultraviolet absorption spectrum suggests that the product is a derivative of 3,4-benzfluorene and therefore must be represented by formula VI. The red quinone, which is obtained from it, probably is the *o*-quinone VII, although the two *p*-quinoid structures VIII and IX cannot be excluded. It is hoped that further experiments on model substances will decide this question.

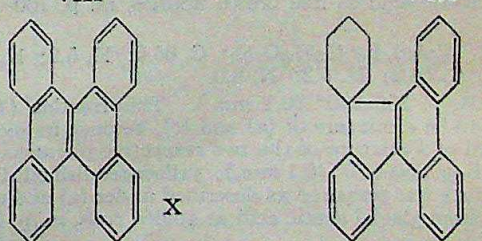
The formation of analogous spirane structures is probable also in the experiments of Rapson.[2] When he started with the oily portion of the cyclization product, he always found appreciable amounts of oily dehydrogenation products besides triphenylene, whereas in the case of crystalline octahydro-triphenylene, "an almost quantitative yield of triphenylene" was obtained with a palladium–charcoal catalyst. But it is strange that no trace of I was detected in our reaction mixture, especially in view of the results from the corresponding reaction of cyclohexenylcyclohexanone with 9-phenanthrylmagnesium bromide. In this case two products could be isolated after aromatization. A small amount of tetrabenznaphthalene (X) was identified as its black picrate. Besides that another picrate was obtained, differing from the former by four to six hydrogen atoms. In analogy with the above results the spirane structure XI is ascribed to it.



VI VII



VIII IX



X XI

It is usually supposed, that spirane formation competes with the cyclization to a six-membered ring in all those cases where dehydration may lead to isomeric olefins.[4] In the present case, a diene is formed during dehydration, which may have either of two structures, and, accordingly, may give rise to two different cyclization products. However, in view of the fact that there was no indication of a second product another mechanism must be considered: the cyclization catalyst as an electrophilic reagent liberates a carbonium ion from the carbinol, and this ion is a resonance hybrid and

XII

Experimental Part

1. **9,9-Spirocyclohexanyl-3,4-benzfluorene (VI).**—To a Grignard solution, prepared from α-bromonaphthalene (0.1 mole) and magnesium (0.1 mole) an equivalent amount of cyclohexenylcyclohexanone in benzene was added, the mixture refluxed for four hours and worked up as usual. Distillation yielded 13 g. (42%) of a fraction b. p. 225–230° (0.8 mm.) (II).

Anal. Calcd. for $C_{22}H_{26}O$: C, 86.2; H, 8.5. Found: C, 85.6; H, 8.2.

For the cyclization of II, benzene proved the most suitable solvent. Twelve grams of carbinol II in benzene (50 cc.) was added dropwise to a suspension of aluminum chloride (15 g.) in benzene at 0°. The color turned quickly to red-violet. After six hours at 0°, the reaction was continued for twelve hours at room temperature, after which time all the aluminum chloride had passed into solution and two layers were formed. The reaction product was divided into three fractions by distillation: (a) b. p. 210–230° (0.1 mm.); thick yellow oil, 4.5 g. Its picrate was prepared in isopropanol solution and crystallized from glacial acetic acid as fine brown needles, m. p. 160–161° (XII?).

Anal. Calcd. for $C_{28}H_{27}O_7N_3$: C, 65.0; H, 5.2; N, 8.1. Found: C, 64.9; H, 5.2; N, 8.0.

(b) B. p. 230–240° (0.1 mm.). This fraction (4 g.) proved to be a mixture of (a) and (c), because its picrate consisted of a mixture of the two respective picrates.

(c) B. p. 250–270° (0.1 mm.); yellow-reddish oil, 1.5 g. The picrate was prepared as described under (a) and crystallized from glacial acetic acid as golden rods, m. p. 169–170°.

Anal. Found: C, 65.3; H, 5.1; N, 8.2.

This substance, according to its analysis, is isomeric with the product, yielding the picrate of m. p. 160–161°. A mixture of both picrates melts at 150–152°.

Dehydrogenation was best attained with fraction (c); the other fractions gave essentially the same end-product, but less pure and in poorer yields.

15 g. of (c) and selenium (25 g.) were heated to 320° for thirty hours. The hot mixture was then stirred carefully into petroleum ether (80°), the solution washed with sodium hydroxide and distilled. The main fraction (9.5 g.) had b. p. 220–240° (0.1 mm.) and consisted of a reddish oil with green fluorescence. This product was purified via its picrate, which was prepared in glacial acetic acid with addition of a little petroleum ether, in order to obtain a homogeneous solution. The picrate crystallizes from glacial acetic acid in red rods, m. p. 141–142°; 7 g of crude hydrocarbon yielded about 8 g. of picrate.

Anal. Calcd. for $C_{28}H_{23}O_7N_3$: C, 65.5; H, 4.45; N, 8.2. Found: C, 65.8; H, 4.2; N, 8.0.

Five grams of this picrate yielded 2.5 g. of spirane VI, b. p. 225–230° (0.05 mm.) as a thick yellow oil with strong green fluorescence. It dissolves readily in petroleum ether or acetone, but sparingly in acetic acid. With concd. sulfuric acid a pink solution is obtained on gentle heating, which turns slowly to green. After long standing, the substance tends to crystallize, but because of its low melting point could not yet be recrystallized satisfactorily.

Anal. Calcd. for $C_{22}H_{20}$: C, 93.0; H, 7.0. Found: C, 93.4; H, 6.9.

Oxidation to the quinone (VII?): 0.25 g. of VI in acetic acid (5 cc.) was boiled with $K_2Cr_2O_7$ (0.5 g.) for five minutes and the quinone precipitated by water. After two crystallizations from high-boiling petroleum ether, it formed beautiful long red plates, m. p. 228° (VIII?). Concd. sulfuric acid dissolves it with cherry-red color.

Anal. Calcd. for $C_{22}H_{18}O_2$: C, 84.1; H, 5.7. Found: C, 84.0; H, 5.8.

Tetrabenznaphthalene (X) and Spirane XI.—The Grignard reaction between 9-bromophenanthrene (26 g.), magnesium (2.5 g.) and cyclohexanylcyclohexanone (18 g.) in benzene, after ten hours of boiling, gave a mixture which after decomposition and distillation yielded 17 g. of a bright yellow sirup, b. p. 270–290° (0.1 mm.). Cyclization of this carbinol (16 g.) was carried out as described above, with aluminum chloride in benzene solution, and gave as the main product a fraction b. p. 320–360° (0.1 mm.), (yield, 10 g.), which was used directly for dehydrogenation.

Ten grams of the cyclization product and selenium (12 g.) were heated to 350° for twenty hours, the mass extracted with hot carbon tetrachloride, washed with sodium hydroxide and fractionated.

(a) B. p. 230–260° (0.2 mm.), reddish oil, 3 g. In acetic acid solution, a plastic picrate was formed. The solvent was decanted and the product kneaded in a mortar with petroleum ether. Thereafter, it could be recrystallized from isopropanol; brown leaflets, m. p. 157–159° (XI).

Anal. Calcd. for $C_{32}H_{25}O_7N_3$: C, 68.2; H, 4.4. Found: C, 68.0; H, 4.0.

(b) B. p. 290–320° (0.1 mm.); dark-red resin, 1.5 g. Here again the picrate which was prepared in acetic solution, first formed a black plastic mass and acquired granular consistency only after trituration with butyl acetate and petroleum ether; yield, 1.8 g. It was dissolved in isopropanol (50 cc.) and nitrobenzene (2 cc.) by prolonged boiling and then crystallized in red-black rods, m. p. 210–212°[5] (X).

This procedure had to be repeated two or three times.

Anal. Calcd. for $C_{32}H_{19}O_7N_3$: C, 68.9; H, 3.4; N, 7.5. Found: C, 68.6; H, 3.2; N, 7.4.

Acknowledgment.—The authors wish to thank Prof. R. N. Jones for his kind coöperation and his help in the discussion of the theoretical problems met with in the present work.

Summary

Cyclization of 1-(α-naphthyl)-2-cyclohexenylcyclohexanol-1 yields a 9,9-spirane derivative of 3,4-benzfluorene instead of the expected 1,2,3,4-dibenzphenanthrene skeleton. The mechanism of this "cyclodehydration" is discussed.

The analogous reaction between cyclohexenylcyclohexanone and 9-phenanthrylmagnesium bromide yielded, besides the corresponding spirane, a small amount of tetrabenznaphthalene.

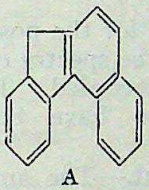
The Spectrographic Characterization of a Hydrocarbon Synthesized by Bergmann and Eschinazi

BY R. NORMAN JONES

Selenium dehydrogenation of the cyclized condensation product of cyclohexenylcyclohexanone with α-naphthylmagnesium bromide yields a product which Bergmann and Eschinazi[1] believed to possess either structure IV or V as shown in their article.

The ultraviolet absorption spectrum provides a method of distinguishing between these two structures, since IV[1] is an alicyclic derivative of



A

3,4-benzphenanthrene and (V)[1] is an alicyclic derivative of chrysene. It is known that alicyclic rings do not alter significantly the spectrum characteristic of the polynuclear aromatic hydrocarbon to which they are attached.[2] The spectrum of (IV)[1] should resemble closely that of 3,4-benzphenanthrene, and the spectrum of (V)[1] should be similar to the spectrum of chrysene.

The spectrum of Bergmann and Eschinazi's hydrocarbon is compared with the spectra of chrysene[3] and 3,4-benzphenanthrene[4] in Fig. 1; but the resemblance to either of these spectra is so slight as to cast considerable doubt on the close relation of the compound to either hydrocarbon.

In Fig. 2 the spectrum of Bergmann and Eschinazi's hydrocarbon is compared with the spectrum of 3,4-benzfluorene[4] (A) which it resembles closely in the region from 2200 to 3600 Å. The low intensity structure between 3800 and 4600 Å., not observed in the spectrum of 3,4-benzfluorene, may be due to a trace of impurity. Assuming an intensity of log E_{molar} = 4.0–4.5 for a hypothetical component responsible for the 4360 Å. maximum, this would indicate a concentration of about 0.1% of impurity. Structure in this region of the spectrum was observed in early determinations of the spectrum of fluorene, but was later shown to be due to impurities.[5] It is also possible that corresponding low intensity structure might be present in the spectrum of 3,4-benzfluorene, but was not recorded by Mayneord and Roe,[4] whose measurements did not extend below log

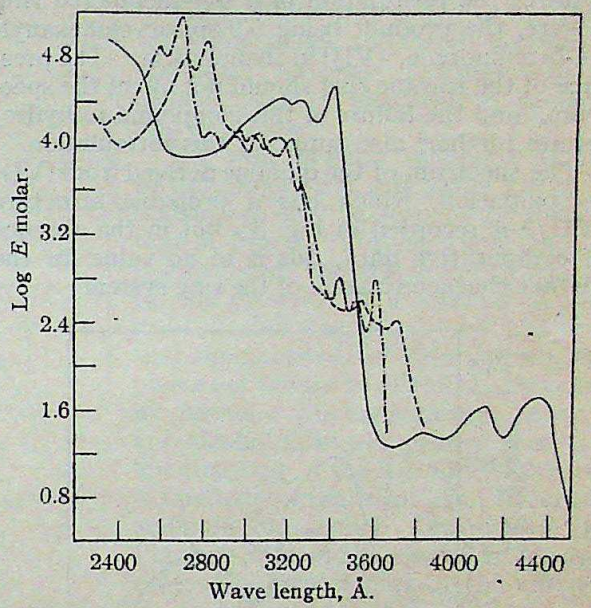

Fig. 1.———, Absorption spectrum of Bergmann and Eschinazi's hydrocarbon; -·-·-·, spectrum of chrysene; – – – – –, spectrum of 3,4-benzphenanthrene.

E_{molar} = 1.6. This explanation would seem more reasonable, as Bergmann and Eschinazi purified their compound through the picrate.

Over the region from 2400 to 3400 Å. the absorption of Bergmann and Eschinazi's hydrocarbon is everywhere more intense than that of 3,4-

benzfluorene. This is unusual, but a similar effect has been recorded by Bachmann and Carmack,[6] who compared the spectra of 3,4-benzpyrene and its 4′,5-dimethylene derivative.

The formulation of Bergmann and Eschinazi's hydrocarbon as a derivative of 3,4-benzfluorene requires the postulation of a five-membered ring closure, the product being 9,9-spirocyclohexanyl-3,4-benzfluorene, (VI)[1] in their article. The presence of the spirane ring should not affect the spectrum,[7] and the failure of this compound to hydrogenate further[1] also supports this formulation.

The spectrum of the quinone derived from (VI)[1] by oxidation, which has a probable structure (VII),[1] is recorded in Fig. 3; but in the absence of comparative data, this is of no value for the further characterization of the ring system.

TABLE I

POSITION AND INTENSITY OF ABSORPTION MAXIMA

Wave length, Å.	Intensity (log E_{molar})
(a) Hydrocarbon (VI)[1] (solvent ethanol)	
3150	4.45
3250	4.43
3395	4.55
3845	1.38
4105	1.61
4360	1.69
(b) Quinone (VII)[1] (solvent ethanol)	
2470	4.28
2680	4.32
3330	3.94
4600	3.49

In Table I data for the position and intensity of the maxima of the spectra of compounds (VI)[1] and (VII)[1] are recorded. The spectrographic methods employed have been reported previously.[8]

Acknowledgment.—The author wishes to express his thanks to Professor L. F. Fieser, of Harvard University, in whose laboratory the spectra were determined, and to acknowledge the financial support of The International Cancer Research Foundation.

Summary

Comparison of the ultraviolet absorption spectrum of a hydrocarbon synthesized recently by Bergmann and Eschinazi, with the spectra of chrysene, 3,4-benzphenanthrene and 3,4-benzfluorene suggests that the new hydrocarbon is 9,9-spirocyclohexanyl-3,4-benzfluorene.

A Spectroscopic Study in the Stereoisomeric Capsanthin Set. *cis*-Peak Effect and Configuration

BY A. POLGÁR AND L. ZECHMEISTER

Recent experiments with some carotenoid hydrocarbons and alcohols have shown that the bending of the molecule by *trans* → *cis* rearrangements which modify the entire extinction curve produces a particularly characteristic change in a certain ultraviolet region of the spectrum.[1] This change which results in a new maximum, the "*cis*-peak," between 320 and 380 mμ has recently been given a theoretical interpretation.[2]

After a chromatographic separation of the main stereoisomers which are present in a mixture formed by iodine catalysis, the height of the *cis*-peak can be determined for each stereoisomer.[1,2,3] This procedure has been used recently to assign tentative configurations to the main observed members of the stereoisomeric sets of α-carotene, β-carotene, lycopene and lutein.[2,3]

In order to provide data for compounds of another type a carotenoid ketone, capsanthin, $C_{40}H_{58}O_3$, which is the main pigment of the red pepper (*Capsicum annuum*) has been investigated. Capsanthin was one of the first C_{40}-carotenoids in which stereochemical effects in the form of spontaneous isomerization were observed by Cholnoky and one of the authors.[4] This was

followed by a more detailed study of the thermal and iodine catalyzed *cis–trans* isomerization of capsanthin, capsorubin, and some of their esters.[5]

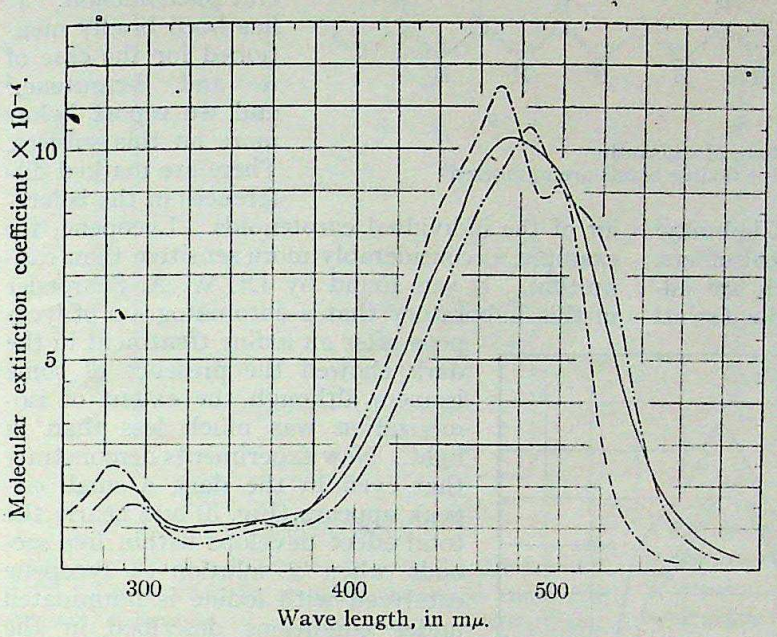

Fig. 1.—Molecular extinction curves of all-*trans*-capsanthin: —— in ethanol; –·– in benzene; and – – ·– – in hexane.

Recent experiments show that capsanthin also undergoes a partial stereoisomerization upon melting its crystals or short exposure of solutions to sunshine.

We shall consider first the general shape of the capsanthin extinction curves, before and after stereoisomerization, and shall then discuss the possibilities for assigning spatial structures to some members of this set.

The extinction curve of natural (all-*trans*)-capsanthin in benzene was determined by Kuhn[6] in the visible region, and by Karrer and Würgler[7] also in the ultraviolet region; however, the latter paper is not available to us.

As one of our goals, we wished to obtain some data concerning the influence of polar solvents upon the shape of the extinction curve, especially upon the fine structure of the fundamental band in the visible region. It has been reported by Cholnoky and one of us[8] that the color of a solution of one milligram of capsanthin in two hundred milliliters of petroleum ether is straw-yellow, but that in alcohol is wine-red. Furthermore, the spectrum in alcohol is so blurred that it was impossible to locate bands with a visual spectroscope. Kuhn and Brockmann[9] noted earlier the same behavior in the polyene diketone, rhodoxanthin, $C_{40}H_{52}O_2$. They correctly attributed this phenomenon to the interaction between polar carbonyls and polar alcohol molecules. According to Kuhn and Brockmann, the effect is displayed only if the carbonyl group stands in conjugation with the carbon–carbon conjugated system. When this conjugation was interrupted by the addition of two hydrogen atoms to rhodoxanthin, the visual maxima in non-polar solvents (hexane) and in alcohol became identical in position and sharpness.

The very definite influence of the solvent upon the extinction curve of capsanthin may be seen by an inspection of Fig. 1. The complete lack of fine structure, which is probably caused by the presence of a number of pigment-alcohol complexes and the mutual superposition of their curves, explains our failure to read visual spectra in alcohol. An examination in hexane–alcohol mixtures proved that the fine structure of the fundamental band is markedly diminished even by small amounts of alcohol. As shown by Fig. 2 as little as 2% alcohol in hexane causes the greater part of the change from the 0% alcohol curve to the 100% alcohol curve.[9a]

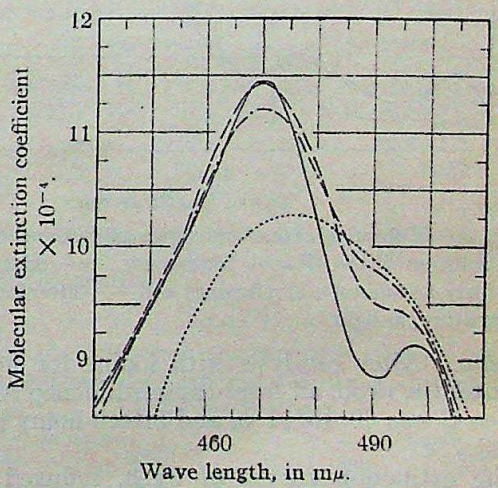

Fig. 2.—Molecular extinction curves of all-*trans*-capsanthin in the visible region: —— in hexane; – – – in hexane, containing 2% ethanol; – – ·– – in hexane, containing 5% ethanol; and ..... in ethanol.

The stereochemical situation in the capsanthin set may be summarized as follows. The number of possible stereoisomers is thirty-two, and the number of the double bonds, which can undergo *trans* → *cis* isomerization, is five[10] (see the formula).

The chromophore of capsanthin
(The stereochemically effective double bonds are numbered)

It was shown in collaboration with Cholnoky[5] that capsanthin forms three main stereoisomers, the neo compounds A, B and C which are adsorbed above the all-*trans* pigment on the Tswett column. After catalysis with iodine for fifteen minutes the ratio, all-*trans*-capsanthin:neo A:neo B:neo C was 69:15:11:5, and fifteen hours later, 66:23:7:4.

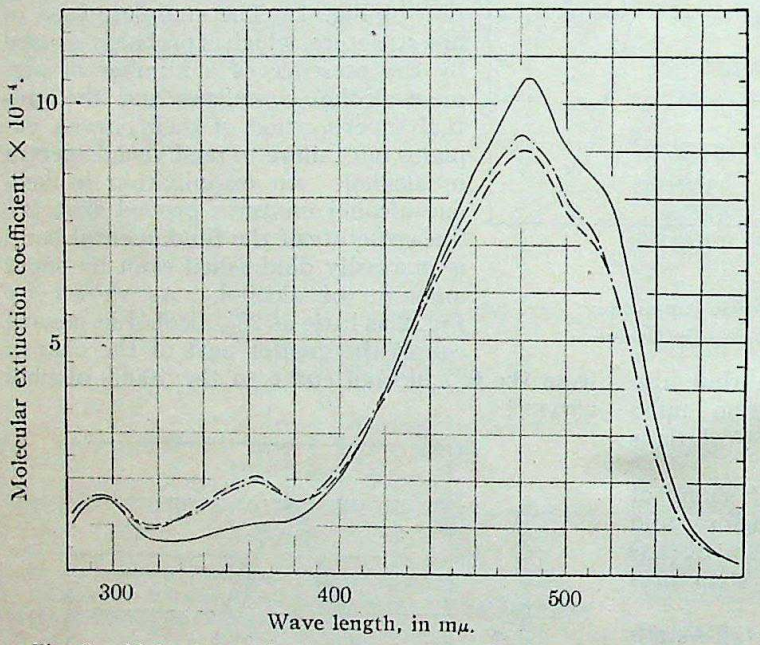

Fig. 3.—Molecular extinction curves of capsanthin in benzene: —— fresh solution of the all-*trans* compound; – – – mixture of stereoisomers after forty-five minutes of refluxing; and – · – · after iodine catalysis at room temperature, in light.

The extinction curves of fresh, refluxed and iodine catalyzed solutions of capsanthin show that the presence of a carbonyl group does not essentially alter the influence of stereoisomerization on the spectral properties. The extinction is diminished in the visible spectrum while in the ultraviolet region a considerable *cis*-peak appears, for example, in benzene at 363 mμ (Fig. 3).

Iodine does not cause the formation of a *cis*-peak in capsanthin solutions in the dark. Figure 4 shows, however, that an illumination as short as five seconds develops about a third of the ultimate effect. The photochemically excited iodine atoms are mainly responsible for this catalysis. As far as we know, the influence of light on the iodine catalysis of carotenoids is a general phenomenon. It has been briefly mentioned for the case of α- and β-carotene,[3] and we report below more on this subject. There are marked differences in the behavior of the individual carotenoids. Lycopene, for example, is considerably more sensitive than capsanthin. It was found by Dr. W. A. Schroeder in this Laboratory that a chromatogram of lycopene after an iodine treatment in the dark showed the presence of some isomers although the extent of isomerization was much less than in light. New experiments demonstrate that even in the dark a small *cis*-peak appears (Fig. 5) and nearly the total effect develops within five seconds when a solution of lycopene catalyzed with iodine is illuminated under conditions described in the Experimental Part.

The configurations of some neocapsanthins can be deduced tentatively from spectroscopic data. The longest wave length maximum of neocapsanthin A or B is shifted 6 mμ relative to that of the all-*trans* compound, and that of neo C is shifted 10.5 mμ. Our interpretation[2,3] demands that the molecules of neocapsanthin A and B contain one *cis* double bond but that the number of such bonds be two in neocapsanthin C.

Although the neocapsanthins A and B cannot be differentiated in the visual spectroscope, this is easily possible by a quantitative investigation of the *cis*-peak region. As shown in Fig. 6, the peak of neo A, which is comparable with the highest *cis*-peaks observed in the α- or β-carotene

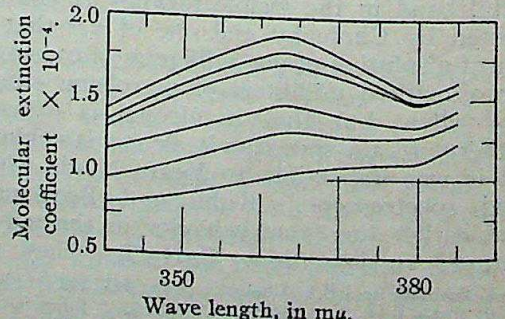

Fig. 4.—Influence of illumination on the development of the *cis*-peak effect in an iodine catalyzed solution of capsanthin, in benzene; curves from bottom to top: after 0 sec., 5 sec., 30 sec., 2½ min., 15 min., and 30 min. illumination.

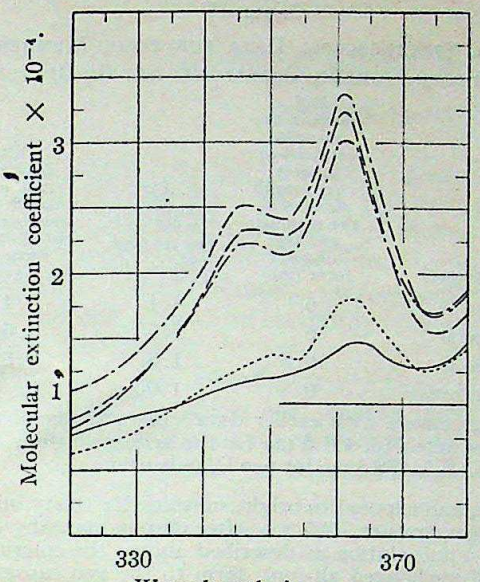

Fig. 5.—Influence of illumination on the development of the *cis*-peak effect in an iodine-catalyzed solution of lycopene, in hexane: ..... after 0 sec., – – – after 5 sec.; – – · – – after 30 sec., and – · – · after 15 min. illumination. The full line denotes the curve taken before the addition of iodine, and without illumination.

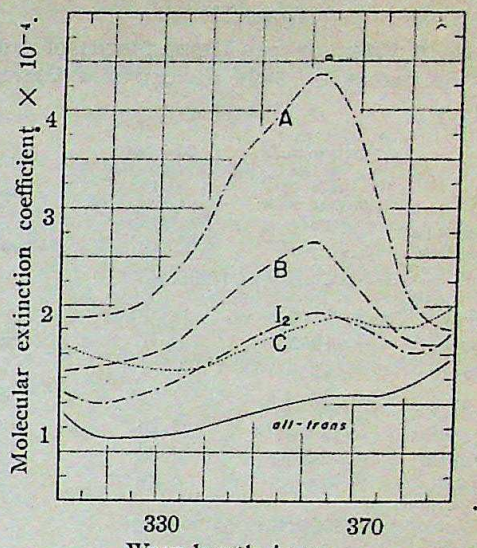

Fig. 6.—Molecular extinction curves of some members of the stereoisomeric capsanthin set in the *cis*-peak region, in benzene; I_2 indicates the equilibrium mixture obtained upon iodine catalysis.

set, is much higher than the peak of neocapsanthin B. Consequently, and in accordance with recent investigations in other stereoisomeric sets, the most probable configuration of neocapsanthin A is that of *6*-mono-*cis*-capsanthin, and of neo B that of *5*-mono-*cis*- or *7*-mono-*cis*-capsanthin.[11] The position of the two *cis* double bonds in neo C cannot be stated definitely. The models do not exclude the possibility that one of these *cis* bonds is located at or near the center of the chromophoric system.

Acknowledgment.—We wish to thank Dr. L. Cholnoky for the preparation of the capsanthin samples.

Experimental Part

Materials and Methods.—The following solvents were used in the optical experiments: benzene (thiophene-free, reagent, Baker and Adamson), purified by shaking with sodium thiosulfate and then distilling; absolute ethanol, distilled over sodium; and hexane (practical, from petroleum, Eastman Kodak Co.), purified by shaking first with fuming sulfuric acid, then with alkaline permanganate, and finally redistilled.

The extinction readings were taken with a Beckman photoelectric spectrophotometer.[12] The extinction curves of all-*trans* pigments drawn in Figs. 1, 2 and 3 are based on average values (Tables I–II) of several independent experiments. The greatest deviation at the visual maxima is ±2.4% in benzene, and ±1.1% in ethanol. Because capsanthin is sparingly soluble in cold hexane, the solution was prepared by shaking crystals with this solvent and then filtering. The concentration was established by the use of extinction values obtained by dissolving capsanthin in absolute alcohol and diluting with 98 volumes of hexane; the maximum in Fig. 2 represented by a full line is, therefore, only approximately correct.

Influence of Illumination on the Development of the *cis*-Peak Effect in Solutions Catalyzed with Iodine.—Fresh solutions were prepared and catalyzed in the dark. After the extinctions had been determined, the solutions which were in 25-ml. volumetric flasks (glass), were placed in horizontal position on white paper and irradiated by means of two fluorescent lamps (3500° white, Mazda, 40 W; length of tube, 120 cm.) from a distance of 60 cm. The gradual development of the peaks of α-carotene, β-carotene, lycopene, and capsanthin is characterized by the data in Table III.

60 min.	8.9	1.90	100

Estimation of *cis*-Peaks of the Neocapsanthins.—The mixture obtained from capsanthin by iodine catalysis in benzene was chromatographed on calcium carbonate (Merck precipitated Heavy Powder) and developed with benzene which contained 1 to 2% acetone. Each neo zone was eluted with ice-cold alcohol, transferred into benzene, washed thoroughly with ice water, dried with sodium sulfate, and investigated spectrophotometrically. The concentrations were established by catalyzing an aliquot part of each solution with iodine, determining the extinction at the wave length of the highest maximum, and calculating the concentration from the corresponding value of the iodine equilibrium curve.[1,2,3] Table IV contains the averages of two independent experiments.

***cis–trans* Isomerization of Capsanthin by Insolation.**—A solution of 2.5 mg. of all-*trans* pigment in 25 ml. of benzene was placed in a transparent quartz test-tube (diameter, 22 mm.) from which the air was displaced with carbon dioxide, and exposed to bright sunshine for thirty minutes (final temperature, 33.5°). After chromatography (23 × 4.8 cm.) and elution as described above, the colorimetric ratio of unchanged all-*trans* form to the neo capsanthins was 65:35. No appreciable quantity of irreversibly formed pigments appeared on the column.

TABLE IV

TYPICAL SPECTROSCOPIC DATA FOR SOME MEMBERS OF THE STEREOISOMERIC CAPSANTHIN SET (in BENZENE)

Member	Diff. between the visually established longest wave length maxima of the member and the all-*trans* form (mμ)	Mol. extinction coeff. at the *cis*-peak $E^{mol.}_{1 cm.} \times 10^{-4}$	Diff. between mol. ext. coeff. of member and of all-*trans* form at *cis*-peak
Neo A	6	4.4	3.4
Neo B	6	2.65	1.60
Neo C	10.5	1.87	0.82
All-*trans*	0	1.05	0

In agreement with earlier data,[5] the visually observed maxima were 513, 481.5 mμ for the neocapsanthins A and B, and 508.5, 478.5 mμ for neo C, in benzene.

***cis–trans* Isomerization of Capsanthin by Melting.**—Five milligrams of pigment, in a sealed tube, filled with carbon dioxide, was melted in a bath of 180° (5° above the melting point) for one minute. The color intensity decreased by about one-third. After cooling in ice-water, the benzene solution of the melt was chromatographed on calcium carbonate as described. The colorimetric ratio of unchanged all-*trans* pigment to the neocapsanthins was 29:71. The neo fraction contained some uninvestigated new isomers; furthermore, a cherry-red zone (3% of the total recovered pigment) appeared below that of all-*trans*-capsanthin. The chromatographic filtrate was slightly colored.

Summary

The interaction of the carbonyl group of capsanthin, $C_{40}H_{58}O_3$, with a polar solvent such as ethanol can be demonstrated by extinction curves. In contrast to the behavior in hexane, no fine structure of the fundamental band is observed in alcoholic solution. As little as 2% alcohol in hexane causes the greater part of the change from the 0% alcohol curve to the 100% alcohol curve. The modification of the extinction curve upon stereoisomerization is similar to that observed with carotenoid hydrocarbons and alcohols. Upon iodine catalysis a marked *cis*-peak develops at 363 mμ (in benzene) for which process light is needed. It is probable on the basis of spectroscopic data that neocapsanthin A contains one *cis* bond which is located at the center of the chromophore. This isomer should be assigned the configuration of 6-mono-*cis*-capsanthin. Neocapsanthin B is probably either 5-mono-*cis*- or 7-mono-*cis*-capsanthin. Neocapsanthin C is a di-*cis*-compound.

Amidino Arsenicals. II. Some Trivalent Arsenicals

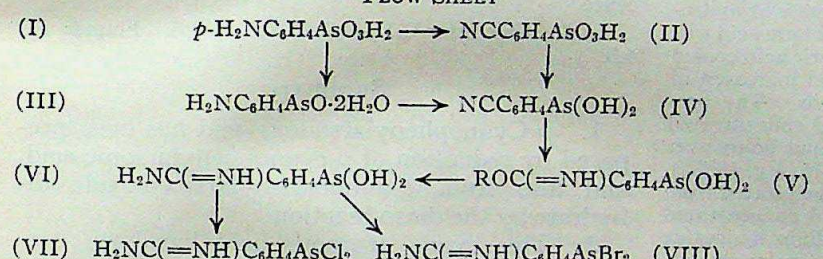
BY FRED LINSKER[1] AND MARSTON TAYLOR BOGERT

In a previous paper,[2] we have described the preparation and some of the properties of *p*-amidinophenylarsonic acid, 4,4′-diamidinoarsenobenzene, and a few intermediate or incidental compounds. The present communication records further progress in the study of the trivalent amidino arsenicals.

Mapharsen and Phenarsine are good examples of the generally recognized greater therapeutic efficiency of the trivalent as compared with the pentavalent arsenicals, the reasons for which need not be discussed here.

The Flow Sheet exhibits the various steps involved in this study.

FLOW SHEET



Acknowledgments.—This investigation, like its predecessor, was made possible by the generous action of Merck & Co., Inc., of Rahway, N. J., in establishing at Columbia University a research fellowship for the purpose of finding better medicaments for the treatment of various tropical diseases. The necessary microanalyses were carried out by Miss Frances E. Marx and Miss Lois E. May, of the Columbia University Department of Chemistry.

Experimental

p-Cyanophenylarsonous Acid (IV) (a) By Reduction of *p*-Cyanophenylarsonic Acid (II).—To a solution of 14 g. of *p*-cyanophenylarsonic acid[2] in 220 cc. of water and 32 cc. of 2 *N* sodium hydroxide, there was added 3.2 g. of potassium iodide. The clear solution was acidified with 84 cc. of dilute (16% by volume) sulfuric acid, cooled to below 10°, and sulfur dioxide passed through the solution for three hours at the rate of 3 bubbles per second, while the temperature was not permitted to rise above 10°. A yellow precipitate soon began to separate, and gradually increased in amount. When the reduction was complete, the flask was removed, stoppered tightly and left in the refrigerator overnight. The yellow-brown crystalline precipitate was filtered out, and consisted of 11 g. (85% yield) of quite pure *p*-cyanophenylarsonous acid. It was further purified by solution in *N* sodium hydroxide and reprecipitation with 5 *N* ammonium chloride solution, washing the precipitate with water until it gave no test for chlorine ion, and then drying in a desiccator over calcium chloride. It formed pale yellow-brown small prisms, which softened at 230° and melted with decomposition at 234° (cor.).

Anal. Calcd. for $C_7H_6O_2AsN$: As, 35.5; N, 6.6. Found: As, 35.3; N, 6.6.

This process is preferable to the succeeding one in that it gives a purer product.

(b) From *p*-Aminophenylarsine Oxide Dihydrate (III).—The arsine oxide dihydrate was prepared from *p*-arsanilic acid by reduction with sulfur dioxide, as described by Ehrlich and Bertheim[3]; yield, 71%; melts with decomposition at 98° (literature, yield, about 71%; m. p. with decomposition, 100°).

A solution of 11 g. of the arsine oxide dihydrate (III) in 120 cc. of water and 13 cc. of hydrochloric acid (sp. gr. 1.12) was cooled to 5° and diazotized with 17 cc. of a 3 *N* sodium nitrite solution. During the diazotization a pale yellow precipitate formed but was not removed. The diazotized mixture was poured slowly into a cuprous cyanide solution prepared from 12.5 g. of copper sulfate pentahydrate, 14 g. of potassium cyanide, and 75 cc. of water. The mixture was warmed until the evolution of nitrogen ceased. After cooling for three hours in the refrigerator, the brown solid which had precipitated was removed, washed with dilute hydrochloric acid and dried; yield, 13 g. Since this crude product was contaminated by considerable copper, it was dissolved in 170 cc. of *N* sodium hydroxide solution, filtered, and the product reprecipitated from the red filtrate by the addition of 45 cc. of 5 *N* ammonium chloride solution; yield, 9 g. (80%) of pale yellow-brown copper-free *p*-cyanophenylarsonous acid (IV); m. p. 230–240° with decomposition; soluble in caustic or carbonated alkali solutions, or in hot alcohol; insoluble in water, cold alcohol, ether, acetone, or ammonium hydroxide solution. It evolved ammonia when heated with caustic alkalies. The product was identical in all respects with that obtained by the reduction of *p*-cyanophenylarsonic acid.

p-Arsonosobenziminoether Hydrochloride (V).—The base of this compound appears in a list of amide-substituted phenylarsine oxides and their derivatives recently published by Eagle, Hogan, Doak and Steinman [as a note in THIS JOURNAL, 65, 1236 (1943)] where its analysis is given, as well as its toxicity and treponemicidal activity, and where it is stated that "Experimental details for the preparation of this compound will be published in a separate paper."

As these details have not yet appeared, so far as we are aware, the details of our own experiments were as follows.

To a suspension of 7 g. of dry finely pulverized *p*-cyanophenylarsonous acid (IV) in 40 cc. of dry ether, there was added 3 cc. of absolute alcohol, the mixture was cooled to 0° and dry hydrogen chloride passed through it for thirty minutes. The cyano acid dissolved and the solution assumed a dark red color. The flask was stoppered tightly and placed in the refrigerator. After several hours, crystallization of the imino ether hydrochloride began, and was complete in five days. The grayish crystals were removed, washed with dry ether and excess of hydrogen chloride eliminated in a vacuum desiccator over solid potassium hydroxide. Dissolved in a little cold absolute alcohol and precipitated by dry ether, the hydrochloride separated in colorless prisms; yield, 9.3 g. (95%). This hydrochloride softened at 150° and melted at 152°, with decomposition and foaming, to a dark liquid. It was easily soluble in water or alcohol, insoluble in ether or acetone. Its aqueous solution precipitated silver chloride from a silver nitrate solution, and liberated ammonia when heated with caustic alkali.

Anal. Calcd. for $C_9H_{13}O_3AsClN$: N, 4.7. Found: N, 4.7.

p-Amidinophenylarsonous Acid Hydrochloride (VI).—Six grams of finely pulverized iminoether hydrochloride (V) was suspended in 60 cc. of a 10% solution of dry ammonia in absolute alcohol. The suspension was warmed in a closed vessel for four hours at 60°, with frequent shaking. The mixture was filtered, and to the filtrate there was added five times its volume of absolute ether. This threw down the amidine hydrochloride as a white voluminous precipitate, which was filtered out rapidly, to avoid prolonged contact with moist air, and placed immediately in a vacuum desiccator over calcium chloride; yield, 4 g., or 80%. It crystallized in colorless needles when its absolute alcohol solution was concentrated. When heated to 210°, it decomposed with foaming. It was very hygroscopic, soluble in water or alcohol, insoluble in ether or acetone. The sample used for analysis was dried at 60° and 20 mm.

Anal. Calcd. for $C_7H_{10}O_2AsClN_2$: As, 28.3; N, 10.6. Found: As, 28.1; N, 10.7.

Due to its great solubility in water, this acid could not be prepared satisfactorily by the reduction of *p*-amidinophenylarsonic acid with sulfur dioxide.

p-Amidinophenyldichloroarsine Hydrochloride (VII).—A solution of 4 g. of *p*-amidinophenylarsonous acid hydrochloride (VI) in 12 cc. of ice-cold 2 *N* hydrochloric acid was filtered into 30 cc. of concentrated hydrochloric acid cooled to 0°. A crystalline precipitate formed and increased in amount on standing overnight in the icebox. The precipitate was collected, washed with ice-cold concentrated hydrochloric acid, and then left for twenty-four hours over solid sodium hydroxide in a desiccator; yield, 4 g. (89%). For further purification, the product was precipitated from its concentrated aqueous solution with cold concentrated hydrochloric acid, and dried over solid sodium hydroxide at 80° and 20 mm. It was easily soluble in water or alcohol, crystallizing from the latter in small colorless prisms. When heated, it sintered at 202°, and melted at 208° with decomposition.

Anal. Calcd. for $C_7H_8AsCl_3N_2$: N, 9.3. Found: N, 9.2.

p-Amidinophenyldibromoarsine Hydrobromide (VIII).—Two g. of *p*-amidinophenylarsonous acid hydrochloride (VI) was dissolved in 4 cc. of dilute cold hydrobromic acid (2 cc. of concentrated hydrobromic acid to 30 cc. of water). The filtered solution was added to 8 cc. of ice-cold concentrated hydrobromic acid. After the mixture had been standing for several hours at 0°, the pale yellow precipitate was collected and purified by a series of precipitations of its aqueous solution by concentrated hydrobromic acid. The pure salt formed starry clusters of elongated prisms, melting with decomposition at 219°; soluble in water, alcohol, or dilute mineral acids; yield, nearly that calculated. The sample for analysis was dried over solid sodium hydroxide at 80° and 20 mm., in an Abderhalden pistol.

Anal. Calcd. for $C_7H_8AsBr_3N_2$: N, 6.4. Found: N, 6.4.

The compound was soluble in water, alcohol, or dilute mineral acids, and was hygroscopic.

p-Arsonobenziminoether Hydrochloride, $R\acute{O}C(=NH)\text{-}C_6H_4AsO_3H_2$.—In our previous article,[2] the formation of this compound from *p*-cyanophenylarsonic acid was described, but the crude product was converted immediately into the corresponding amidino compound.

We have since purified this crude product by drying it *in vacuo* over solid caustic soda, and crystallizing it by concentration of its alcoholic solution. It formed colorless prisms which decomposed at 130° with strong effervescence.

Anal. Calcd. for $C_9H_{13}O_4AsClN$: N, 4.5. Found: N, 4.3.

Summary

1. *p*-Cyanophenylarsonous acid has been prepared by reduction of *p*-cyanophenylarsonic acid, and also from *p*-aminophenylarsine oxide dihydrate by the diazo reaction.

2. This cyano arsonous acid has been converted, through its imino ether, into the *p*-amidinophenylarsonous acid and, from the latter, the *p*-amidinophenyldihalo arsines have been prepared.

3. Certain of these new products are now being tested pharmacologically.

p-Arsenosobenzoylurea and Related Compounds[1]

BY H. G. STEINMAN, G. O. DOAK AND HARRY EAGLE

In previous papers of this series[2] we have described various amide-substituted aromatic arsenoso compounds.[3] Because of the interesting effect of the amide group in modifying the pharmacologic properties of arsenoso compounds we have extended the study to include compounds in which two or more amide groups were connected on a single side chain.

Two methods were used for the preparation of these compounds: namely, (1) the customary Bart reaction or the Scheller modification[4] with the corresponding amines and (2) the coupling of the appropriate dichloroarsinoacyl chlorides with the desired aliphatic amino acids or directly with the amino acid amides when available. All nitro compounds were reduced catalytically to the corresponding amines by the method of Stevinson and Hamilton.[5]

Experimental Part

p-Arsenosobenzoylurea.—*p*-Aminobenzoylurea[6] yielded *p*-arsonobenzoylurea with the customary Bart reaction. *p*-Arsenosobenzoylurea was obtained on reduction with

sulfur dioxide in the usual manner. Attempts to prepare the arsenoso compound directly by treating *p*-dichloroarsinobenzoyl chloride with either (a) urea in pyridine, (b) sodium urea in benzene, or (c) silver cyanate in benzene followed by ammonia, proved unsuccessful.

The action of sodium urethan upon *p*-dichloroarsinobenzoyl chloride in benzene or in pyridine gave products of indefinite composition. In ether a white solid which analyzed for the ethyl ester of bis-(*p*-arsenosobenzoyl)-carbamic acid was obtained.

Anal. Calcd. for $C_{17}H_{13}As_2NO_6$: As, 31.4; N, 2.94. Found: As, 31.2; N, 2.85.

p-Nitrobenzoyl Isocyanate.—This substance was prepared in 63% yield by refluxing *p*-nitrobenzoyl chloride with silver cyanate in benzene for seventy-two hours.[7] It was recrystallized from ethyl acetate under anhydrous conditions in rectangular prisms, m. p. 209–210°.

Anal. Calcd. for $C_8H_4N_2O_4$: N, 14.6. Found: N, 14.7.

1-(*p*-Arsenosobenzoyl)-3-(2-hydroxyethyl)-urea.—*p*-Nitrobenzoyl isocyanate condensed with 2-aminoethanol in benzene to give 1-(*p*-nitrobenzoyl)-3-(2-hydroxyethyl)-urea in 30% yield. On recrystallization from water needles melting at 186–187° were obtained.

Anal. Calcd. for $C_{10}H_{11}N_3O_5$: N, 16.6. Found: N, 16.3.

Catalytic reduction gave 1-(*p*-aminobenzoyl)-3-(2-hydroxyethyl)-urea in 70% yield. It crystallized from water in long colorless needles, m. p. 230.5–231.5°.[8]

Anal. Calcd. for $C_{10}H_{13}N_3O_3$: N, 18.8. Found: N, 18.7.

The amine derivative underwent the Bart reaction to give 1-(*p*-arsonobenzoyl)-3-(2-hydroxyethyl)-urea, from which the arsenoso compound was obtained on reduction with sulfur dioxide. An attempt to prepare this compound by heating *p*-arsonobenzoyl chloride[9] with silver cyanate and then treating the reaction mixture with 2-aminoethanol was unsuccessful.

Attempted Preparation of 1-(*p*-Arsenosobenzoyl)-3-(2,3-dihydroxypropyl)-urea.—3-Amino-1,2-propanediol was condensed with *p*-nitrobenzoyl isocyanate to give 1-(*p*-nitrobenzoyl)-3-(2,3-dihydroxypropyl)-urea. It was recrystallized first from alcohol and finally from water, m. p. 197–199°; yield 22%.

Anal. Calcd. for $C_{11}H_{13}N_3O_6$: N, 14.8. Found: N, 15.1.

In contrast to the behavior of the lower homolog, the nitro compound gave only *p*-aminobenzamide when reduced with Raney nickel and hydrogen.

1-(*p*-Arsenosobenzoyl)-biuret.—On refluxing *p*-nitrobenzoyl isocyanate with urea in benzene for twenty-four hours 1-(*p*-nitrobenzoyl)-biuret was obtained as a powder melting at 203–205°; yield 50%.

Anal. Calcd. for $C_9H_8N_4O_5$: N, 22.2. Found: N, 21.8.

Reduction in alcoholic suspension with Raney nickel gave 1-(*p*-aminobenzoyl)-biuret in 90% yield. It crystallized from alcohol in fine needles sintering about 270°.

Anal. Calcd. for $C_9H_{10}N_4O_3$: N, 25.2. Found: N, 24.4.

The Bart reaction with this amine yielded the desired 1-(*p*-arsonobenzoyl)-biuret which was readily reduced to the arsenoso derivative.

p-Arsenoso-α-toluylurea.—Urea was refluxed in benzene for eighteen hours with *p*-dichloroarsino-α-toluyl chloride. The resulting product upon hydrolysis yielded *p*-arsenoso-α-toluylurea. The Bart reaction with *p*-amino-α-toluylurea[6] did not yield any arsonic acid. An attempt to prepare the arsenoxide directly by coupling sodium urea with the methyl ester of *p*-arsenoso-α-toluic acid also failed.

N^{α}-(*p*-Arsenosophenyl)-glycylurea.—This compound was obtained from N^{α}-(*p*-arsonophenyl)-glycylurea[10] by reduction with sulfur dioxide.

α-(*p*-Arsonobenzamido)-acetamide.—*p*-Nitrobenzoyl chloride combined readily with glycinamide hydrochloride[11] in sodium bicarbonate solution to give α-(*p*-nitrobenzamido)-acetamide. It crystallized from alcohol in needles, m. p. 239–240° with decomposition.

Anal. Calcd. for $C_9H_9N_3O_4$: N, 18.8. Found: N, 18.5.

Reduction in alcoholic suspension with Raney nickel gave α-(*p*-aminobenzamido)-acetamide in 75% yield. It crystallized from alcohol in rectangular prisms, m. p. 228° with decomposition.

Anal. Calcd. for $C_9H_{11}N_3O_2$: N, 21.8. Found: N, 21.8.

The compound was best isolated as the sulfate by adding alcoholic sulfuric acid to the original alcohol solution of the amine. It separated in platelets charring above 250°.

Anal. Calcd. for $C_{18}H_{22}N_6O_4 \cdot H_2SO_4$: N, 17.4. Found: N, 17.5.

This salt yielded the desired arsonic acid with the Bart reaction.

α-(*p*-Arsenosobenzamido)-acetamide.—Although this arsenoxide could be produced by the reduction of α-(*p*-arsonobenzamido)-acetamide or by the direct ammonolysis of the methyl ester of *p*-arsenosohippuric acid,[12] it was more conveniently obtained by the direct condensation of *p*-dichloroarsinobenzoyl chloride (0.1 mole) with glycinamide hydrochloride (0.15 mole) in 10% sodium carbonate solution (500 cc.).

α-[α-(*p*-Arsenosobenzamido)-acetamido]-acetamide.—N-Glycylglycine coupled readily with *p*-dichloroarsinobenzoyl chloride in 1 *N* potassium hydroxide solution to give N-(*p*-arsenosohippuryl)-glycine. The methyl ester could not be prepared by esterification with methyl alcohol in the presence of anhydrous hydrogen chloride. It was prepared successfully, however, through the silver salt.

Anal. Calcd. for $C_{11}H_{10}AgAsN_2O_5 \cdot H_2O$: As, 16.6; N, 6.21. Found: As, 16.7; N, 6.17.

The desired amide was obtained on treating this ester with aqueous ammonia at −25° for several days and then allowing the ammoniacal solution to evaporate slowly.

β-(*p*-Arsenosobenzamido)-propionamide.—β-Alaninamide was prepared by the Raney nickel reduction of α-cyanoacetamide in absolute alcohol. The hydrochloride was isolated by acidifying the reaction mixture to *p*H 7.7 with alcoholic hydrogen chloride and cooling overnight at −25°. On recrystallization from methanol it was obtained in 70% yield, m. p. 149°.[13] When condensed with *p*-dichloroarsinobenzoyl chloride in the usual manner (sodium carbonate solution) the desired β-(*p*-arsenosobenzamido)-propionamide was formed.

α-Amino-N^{α}-(*p*-arsenoso-α-toluyl)-acetamide.—*p*-Dichloroarsino-α-toluyl chloride was added to glycinamide hydrochloride in sodium carbonate solution and the reaction mixture concentrated at 40° on the water pump to one-third the original volume. On standing overnight at 5° the desired amide precipitated out.

α-(*p*-Arsenosophenylsulfonamido)-acetamide.—Similarly, *p*-arsenosobenzenesulfonyl chloride prepared by the partial hydrolysis of *p*-dichloroarsinobenzenesulfonyl chloride yielded α-(*p*-arsenosophenylsulfonamido)-acetamide on coupling with glycinamide hydrochloride as above.

(7) *Cf.* Billeter, *Ber.*, **36**, 3218 (1903).

(8) Charlton and Day [*J. Org. Chem.*, **1**, 552 (1937)] prepared the isomeric β-*p*-nitrobenzoxyethylurea which melted at 183–183.4° (cor.). That this compound is different from the urea derivative reported here is shown by the fact that the amino derivative which Charlton and Day obtained melted at 203° (cor.).

(9) *p*-Dichloroarsinobenzoyl chloride in carbon tetrachloride was oxidized with chlorine to *p*-tetrachloroarsinobenzoyl chloride. This was converted to *p*-arsonobenzoyl chloride on partial hydrolysis with cold water. *Anal.* Calcd. for $C_7H_4AsClO_4$: As, 28.3; Cl, 13.4. Found: As, 28.4; Cl, 13.6.

Attempted Preparation of Sulfur Ureas.—In contrast to the behavior of urea, sulfamide[14] did not condense with *p*-nitrobenzoyl chloride when refluxed in benzene for forty-eight hours or in ethyl acetate for twenty-four hours. Potassium sulfamide[15] also failed to condense with either *p*-nitrobenzoyl chloride or *p*-nitrobenzenesulfonyl chloride when refluxed in benzene for forty-eight hours.

The table lists the arsonic acids and arsenoso compounds which were prepared. Recrystallization was done from water (W). Melting points below 200° were taken in a double-walled sulfuric acid bath using Anschütz thermometers with a Bureau of Standards report; no stem correction was made. Melting points above 200° were made in a copper block with a thermometer standardized against the same set of Anschütz thermometers. All analytical results were the average of two or more determinations.

Acknowledgment.—The authors wish to acknowledge the assistance given by Leon D. Freedman throughout the course of the work.

Summary

A number of arsonic acids and arsenoso compounds containing two or more amide groups on a single side chain have been prepared.

Arsenoso Compounds Containing Amide Groups[1]

By G. O. Doak, H. G. Steinman and Harry Eagle

Among the various types of aromatic arsenoso compounds which have been described in previous publications from this Laboratory, those containing amide groups have been of particular interest from the pharmacological viewpoint. The present paper gives the results of further research on this class of compounds.

For the oxidation of tolylarsonic acids and the esterification of the resulting arsonobenzoic acids the methods of Cohen, King and Strangeways[2] were used. The catalytic method of Stevinson and Hamilton[3] was used for the reduction of nitrobenzenearsonic acids to the corresponding amino compounds. Cyanobenzenearsonic acids were prepared and isolated by the method previously described,[4] except that cuprous cyanide was substituted for nickel cyanide. In contrast to the findings of Korczynski and Fandrich[5] with non-arsenated aromatic amines the use of cuprous cyanide gave a larger yield in this particular reaction. The Scheller–Bart reaction[6] was used for the preparation of **4-nitro-, and 5-nitro-*o*-toluenearsonic acids.** While the yields were larger by this procedure as compared to the

customary Bart reaction,[7] considerable difficulty was experienced in removing inorganic arsenic. Contrary to the statement of Maschmann[7c] the preparation of 2-arsono-4-nitrobenzoic acid by the oxidation of 2-methyl-5-nitrobenzenearsonic acid did not proceed smoothly and repeated recrystallizations were necessary in order to obtain an analytically pure sample. For the preparation of 2-arsono-5-nitrobenzoic acid the method of Karrer[8] was found preferable to the oxidation of 2-methyl-4-nitrobenzenearsonic acid.

N-Substituted arsenosobenzamides were prepared by the condensation of dichloroarsinobenzoyl chlorides with the appropriate amine as described for the preparation of *p*-arsenoso-N-(2,3-dihydroxypropyl)-benzamide.

Experimental Part

5-Arsenosoisophthalamide.—The Bart reaction applied to 3,5-xylidine gave **3,5-xylenearsonic acid** which was then oxidized with potassium permanganate. An **acid potassium salt of 5-arsonoisophthalic acid,** with the composition $H_2O_3AsC_6H_3(COOH)_2 \cdot KHO_3AsC_6H_3(COOH)_2$, crystallized from solutions strongly acid to congo red. This acid salt, suspended in chloroform, was treated with phosphorus tri- and pentachloride and the reaction mixture added to cold aqueous ammonia. Instead of the expected amide we obtained **5-arsenosoisophthalic acid.** This compound was esterified to **5-arsenosoisophthalic acid, dimethyl ester,** which gave the desired compound when heated with ammonia in a sealed tube at 100° for six hours.

6-Arsenosoisophthalamic Acid.—2-Arsono-5-nitrobenzoic acid[8] on reduction gave **5-amino-2-arsonobenzoic acid.** The Sandmeyer reaction applied to this compound gave **2-arsono-5-cyanobenzoic acid** in impure form. We were unable to obtain an analytically pure sample by repeated recrystallization from either water or alcohol. Oxidation of the slightly impure nitrile with 30% hydrogen peroxide gave **6-arsonoisophthalamic acid.** Reduction gave the desired arsenoso compound.

6-Arsenosoterephthalamic Acid.—2-Arsono-4-nitrobenzoic acid was reduced catalytically to 4-amino-2-arsonobenzoic acid.[7c] By a series of reactions similar to those described above we obtained **2-arsono-4-cyanobenzoic acid, 2-arsonoterephthalamic acid** and finally the desired arsenoso compound.

2-Amino-4-arsenosobenzamide.—This compound has been previously described[9] but the following procedures offer some improvement. The acid potassium salt of 2-nitro-4-arsonobenzoic acid,[2] suspended in chloroform, was treated with phosphorus tri- and pentachlorides. The solvent was removed *in vacuo* and the residue added to cold aqueous ammonia. The resulting **4-arsenoso-2-nitrobenzamide** was oxidized to **4-carbamyl-3-nitrobenzenearsonic acid** with 30% hydrogen peroxide. Catalytic reduction gave 4-carbamyl-*m*-arsanilic acid which was reduced to the arsenoso compound with sulfur dioxide.

The compound was more satisfactorily prepared from the methyl ester of 4-arsenosoanthranilic acid[2] by heating in a sealed tube with aqueous ammonia for sixty hours at 90°.

2-Acetamido-4-arsenosobenzamide.—While this compound was prepared readily by acetylation of 2-amino-4-arsenosobenzamide, we were unable to prepare it by reduction of the corresponding arsonic acid. We were also unable to convert 2-acetamido-4-arsonobenzoic acid to the amide by treatment with phosphorus tri- and pentachlorides, and adding the mixture to ammonia.

4-Arsenososalicylamide.—This compound was obtained by reduction of the corresponding arsonic acid.[2]

5-Arsenososalicylamide.—5-Arsonosalicylic acid[10] esterified with methanol gave **5-arsonosalicylic acid, methyl ester,** which possessed a faint but definite wintergreen odor. Ammonolysis at 100° in a sealed tube resulted in splitting arsenic from the ring. Ammonolysis at 0° for several days gave **3-carbamyl-4-hydroxybenzenearsonic acid.** Reduction of this arsonic acid gave the desired compound.

3-Amino-5-dichloroarsinosalicylamide Hydrochloride.—Esterification of 3-amino-5-arsonosalicylic acid[9] gave 3-amino-5-arsonosalicylic acid, methyl ester. This compound was not purified but added directly at 0° to aqueous ammonia, especially prepared from oxygen free water. After standing for three days the ammonia was removed in a stream of nitrogen and the solution acidified. **5-Carbamyl-4-hydroxy-*m*-arsanilic acid** precipitated.

Anal. Calcd. for $C_7H_9AsN_2O_5$: N, 10.2. Found: N, 10.2.

Reduction in hydrochloric acid solution gave the dichloroarsino hydrochloride compound, m. p. 177–178°.

Anal. Calcd. for $C_7H_7AsCl_2N_2O_2 \cdot HCl \cdot H_2O$: As, 21.3; N, 7.97. Found: As, 21.8; N, 8.07.

As this compound was unstable in alkaline solution the arsenoso compound was not prepared.

***p*-Arsenosobenzimido Ethyl Ether.**—*p*-Cyanobenzenearsonic acid was reduced with sulfur dioxide and hydriodic acid in 12 *N* sulfuric acid and the precipitate treated with sodium bicarbonate solution. The resulting ***p*-arsenosobenzonitrile** (2.5 g.) was suspended in 10 ml. of ether, 0.7 ml. of 95% alcohol added, and the mixture saturated with hydrogen chloride at 0°. After standing two days at 10°, the ***p*-dichloroarsinobenzimido ethyl ether hydrochloride** was filtered off and thoroughly washed with ether. The yield was 53%, m. p. 141°.

Anal. Calcd. for $C_9H_{10}AsCl_2NO \cdot HCl \cdot H_2O$: As, 21.5; N, 4.02. Found: As, 21.3; N, 4.06.

This was hydrolyzed with sodium bicarbonate solution to the arsenoso derivative.

***p*-Arsenoso-N-(2,3-dihydroxypropyl)-benzamide.**—*p*-Dichloroarsinobenzoyl chloride (8.6 g.) in 20 ml. of acetone was added dropwise and with cooling to a solution of 2.8 g. of 3-amino-1,2-propanediol in 100 ml. of 10% sodium carbonate solution. After standing overnight the precipitated arsenoso compound was filtered, washed, and finally recrystallized from 0.1% sodium bicarbonate solution.

***p,p'*-Diarsenoso-1,2-dibenzoylhydrazine.**—Hydrazine hydrate was added to an excess of *p*-dichloroarsinobenzoyl chloride in pyridine and benzene. The compound was purified by dissolving in sodium hydroxide solution and precipitating with acid.

***p*-Arsenoso-N-(2-acetamidoethyl)-benzamide.**—*p*-Dichloroarsinobenzoyl chloride was condensed with glycinonitrile sulfate in sodium carbonate solution and the resulting ***p*-arsenoso-N-(cyanomethyl)-benzamide** recrystallized from 0.1% sodium bicarbonate solution. Oxidation with iodine in sodium bicarbonate solution gave ***p*-(cyanomethyl)-carbamylbenzenearsonic acid.** Neither the arsonic acid nor the arsenoso compound could be reduced to the amine. No reduction occurred with the method of Carothers and Jones.[11] Reduction of the arsonic acid by Hartung's method[12] gave *p*-arsonohippuric acid. Reduction of the arsonic acid employing Raney nickel gave a mixture of amines. When *p*-dichloroarsinobenzoyl chloride was coupled with an excess of ethylenediamine in sodium carbonate solution only ***p,p'*-diarsenoso-N,N'-dibenzoylethylenediamine** was obtained. The desired compound was finally prepared by coupling the acid chloride with N-(2-aminoethyl)-acetamide.[13] The crude material was recrystallized twice from acetic acid and finally from water.

α-Amino-p-dichloroarsinoacetanilide Hydrochloride.—Reduction of the corresponding arsonic acid[14] in hydrochloric acid gave this dichloroarsine. It could not be successfully hydrolyzed to the arsenoso derivative.

Anal. Calcd. for $C_8H_9AsCl_2N_2O \cdot HCl$: As, 22.6; N, 8.45. Found: As, 22.3; N, 8.45.

p'-Arsenoso-p-carbamylbenzanilide.—By means of the Schotten–Baumann reaction *p*-toluyl chloride was condensed with atoxyl to give **N-p-toluylarsanilic acid.** This compound was oxidized with potassium permanganate in neutral solution, in the presence of magnesium sulfate. From the reaction mixture terephthalic acid was isolated in quantitative yield. According to German Patent 191,548[15] terephthalyl chloride condenses with arsanilic acid to give *p*-arsonoterephthalanilic acid. In several experiments, using various experimental conditions, we obtained a mixture of this compound and N,N'-terephthaloyldiarsanilic acid. It was found that the two compounds could be separated by the differential solubilities of their magnesium salts, as described for the separation of a similar mixture in the biphenyl series,[16] but the yield was poor. The desired compound was finally obtained by the following synthesis. *p*-Cyanobenzoic acid (14.7 g.) and 7.9 g. of pyridine were dissolved in 1 liter of absolute ether and the mixture treated with 11.9 g. of thionyl chloride according to the directions of Carré and Libermann.[17] While the resulting *p*-cyanobenzoyl chloride could not be readily separated from pyridine hydrochloride, this was found unnecessary. After removing the solvent the residue was triturated with 43 g. of arsanilic acid and then warmed on the water-bath for one hour. An excess of 10% hydrochloric acid was added and the mixture stirred for one hour to dissolve any unchanged arsanilic acid. The resulting **N-(p-cyanobenzoyl)-arsanilic acid** was purified through its magnesium salt. Oxidation with 30% hydrogen peroxide gave **N-(p-carbamylbenzoyl)-arsanilic acid,** which was reduced to the desired arsenoso derivative.

p-(p-Carbamylphenylsulfonyl)-benzenearsonic Acid.—The Scheller–Bart reaction, applied to *p*-amino-*p'*-nitrodiphenyl sulfide,[18] gave **p-(p-nitrophenylthio)-benzenearsonic acid** which was reduced catalytically to **p-(p-aminophenylthio)-benzenearsonic acid.** The Sandmeyer reaction applied to this amine gave **p-(p-cyanophenylthio)-benzenearsonic acid.** This nitrile was then oxidized with an excess of 30% hydrogen peroxide in alkaline solution. **p-(p-Carbamylphenylsulfonyl)-benzenearsonic acid** precipitated when the alkaline solution was acidified. Unfortunately all attempts to reduce this compound to the corresponding arsenoso derivative resulted in partial hydrolysis of the amide group.

The table lists the arsonic acids and arsenoso compounds which are new compounds or are known compounds prepared by a new procedure. Under "description," the letters in parentheses refer to the solvent used for crystallizing: W = water, A = ethyl alcohol, M = methanol and AA = acetic acid. Melting points were taken by the procedure described in paper VI. All analytical results are the average of two or more determinations.

Acknowledgment.—The authors wish to acknowledge the assistance given by Leon D. Freedman throughout the course of the work.

Summary

A number of arsonic acids and arsenoso compounds containing amide groups have been prepared.

Arsonic Acids and Arsenoso Compounds Containing the Azo Linkage[1]

BY G. O. DOAK, H. G. STEINMAN AND HARRY EAGLE

The customary preparation of arsonic acids containing the azo linkage consists in the coupling of diazotized aminoarylarsonic acids with phenols and amines. We have also prepared such compounds by coupling diazo compounds with hydroxyarylarsonic acids and by the application of the Scheller–Bart reaction[2] to aminoazo compounds.

While it has been stated that *o*- and *m*-hydroxybenzenearsonic acids[3] and *m*-arsanilic acid[4] couple with diazo compounds, the only evidence for such a reaction was color formation. Benda[5] obtained only arsenic acid and the corresponding phenylazophenol from *p*-hydroxybenzenearsonic acid and diazo compounds. Lawrence and Hamilton,[6] however, have successfully coupled aminonaphthalenearsonic acids.

In this Laboratory it has been found that diazo compounds couple with *o*- and *m*-hydroxybenzenearsonic acids, the coupling occurring in *para* position to the hydroxy group. Where the para position is blocked, *e. g.*, *p*-hydroxybenzenearsonic acid, the arsonic acid group is partially replaced by the phenylazo group. In addition, however, some coupling occurs in *ortho* position to the hydroxy group. The resulting azoarsonic acid then reacts further with the diazo compound to give the *bis*-(phenylazo)-phenol. The extent to which each of these three reactions occurs depends not only upon the strength of the reactants as coupling agents but is also influenced by the *p*H of the reaction mixture. The results of a series of experiments are given in Table I.

Experimental Part

A. The Coupling of Diazo Compounds with Hydroxyarylarsonic Acids.—The following description illustrates the general procedure that was followed.

TABLE I

THE COUPLING OF DIAZO COMPOUNDS WITH HYDROXYARYLARSONIC ACIDS IN RELATION TO *p*H

Arsonic acid	Diazo compound from	*p*H	% Yield of products: Phenylazophenol	Phenylazoaryl-arsonic acid	*bis*-(Phenylazo) phenol
p-HOC_6H_4-	Aniline	5.8–6.6[a]	36.9	0.5	4.6
		7.3–7.4[b]	39.4	5.9	12.2
		8.5–9.5[c]	9.4	0	27.8
4-$HOC_{10}H_6$-1-	Aniline	7.1–7.4[b]	34.4	20.0	33.8
p-HOC_6H_4-	Sulfanilamide	5.4–6.5[a]	[e]	0	
		7.1–7.5[b]	[e]	0	
p-HOC_6H_4-	*m*-Toluidine	7.4–7.5[b]	No coupling		
m-HOC_6H_4-	Aniline	7.0–7.1[b]	0	95	0
		8.9–9.1[d]	0	98	0
o-HOC_6H_4-	Aniline	8.9–9.1[d]	0	88	0
2,4-$(HO)_2C_6H_3$-	Aniline	7.6–7.9[b]		84[f]	
		8.5–9.5[c]	[g]	5.6[f]	[g]

[a] Phosphate buffer. [b] Sodium bicarbonate buffer. [c] In sodium carbonate solution. [d] In sodium hydroxide solution. [e] Analysis indicated that a mixture of phenylazophenols was obtained, which could not be readily separated. [f] This compound was 3,5-*bis*-(phenylazo)-2,4-dihydroxybenzenearsonic acid, obtained with an excess of the diazo solution. We were unable to obtain a phenylazo-2,4-dihydroxybenzenearsonic acid free from the *bis* compound. [g] A mixture was obtained from which only 2,4-*bis*-(phenylazo)-resorcinol could be obtained in a pure state.

4-Hydroxy-3-phenylazobenzenearsonic Acid.—The diazo solution, prepared from 0.93 g. (0.01 mole) of aniline and 0.03 mole of hydrochloric acid was added slowly to a solution of sodium *p*-hydroxyphenylarsonate (2.94 g. of the trihydrate, 0.01 mole) and 2.52 g. of sodium bicarbonate in 50 ml. of water, maintaining the temperature at 10°. The initial and final *p*H values were 7.4 and 7.3 (glass electrode). The reaction mixture was stirred for one hour, filtered and the residue washed with 100 ml. of warm 10% sodium carbonate solution. The insoluble fraction (0.37 g.) was recrystallized from alcohol. Analysis and melting point (131°) identified this substance as 2,4-*bis*-(phenylazo)-phenol. The combined filtrate and washings were acidified to congo red and cooled in the icebox for twenty-four hours. The mixture was filtered, the precipitate washed with 10 ml. of cold water and dried. Arsenic acid was determined in the filtrate as magnesium pyroarsenate. The dry precipitate was extracted with ether and the ether insoluble fraction (0.174 g.) recrystallized several times from water. This substance was identical with the 4-hydroxy-3-phenylazobenzenearsonic acid later prepared by the Scheller–Bart reaction. The ether soluble fraction gave *p*-phenylazophenol (0.78 g.) and 2,4-*bis*-(phenylazo)-phenol (0.15 g.) on fractional crystallization from alcohol. In subsequent reactions it was found advantageous to partially neutralize the diazo solution before coupling.

4-Hydroxy-3-phenylazo-1-naphthalenearsonic Acid.—4-Hydroxy-1-naphthalenearsonic acid has been previously described.[7] The yield has been increased considerably by the following modification. 4-Amino-1-naphthyl benzoate hydrochloride was treated with ammonia to give the free base. It was also obtained by reducing 4-nitro-1-naphthyl benzoate in alcohol, employing Raney catalyst. **4-Amino-1-naphthyl benzoate** crystallized from aqueous alcohol in plates, m. p. 107.2–107.6°. The yield was 95% by either procedure.

Anal. Calcd. for $C_{17}H_{13}NO_2$: N, 5.32. Found: N, 5.40.

The Scheller–Bart reaction applied to this amine gave **4-arsono-1-naphthyl benzoate** in 19% yield. It crystallized from aqueous alcohol in plates; m. p. 199.8–200°.

Anal. Calcd. for $C_{17}H_{13}AsO_5$: As, 20.1. Found: As, 19.8.

4-Hydroxy-1-naphthalenearsonic acid was prepared from this ester by hydrolyzing in methanol solution with dry hydrogen chloride in the cold. The solution was diluted with water, the methyl benzoate extracted with ether and the arsonic acid recrystallized from water. The yield was 57%.

Anal. Calcd. for $C_{10}H_9AsO_4$: As, 28.0. Found: As, 28.0.

The above arsonic acid (9 g.) was coupled with benzenediazonium chloride at *p*H 7.1–7.4. After standing for two hours at 10° the mixture was acidified to congo red. The precipitate which formed was dried and extracted with benzene. The benzene insoluble fraction was then extracted with boiling 10% sodium bicarbonate solution. This solution when cooled deposited a small amount of solid which was added to the bicarbonate insoluble fraction. When the bicarbonate solution was acidified to congo red 4-hydroxy-3-phenylazo-1-naphthalenearsonic acid precipitated (2.51 g.). It was recrystallized from aqueous alcohol.

The benzene soluble fraction (4.0 g.), after recrystallizing first from benzene and finally from amyl alcohol, was identified as 2,4-*bis*-(phenylazo)-1-naphthol by analysis and melting point (190–191°). The bicarbonate insoluble fraction (2.87 g.), after recrystallizing several times from amyl alcohol was similarly identified as 4-phenylazo-1-naphthol, m. p. 206°.

3-Amino-4-hydroxy-1-naphthalenearsonic Acid.—The preceding azoarsonic acid was converted to the monosodium salt and reduced catalytically, employing Raney nickel. The solution was filtered directly into dilute hydrochloric acid and the arsonic acid which precipitated purified by the method of Christiansen.[8] It was obtained as white needles which colored rapidly in the air and slowly when preserved in an atmosphere of hydrogen. It decomposed on heating. The yield was 52%.

Anal. Calcd. for $C_{10}H_{10}AsNO_4 \cdot H_2O$: As, 24.9. Found: As, 24.4.

3-Hydroxy-1,4,α-naphthisoöxazine-6-arsonic Acid.—This compound was prepared by the method of Newberry, Phillips and Stickings[9] for the corresponding benzene analog, employing chloroacetyl chloride. It crystallized from water in clusters of needles.

Anal. Calcd. for $C_{12}H_{10}AsNO_5$: As, 23.2. Found: As, 22.7.

The formation of the cyclic arsonic acid offers considerable evidence for the coupling of 4-hydroxy-1-naphthalenearsonic acid in the 3-position.

2-Hydroxy-5-phenylazobenzenearsonic Acid.—The crude product from the coupling of *o*-hydroxybenzenearsonic acid and benzenediazonium chloride was purified through the magnesium salt and finally by recrystallizing from water. It was reduced catalytically, employing

[a] By the Scheller–Bart reaction. [b] By coupling. [c] Doak, Eagle and Steinman, THIS JOURNAL, 64, 1064 (1942), footnote[c] to Table I. [d] The corresponding arsonic acid was prepared by the method of Barrowcliff, Pyman and Remfry, *J. Chem. Soc.*, 93, 1893 (1908). [e] The corresponding arsonic acid was prepared according to German Patent 212,018, Raiziss and Gavron, "Organic Arsenical Compounds," Chemical Catalog Co., 1923, p. 286.

Raney nickel, and the resulting 6-hydroxy-*m*-arsanilic acid reduced in hydrochloric acid solution to 4-amino-2-dichloroarsinophenol hydrochloride, m. p. 183–183.4°.

Anal. Calcd. for $C_6H_7AsCl_3NO \cdot H_2O$: As, 24.3; N, 4.54. Found: As, 24.3; N, 4.61.

This compound was identical with the compound prepared by the reduction of an authentic sample of 6-hydroxy-*m*-arsanilic acid, thus establishing that *o*-hydroxybenzenearsonic acid coupled in the 5-position.

5-Hydroxy-2-phenylazobenzenearsonic Acid.—The crude reaction product from the coupling of *m*-hydroxybenzenearsonic acid and benzenediazonium chloride was purified by dissolving in warm sodium bicarbonate solution and precipitating with acid. It was finally recrystallized several times from water. This was similarly reduced to 5-hydroxy-*o*-arsanilic acid which gave **5-amino-4-dichloroarsinophenol hydrochloride**, m. p. 128–128.2°, on reduction in hydrochloric acid.

Anal. Calcd. for $C_6H_7AsCl_3NO \cdot H_2O$: As, 24.3; N, 4.54. Found: As, 24.1; N, 4.73.

This compound depressed the melting points of authentic samples of 2-amino-3-dichloroarsino- and 4-amino-5-dichloroarsinophenol hydrochlorides.[10] The structure of the coupled product as 5-hydroxy-2-phenylazobenzenearsonic acid was thus established.

B. The Scheller–Bart Reaction with Aminoazo Compounds

***p*-Phenylazobenzenearsonic Acid.**[11]—This compound was prepared by both the customary Bart reaction and the Scheller modification, but the latter method gave a somewhat larger yield. The compound was reduced catalytically, employing Raney nickel, to arsanilic acid and aniline which were identified by converting to *p*-dichloroarsinoaniline hydrochloride and acetanilide, respectively, and comparing with authentic samples of these two substances.

***p*-(*p*-Tolylazo)-benzenearsonic Acid.**—This was prepared from *p*-(*p*-tolylazo)-aniline which was obtained by a modification of the method of Nietzki.[12] *p*-(*p*-Tolylazo)-benzenearsonic acid, when oxidized with potassium permanganate gave ***p*-(*p*-arsonophenylazo)-benzoic acid.** The recrystallized compound, suspended in chloroform, was treated with phosphorus tri- and pentachlorides and the clear orange solution added to aqueous ammonia. ***p*-(*p*-Arsenosophenylazo)-benzamide** precipitated from this solution. No satisfactory means of purifying this compound was found.

***p*-(*p*-Arsenosophenylazo)-(N-2-hydroxyethyl)-benzamide** was obtained in a similar manner by using an aqueous solution of 2-aminoethanol instead of ammonia.

4-Hydroxy-3-phenylazobenzenearsonic Acid.[13]—This compound was prepared from the Scheller–Bart reaction applied to 4-amino-2-phenylazophenol. This latter compound was obtained by a slight modification of the method of Woroshzow.[14] The Scheller–Bart reaction was unsuccessful with the two following other amines which together with the two corresponding intermediate acetyl derivatives were prepared by the method of Woroshzow.[14]

***p*-(5-Amino-2-hydroxyphenylazo)-benzenesulfonic Acid.**—*Anal.* Calcd. for $C_{12}H_{11}N_3O_4S$: N, 14.3; S, 10.9. Found: N, 14.1; S, 11.5.

***p*-(5-Amino-2-hydroxyphenylazo)-benzenesulfonamide.**—*Anal.* Calcd. for $C_{12}H_{12}N_4O_3S$: N, 19.2. Found: N, 18.5.

Sodium Salt of *p*-(5-Acetamido-2-hydroxyphenylazo)-benzenesulfonic Acid.—*Anal.* Calcd. for $C_{14}H_{12}N_3NaO_5S$: N, 11.8; Na, 6.44. Found: N, 11.7; Na, 5.78.

***p*-(5-Acetamido-2-hydroxyphenylazo)-benzenesulfonamide.**—*Anal.* Calcd. for $C_{14}H_{14}N_4O_4S$: N, 16.8; S, 9.6. Found: N, 16.5; S, 10.1.

2-Amino-4-(*p*-arsenosophenylazo)-phenol.—*p*-Arsonobenzenediazonium chloride by coupling with *o*-acetamidophenol gave ***p*-(3-acetamido-4-hydroxyphenylazo)-benzenearsonic acid.** This was hydrolyzed with hydrogen chloride in methanol solution to give *p*-(3-amino-4-hy-

droxyphenylazo)benzenearsonic acid hydrochloride. The last traces of methanol were removed *in vacuo* at 100°. The compound showed the typical properties of an *o*-aminophenol. When this was reduced with sulfur dioxide a red insoluble product was obtained, the structure of which could not be determined.

Table II lists the arsonic acids and arsenoso compounds which were prepared. Melting points were taken by the procedure described in paper VI. All analytical results are the average of two or more determinations. The crystalline arsonic acids were recrystallized from either water or alcohol. The yields given are for the purified compounds.

Acknowledgment.—The authors wish to acknowledge the assistance given by Leon D. Freedman throughout the course of the work.

Summary

Arsonic acids containing the azo linkage have been prepared by coupling diazo compounds with hydroxyarylarsonic acids and by the Scheller–Bart reaction applied to aminoazo compounds. A number of these arsonic acids have been reduced to the corresponding arsenoso derivatives.

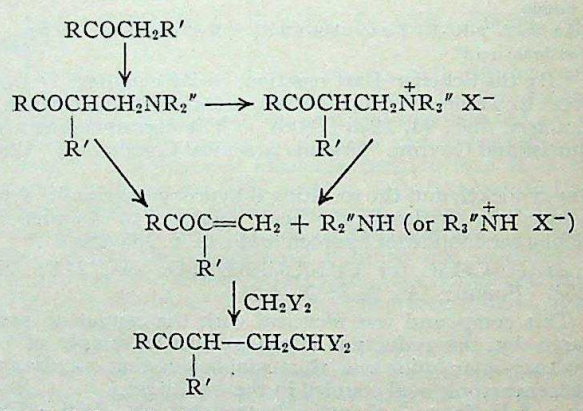
Carbon-Alkylation with Quaternary Ammonium Salts. A New Approach to the Synthesis of Compounds Containing the β-Indolemethylene Group

BY H. R. SNYDER, CURTIS W. SMITH AND JOHN M. STEWART

Although simple quaternary ammonium salts have been used as alkylating agents in the preparation of numerous sulfur-,[1] oxygen-[2,3,4,5] and nitrogen-[6,7] alkylated substances, they have not appeared promising as reagents for the preparation of carbon-alkyl derivatives. For example, benzyldimethylphenylammonium chloride has been found not to yield phenacetonitrile by reaction with sodium cyanide in water,[1] and certain salts containing allyl groups attached to the nitrogen atom have been found not to produce allylphenols by reaction with phenolic substances.[3]

Successful reactions of quaternary salts derived from Mannich bases with active methylene compounds have been reported,[8,9] but these reactions have been interpreted as consisting not in simple alkylation but in Michael condensations of the active methylene compounds with vinyl ketones formed by decomposition of the quaternary salts of the Mannich bases.[10] The Mannich bases themselves react similarly in the presence of catalytic amounts of sodium, presumably also by decomposition to the vinyl ketones and the amines. The reactions are summarized in the following scheme.



In a study of the action of quaternary ammonium salts containing a benzyl group on sodium derivatives of acetoacetic ester and malonic ester it now has been found that carbon-alkylation occurs. Sodio acetoacetic ester reacts with benzyldimethylphenylammonium chloride in boiling ethanol to produce about 60% yields of crude ethyl α-benzylacetoacetate. Under the same conditions the sodium derivative of malonic ester reacts with the salt to give a yield of about 40% of diethyl benzylmalonate. The reactions probably proceed by an ionic path.

$$C_6H_5CH_2N^+(CH_3)_2C_6H_5 \longrightarrow$$

$$C_6H_5N(CH_3)_2 + [C_6H_5CH_2^+] \xrightarrow{CH(CO_2C_2H_5)_2^-} C_6H_5CH_2CH(CO_2C_2H_5)_2$$

There is no possibility of decomposition of this quaternary salt to an olefinic substance, according to the mechanism indicated above for reactions of the salts obtained from Mannich bases. As might have been expected, the amine, benzylmethylaniline, was found ineffective in these alkylations.

When benzylmethylpiperidinium chloride was allowed to react with the sodium derivative of malonic ester in ethanol solution the yield of diethyl benzylmalonate was only 5%. When the reaction was carried out in boiling 1-butanol the yield of crude ester (*ca.* 50%) was much improved, but the product apparently consisted of a mixture of ethyl and *n*-butyl esters. In order to effect the reaction at temperatures

above the boiling point of ethanol, but without the risk of transesterification of the product, the reaction mixture in ethanol was heated in an autoclave at temperatures between 110 and 130°. The best yield obtained by this procedure was about 35%. The residue from the distillation of diethyl benzylmalonate was shown to contain diethyl dibenzylmalonate.

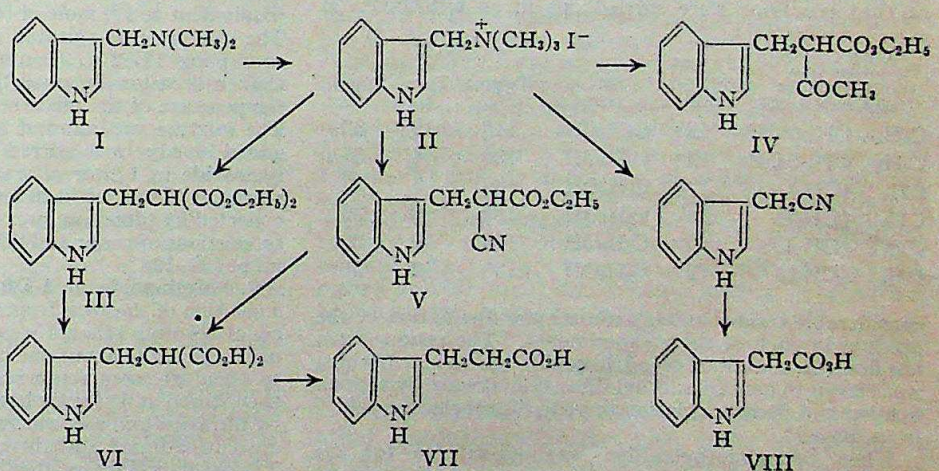
The occurrence of the ester of dibenzylmalonic acid is not surprising. Other side-reactions which might be expected in alkylations with benzylmethylpiperidinium chloride are the decomposition of the salt to an olefin, and the reaction with the alcohol used as solvent to form benzyl ethyl ether.[10a] That olefin formation is impossible with benzyldimethylphenylammonium chloride may account for the higher yields of diethyl benzylmalonate obtained with this salt.

Experimental conditions chosen with the view to the suppression of dialkylation and ether formation have resulted in further improvement of the yield of diethyl benzylmalonate. For example, when an ethanol solution of equivalent amounts of benzyldimethylphenylammonium ethoxide and malonic ester was added dropwise to an equivalent quantity of hot malonic ester with provision for removal of ethanol by distillation as rapidly as it entered the reaction mixture, the yield of diethyl benzylmalonate was slightly above 50%. When the chloride was added to a mixture of the sodium derivative of malonic ester and excess malonic ester, prepared by adding sodium ethoxide to an excess of malonic ester and removing most of the ethanol by distillation under diminished pressure, the yield was a little over 70%. When the reaction was carried out by adding the salt to the sodium derivative prepared from metallic sodium and excess malonic ester the yield was about 80%. These are the best conditions so far discovered. Substitution of benzylmethylpiperidinium iodide and benzyltriethylammonium iodide for the benzyldimethylphenylammonium chloride resulted in yields of 43 and 62%, respectively.

Alkylations of the type studied will be most useful in synthesis when the quaternary ammonium salts are more accessible than the alkyl halides. Gramine [3-dimethylaminomethylindole, (I)] can be prepared readily from indole[11] and it is converted easily to quaternary ammonium salts, such as the methiodide (II), which contain a radical of the benzyl type.

In a preliminary study of the use of gramine methiodide as an alkylating agent it has been found that this salt is more reactive than those containing a simple benzyl group. Reaction of II with the sodium derivative of malonic ester produced the substituted malonic ester (III) in 85% yields. Condensations with acetoacetic ester and cyanoacetic ester also were successful, although the products (IV and V) were oils which were not purified. The malonic ester condensation product was saponified and the malonic acid (VI) was decarboxylated to β-indolepropionic acid (VII). Hydrolysis of the crude cyanoacetic ester condensation product (V) gave the same malonic acid (VI). β-Indoleacetic acid (VIII) was prepared from the salt (II) and potassium cyanide in water solution, but in better yields from the salt (II) and potassium silver cyanide; the intermediate nitrile was not isolated in the pure state.

The greater reactivity of gramine methiodide, as compared to benzyltrimethylammonium salts, suggested that the possibility of alkylation with the free tertiary amine be reëxamined. Reaction occurred when gramine was heated with malonic ester containing a trace of the sodium derivative. The reaction, which could be followed by noting the evolution of dimethylamine, was very slow, however; the yield of ethyl α-carbethoxy-β-(3-indole)-propionate (III) obtained from a reaction carried out for fifty-three hours at temperatures between 120 and 150° was only about 40%.



I II IV III V VI VII VIII

Further studies of the application of these and similar reactions in the synthesis of indole derivatives are in progress.

Experimental

1. Benzyldimethylphenylammonium Chloride and the Sodium Derivative of Acetoacetic Ester in Ethanol.—To a solution of 1.15 g. (0.05 mole) of sodium in 100 cc. of absolute ethanol were added 7.15 g. (0.055 mole) of acetoacetic ester and 10.6 g. (0.05 mole) of benzyldimethylphenylammonium chloride. The mixture was heated under

(10a) Ingold and Patel [*J. Chem. Soc.*, 68 (1933)] obtained 65% yield of the ether from benzyltrimethylammonium iodide and sodium ethoxide in ethanol.

(11) Kuhn and Stein, *Ber.*, **70**, 567 (1937).

reflux for a total of three and one-half hours (heating was interrupted after the first half hour to permit the removal of sodium chloride by filtration). About half of the ethanol was removed by evaporation and the residual solution was poured into a cold solution of 15 cc. of concentrated hydrochloric acid and 250 cc. of water. The aqueous phase was separated and extracted with three 50-cc. portions of ether. The ether extracts were combined with the organic layer and dried over sodium sulfate. Distillation yielded 6.6 g. (60%) of ethyl α-benzylacetoacetate boiling at 140–150 (2–3 mm.). The dinitrophenylhydrazone melted at 71.5°.

Anal. Calcd. for $C_{19}H_{20}N_4O_6$: C, 57.00; H, 5.04. Found: C, 57.19; H, 5.04.

2. Benzyldimethylphenylammoniuum Chloride and the Sodium Derivative of Malonic Ester in Ethanol.—To a solution of 2.3 g. (0.10 mole) of sodium in 80 cc. of absolute ethanol were added 17 g. (0.11 mole) of malonic ester and 28 g. (0.12 mole) of the quaternary chloride. The mixture was refluxed for ten hours. The ethanol was removed by evaporation and the residue was worked up in a manner similar to that described in 1. The diethyl benzylmalonate, b. p. 128–133° (6 mm.), weighed 9.4 g. (37.6%). The diamide[12] melted at 225°.

3. Benzylmethylpiperidinium Chloride and the Sodium Derivative of Malonic Ester in Ethanol and in Butanol.—The reaction in ethanol, run as in (2) gave a 5% yield of diethyl benzylmalonate. From the reaction in boiling *n*-butanol 52% yield of an oil boiling at 163–173 (4 mm.) was obtained. This product reacted very slowly with concentrated aqueous ammonia to give benzylmalonamide, m. p. 225°. The oil was probably a mixture of the ethyl butyl and dibutyl esters.

4. Various Quaternary Ammonium Salts and the Sodium Derivative of Malonic Ester.—The procedure used in the following experiments differed from that of (2) only in that reactions were carried out in an autoclave. A

Organic residues other than $C_6H_5CH_2$ in $C_6H_5CH_2NR_3^+X^-$	Anion	Solvent	Temp., °C.	Time, hr.	Yield, %
C_6H_5-, CH_3-, CH_2-	Cl^-	C_2H_5OH	115	12	32
C_6H_5-, CH_3-, CH_3-	Cl^-	C_2H_5OH	130	4	36
CH_3-, -$(CH_2)_5$-	I^-	C_2H_5OH	120	6	22
CH_3-, -$(CH_2)_5$-	I^-	C_2H_5OH	135	9	36
CH_3-, -$(CH_2)_5$-	Cl^-	C_2H_5OH	135	10	20
CH_3-, -$(CH_2)_5$-	Cl^-	C_2H_5OH	130	12	26

considerable residue remained after the distillation of the product in each of these experiments. The residue from the first run contained an oil, b. p. 170–183 (3 mm.), which was shown to contain diethyl dibenzylmalonate by saponification and decarboxylation to yield dibenzylacetic acid,[12] m. p. 88–89°.

When benzylmethylaniline was substituted for the quaternary salt in the second experiment, no diethyl benzylmalonate was obtained.

5. Benzyldimethylphenylammonium Ethoxide and the Sodium Derivative of Malonic Ester, with Removal of ethanal by Distillation.—The quaternary ethoxide was prepared by adding 25 g. (0.10 mole) of the quaternary chloride to 2.3 g. (0.10 mole) of sodium in 165 cc. of absolute ethanol and filtering from precipitated sodium chloride. The resulting solution was mixed with 16 g. (0.10 mole) of malonic ester and added over a period of about one hour to 16 g. (0.10 mole) of malonic ester in a distilling apparatus. During this period, and for two hours after the addition was complete, the oil-bath surrounding the flask containing the malonic ester was maintained at 150°. The bath temperature was then reduced to 110° for ten hours. The diethyl benzylmalonate, isolated essentially as described in (2), weighed 12.8 g. (51.3%).

6. Benzyldimethylphenylammonium Chloride and the Sodium Derivative of Malonic Ester without Solvent.—(a) A mixture of the sodium derivative of malonic ester and free malonic ester was prepared from 2.3 g. (0.10 mole) of sodium dissolved in 40 cc. of ethanol and 40 g. (0.25 mole) of malonic ester and removal of the ethanol by heating the mixture under 30 mm. pressure in an oil-bath at 50°. To the residue was added 27 g. (0.12 mole) of the quaternary chloride and the stirred mixture was suspended in an oil-bath which was heated to 110° over a period of two hours and then maintained at this temperature for six hours. The diethyl benzylmalonate, isolated essentially as in (2), weighed 18.2 g. (73%).

(b) The sodium derivative of malonic ester was prepared from 2.3 g. (0.10 mole) of powdered sodium and 40 g. (0.25 mole) of malonic ester in the presence of 100 cc. of anhydrous ether by stirring the mixture for six hours. To this mixture was added 27 g. (0.12 mole) of the finely ground quaternary chloride. The ether was removed by raising the temperature of the oil-bath to 110° over a period of about two hours. The stirred mixture was then heated at 140° for three hours. The yield of diethyl benzylmalonate was 19.7 g. (79%).

7. Other Quaternary Ammonium Salts Under the Approximate Conditions of Experiment 6-b.—In these experiments dibutyl ether (*ca.* 50 cc.) was added to facilitate stirring. N-Benzylmethylpiperidinium iodide gave a 43% yield of diethyl benzylmalonate, although the period of heating was extended by two hours. Benzyltriethylammonium iodide gave a 62.5% yield of the ester. With benzyltrimethylammonium bromide, evolution of trimethylamine began at 90°, continued for two hours with the oil-bath at 110–120°, and was completed after an additional half-hour at 140°. The yield of the ester was 77%.

8. 3-Dimethylaminomethylindole (Gramine).—The procedure was a modification of that of Kuhn and Stein.[11] To 135 g. of 35% dimethylamine (equivalent to 1.05 mole) at 5° was added 140 g. (2.33 moles) of glacial acetic acid. The mixture was cooled to 5° and 76 g. of 40% formalin (equivalent to 1.0 mole of formaldehyde) at 5° was added. The mixture was agitated mildly and poured into a flask containing 117.2 g. (1 mole) of indole. The flask was shaken occasionally until the indole had dissolved. The temperature of the mixture rose to 56° during this period. The mixture was allowed to stand for ten hours and was added slowly to a stirred solution of 140 g. of sodium hydroxide in 1 liter of water. The resulting suspension was cooled in an ice-bath for two hours. The gramine was collected by filtration, pressed dry, washed with three 100-cc. portions of water and dried in an oven at 50° overnight; m. p. 127–128°.

9. Methiodide of 3-Dimethylaminomethylindole.—To a solution of the base from the previous experiment in 750 cc. of absolute ethanol was added 156 g. of methyl iodide over a period of about one hour. The mixture was allowed to stand at room temperature for twelve hours and was then stored at 0° for six hours. The product was collected by filtration and was washed with three 100-cc. portions of absolute ethanol and three 100-cc. portions of dry ether. The dried product weighed 248.4 g. (80%, based on indole).

10. Ethyl α-Carbethoxy-β-(3-indole)-propionate.—The sodium derivative of malonic ester was prepared by stirring for twelve hours a mixture of 1.15 g. (0.05 mole) of powdered sodium, 75 cc. of butyl ether and 20 g. (0.125 mole) of malonic ester. To the resulting paste was added 17.5 g. of gramine methiodide. This mixture was heated, with stirring, for two hours with the oil-bath at 110° and for four hours with the oil-bath at 145°. The cooled mixture was stirred with three 100-cc. portions of water. The combined aqueous washings were extracted with three 100-cc. portions of ether and the ether extracts were added to the organic layer from the first extractions. The solution was dried and the solvents and excess malonic ester were removed by distillation, first from a steam-bath and finally at 5 mm. pressure with an oil-bath at 90°. The residual red liquid was poured slowly into 75 cc. of high-boiling petroleum ether, with cooling and stirring. The solid which soon formed was triturated with the cold solvent and collected by filtration; it weighed 16 g. (calcd. 14.5 g.) and melted at 60°.

The crude material was recrystallized by dissolving 13 g. in 30 cc. of hot ethanol and 15 cc. of hot water. After decolorization of the hot solution the filtrate was cooled to 50° and an additional 5 cc. of water was added. Crystallization was induced by careful cooling and stirring. After drying in a vacuum desiccator the product weighed 10 g. (85%, based on sodium) and melted at 61°. The analytical sample, prepared by a second recrystallization, melted at 62°. Ethyl α-carbethoxy-β-(3-indole)-propionate is soluble in benzene, toluene, chloroform and ethanol, and substantially insoluble in water, petroleum ether and carbon tetrachloride.

Anal. Calcd. for $C_{16}H_{19}NO_4$: C, 66.42; H, 6.62. Found: C, 65.93; H, 6.53.

11. α-Carboxy-β-(3-indole)-propionic Acid.—The ester was saponified by heating under reflux with 30% aqueous sodium hydroxide for six hours. The acid, after recrystallization from water, was obtained in 87% yield; m. p. 178° (dec.). The acid is very soluble in ethanol, and quite insoluble in chloroform and benzene.

Anal. Calcd. for $C_{12}H_{11}NO_4$: C, 61.77; H, 4.75. Found: C, 61.51; H, 4.88.

The diamide, prepared by allowing a mixture of the ester with ten times its weight of concentrated aqueous ammonia to stand for two weeks, crystallized from aqueous ethanol or acetone; m. p. 206°.

Anal. Calcd. for $C_{12}H_{13}N_3O_2$: C, 62.32; H, 5.66. Found: C, 62.53; H, 5.59.

12. β-(3-Indole)-propionic acid was prepared by heating the dibasic acid in an oil-bath at 180–190° for about fifteen minutes (until frothing stopped). The crude material, obtained by decolorizing a solution in 5% aqueous sodium hydroxide and reprecipitation by treatment with acid, melted at 120–123° (yield 75%). One recrystallization from water raised the melting point to 132–133°.

Anal. Calcd. for $C_{11}H_{11}NO_2$: C, 69.82; H, 5.86. Found: C, 68.96; H, 6.06.

The nitroso derivative melted at 135° (lit.,[13] 135°).

13. Ethyl α-cyano-β-(3-indole)-propionate was prepared by a procedure similar to that of (10). The crude material, obtained in 87% yield, was an oil which could not be crystallized. However, saponification with alcoholic potassium hydroxide gave α-carboxy-β-(3-indole)-propionic acid, m. p. 176°, which was shown by mixed melting point to be identical with the acid obtained in (11).

14. Ethyl α-Aceto-β-(3-indole)-propionate was obtained as an oil when acetoacetic ester was used in the procedure of (10). The dinitrophenylhydrazone prepared from the oil melted at 133.5°.

Anal. Calcd. for $C_{21}H_{21}N_5O_6$: C, 57.39; H, 4.82. Found: C, 57.51; H, 5.02.

15. 3-Indoleacetic Acid.—To a solution of potassium silver cyanide, prepared from 4.25 g. (0.025 mole) of silver nitrate and 3.2 g. (0.05 mole) of potassium cyanide in 28 cc. of water, was added 8 g. (0.025 mole) of gramine methiodide. The solution was heated under reflux for one and one-half hours, during which period trimethylamine was steadily evolved. The cooled solution was extracted with three 30-cc. portions of ether. Removal of the ether from the dried extracts gave a light red oil (4.8 g.). This oil was added to 75 cc. of 20% aqueous potassium hydroxide and the mixture was heated under reflux for ten hours. The acid, recovered by acidification of the cold mixture, was dissolved in 75 cc. of hot water and, after decolorization, was allowed to crystallize. The pure acid weighed 2 g. (46%), m. p. 164.5–165.5°.

Anal. Calcd. for $C_{10}H_9NO_2$: C, 68.56; H, 5.18. Found: C, 68.57; H, 5.20.

In an experiment in which gramine methiodide was treated with twice the theoretical amount of potassium cyanide in boiling water for four hours, 3-indoleacetic acid was obtained in only 11.4% yield.

(13) Beilstein, "Handbuch der organische Chemie," Julius Springer, Berlin, 1935, ed. 4, Vol. XXII, p. 69.

16. 3-Dimethylaminomethylindole and Malonic Ester.—A mixture of 17.4 g. (0.1 mole) of 3-dimethylaminomethylindole and 49 g. (0.3 mole) of malonic ester was warmed until complete solution resulted and then approximately 0.05 g. (0.002 mole) of sodium was added. This mixture was heated in an oil-bath at 120° for five hours, during which time a slow evolution of dimethylamine occurred. At the end of five hours another 0.05 g. of sodium was added and the mixture was heated at 130° for nineteen hours. Another 0.05 g. of sodium was added and the mixture was heated at 150° for seventeen hours. The evolution of amine had become almost imperceptible. After the addition of another 0.05 g. of sodium and heating at 150° for twelve hours, heating of the now slightly amber solution was discontinued.

The reaction mixture was poured into 100 cc. of water containing 10 cc. of concentrated hydrochloric acid and extracted with three 150-cc. portions of ether. The combined ether extracts were washed with two 150-cc. portions of 10% sodium bicarbonate solution and dried over anhydrous sodium sulfate. After removal of the ether on a steam-cone the residue was heated under reduced pressure (140° (3 mm.)) to remove the excess malonic ester. The residue, 22 g. (76%) of a red viscous oil, did not crystallize on standing in the icebox overnight. About 0.5 cc. of this oil was extracted with low-boiling petroleum ether and allowed to stand for two days. This partly crystalline mixture was transferred to a clay plate which absorbed the oil; the solid melted at 59–61.5°. After two recrystallizations from ethanol and water the ethyl α-carbethoxy-β-(3-indole)-propionate melted at 62°; a mixture with a known sample also melted at 62°.

The remaining oil (about 21.5 g.) was extracted with 50 cc. of low-boiling petroleum ether and added to a solution of 22 g. of potassium hydroxide in 220 cc. of 90% ethanol. The solution was refluxed for three hours. Most of the ethanol was removed by distillation from the steam-bath and steam was passed into the residue until about 500 cc. of distillate had collected. The residual solution (volume, 250 cc.) was separated from a small amount of insoluble material, cooled, and acidified with 60 cc. of concentrated hydrochloric acid. The red solid which separated when the acidified mixture was stored in an icebox for twenty-four hours was collected and dissolved in 100 cc. of water containing 3 g. of sodium hydroxide and about 0.01 g. of sodium hydrosulfite. The solution was decolorized with charcoal and acidified. The crude α-carboxy-β-(3-indole)-propionic acid, m. p. 172–175° (dec.), weighed 9.6 g. (41%). A sample recrystallized from water melted at 178° (dec.) and a mixed melting point with a known sample showed no depression.

Summary

Benzyldimethylphenylammonium chloride and other quaternary ammonium salts containing a benzyl group are shown to react with the sodium derivatives of malonic ester and acetoacetic ester to yield C-benzyl derivatives. Diethyl benzylmalonate is obtained in approximately 80% yields by this method.

The method of C-alkylation is applied to the synthesis of a number of substances containing the β-indolemethylene group; the methiodide of gramine (β-dimethylaminomethylindole), easily prepared from indole, formaldehyde, dimethylamine and methyl iodide, is used as the alkylating agent. Malonic, acetoacetic and cyanoacetic esters are alkylated in this way. The products from malonic and cyanoacetic esters, by hydrolysis and decarboxylation, are converted to β-indolepropionic acid. β-Indoleacetic acid is prepared by hydrolysis of the nitrile obtained

from gramine methiodide and potassium silver cyanide.

The tertiary amine (gramine) reacts with malonic ester in the presence of a small amount of the sodium derivative of the ester to yield ethyl α-carbethoxy-β-(3-indole)-propionate. However, the yield of alkylation product obtained from the amine is inferior to that obtained from the amine methiodide.

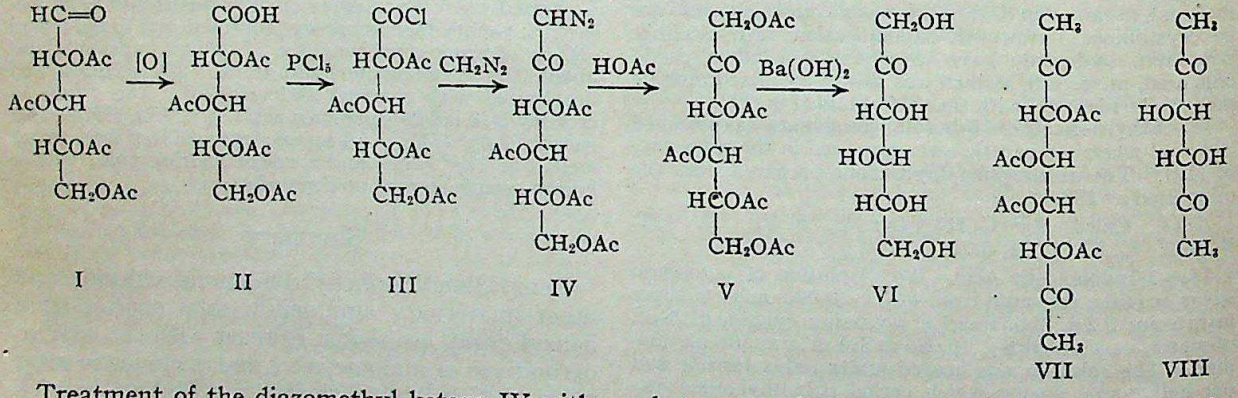
The Action of Diazomethane upon Acyclic Sugar Derivatives. VI.[1] D-Sorbose[2]

BY M. L. WOLFROM, S. M. OLIN AND EVAN F. EVANS[3]

In continuation of our work upon the action of diazomethane upon acyclic sugar derivatives, we have synthesized 1-desoxy-1-diazo-*keto*-D-sorbose tetraacetate (IV) from D-xylonyl chloride tetraacetate (III). D-Xylonic acid tetraacetate (II) was prepared by the oxidation of *aldehydo*-D-xylose tetraacetate (I) according to the procedure reported by Major and Cook.[4] We describe an improved preparation of *aldehydo*-D-xylose tetraacetate[5] from D-xylose diethyl mercaptal tetraacetate, utilizing the general techniques of Wolfrom and Konigsberg.[6] The constants of Major and Cook[4] for I (m. p. 90–91°, spec. rot. +22.5° in absolute chloroform, for the L-form) have been verified. The rotation value differs appreciably from that previously reported[5] (m. p. 87–89°, spec. rot. −16° in chloroform, for the D-form). D-Xylonyl chloride tetraacetate has apparently not been recorded, although Major and Cook[7] described the D,L form.



Treatment of the diazomethyl ketone IV with acetic acid yielded *keto*-D-sorbose pentaacetate, enantiomorphic with the substance prepared by Arragon[8] and, nearly simultaneously, by Schlubach and Vorwerk[9] through the direct acetylation of L-sorbose. The acyclic nature of *keto*-L-sorbose pentaacetate was demonstrated by Cramer and Pacsu[10] and shortly later by Arragon.[11] We report herein a crystalline oxime of *keto*-L-sorbose pentaacetate. To our knowledge, this is the first nitrogen condensation product obtained for an acyclic or *keto* form of a ketohexose pentaacetate, previous attempts[10,12] having been unsuccessful. We record also the D,L form of *keto*-sorbose pentaacetate.

Careful saponification of *keto*-D-sorbose pentaacetate led to the synthesis of D-sorbose. Previous saponifications of the enantiomorphic derivative have been recorded by Schlubach and Vorwerk[9] and by Arragon.[11] This synthesis of D-sorbose from D-xylose compares with the synthesis of L-sorbose reported by Gätzi and Reichstein.[13] These workers oxidized diethylidene-(*levo*)-sorbitol to diethylidene-L-xylonic acid. From the crystalline acid chloride of the latter substance a sirupy diazomethyl ketone was obtained which on acid hydrolysis yielded crystalline L-sorbose. D-Sorbose (earlier psuedo-tagatose, *l*-sorbose) was first synthesized by Lobry de Bruyn and Alberda van Ekenstein[14] by the action of dilute aqueous alkali upon D-galactose. It was later formed from D-gulose and D-idose

by aqueous alkali[15] and by pyridine.[16] Fischer and Baer[17] have demonstrated the formation of D-sorbose (and D-fructose) by the action of dilute alkali upon D-glyceraldehyde.

We include herein the synthesis of a derivative of a dicarbonyl-octose. The diazomethyl ketone obtained[18] from mucyl dichloride tetraacetate and designated 1,8-bisdiazomucyldimethane tetraacetate, was reduced with hydriodic acid according to the procedure of Wolfrom and Brown,[19] yielding the crystalline substance VII, designated mucyldimethane tetraacetate. In the C_6 series, a dicarbonyl hexose of a similar type has been isolated in crystalline form by Micheel,[20] who employed an entirely different method of synthesis. In this excellent work, the long-known 1,6-dichloro-D-mannitol[21] was converted through a series of crystalline intermediates into D-(*levo*)-tartaryldimethane, VIII, designated 1,4-dimethyl-1,4-diketo-tetrose by Micheel and Horn.

All compounds described herein were obtained in crystalline form.

Experimental

Improved Preparation of *aldehydo*-D-Xylose Tetraacetate (I).[22]—To a solution of 40 g. of mercuric chloride in 100 cc. of acetone in a 1-liter 3-necked flask was added 5 cc. of water and 25 g. of powdered cadmium carbonate and the mixture was stirred vigorously for ten minutes. To this was added a solution of 15 g. of D-xylose diethyl mercaptal tetraacetate[5] in 100 cc. of acetone and the resulting mixture was maintained at room temperature and under vigorous mechanical stirring for twelve hours, whereupon it was filtered and the solvent removed from the filtrate under reduced pressure and in the presence of a little fresh cadmium carbonate. The residual cake was extracted thrice with 75-cc. portions of warm chloroform and the combined extracts washed with 10% aqueous potassium iodide (to the disappearance of the red complex first formed) and then with water (to a negligible halide test with silver nitrate). The sirup obtained on solvent removal (reduced pressure) from the washed and dried extract was crystallized from anhydrous ether; yield 6 g. (3 crops), m. p.[23] 87–89°, spec. rot. −22.5° (20°, *c* 2.5, abs. $CHCl_3$, D line). Further purification from anhydrous ether yielded pure *aldeydo*-D-xylose tetraacetate; m. p. 90–91°, spec. rot. −23.3° (22°, *c* 4, abs. $CHCl_3$, D line). These constants are in agreement with those reported by Major and Cook[4] (m. p. 90–91°, spec. rot. +22.5° in abs. $CHCl_3$ for the enantiomorph) but differ in rotation from those reported[5] previously from this Laboratory (m. p. 88–89°, spec. rot. −16° in $CHCl_3$). The melting point of 90–91° and the specific rotation of −23° ($CHCl_3$) may then be accepted for *aldehydo*-D-xylose tetraacetate.

Anal. Calcd. for $C_5H_6O_5(CH_3CO)_4$: CH_3CO, 12.6 cc. 0.1 *N* NaOH per 100 mg. Found: CH_3CO, 12.5 cc.

(23) All melting points herein reported were taken in Pyrex melting point tubes.

D-Xylonyl Chloride Tetraacetate (III).[24]—D-Xylonic acid tetraacetate (3.0 g.), prepared by the oxidation of *aldehydo*-D-xylose tetraacetate according to the procedure of Major and Cook,[4] was shaken for one hour in ether (160 cc.) and phosphorus pentachloride (2.0 g.). The product (2.0 g.) crystallized from the filtered reaction mixture on standing overnight at icebox temperature and a further quantity (0.6 g.) was obtained from the mother liquor on addition of petroleum ether; total yield 2.6 g. (89%). Pure material was obtained on recrystallization from anhydrous ether; m. p. 72–73°, spec. rot. −14° (25°, *c* 5, abs. $CHCl_3$, D line). The substance crystallized in prismatic crystals.

Anal. Calcd. for $C_5H_6O_5Cl(CH_3CO)_4$: Cl, 10.05; saponification value (5 equiv.), 14.2 cc. 0.1 *N* NaOH per 100 mg. Found: Cl, 9.80; saponification value, 14.0 cc.

1-Desoxy-1-diazo-*keto*-D-sorbose Tetraacetate (IV).[24]—The diazomethane used in this work was prepared by the method of Werner[25] as modified by Arndt.[26] The ethereal solution of diazomethane was dried over potassium hydroxide pellets and was used at concentrations of 0.015–0.025 g. of diazomethane per cc. of solution. The concentration was determined by titration against benzoic acid.[27]

A solution of D-xylonyl chloride tetraacetate (8.3 g.) in sodium-dried ether (30 cc.) was poured slowly with stirring into 100 cc. of a dry, ether solution of diazomethane containing 2.3 g. of diazomethane. There was a vigorous evolution of nitrogen gas during the addition, and the crystallization of the reaction product, which began almost immediately after the addition of the acid chloride was complete, was allowed to complete itself at icebox temperature; yield 7.7 g. (92%), m. p. 122–124°, spec. rot. +43° (25°, *c* 5, abs. $CHCl_3$, D line). Pure material was obtained on recrystallization from five parts of acetone by the addition of like volumes each of ether and petroleum ether; m. p. 124.5–125.5°, spec. rot. +44.5° (25°, *c* 5, abs. $CHCl_3$, D line).

This diazomethyl ketone formed individual canary-yellow crystals that were insoluble in ether and petroleum ether but were very soluble in acetone, chloroform and alcohol.

Anal. Calcd. for $C_{14}H_{18}O_8N_2$: C, 46.93; H, 5.06; N, 7.82. Found: C, 46.94; H, 5.09; N, 7.33.

***keto*-D-Sorbose Pentaacetate (V).**[24]—A solution of 1-desoxy-1-diazo-*keto*-D-sorbose pentaacetate (2.0 g.) in glacial acetic acid (25 cc.) was refluxed until the cessation of nitrogen evolution (*ca.* twenty minutes). The crystalline solid obtained on pouring the cooled solution onto a mixture of ice and water and partially neutralizing the acetic acid with sodium bicarbonate, was removed by filtration and washed with water; yield 1.6 g. (73%), m. p. 91–94°, spec. rot. −1.9° (25°, *c* 4, abs. $CHCl_3$, D line). Pure material (elongated prisms) was obtained on recrystallization from methanol (decolorizing carbon)–water; m. p. 97.5–98.5°, spec. rot. −2.5° (25°, *c* 4, abs. $CHCl_3$, D line). For the enantiomorph, the following constants are reported: m. p. 99°, spec. rot. +2.8° (20°, $CHCl_3$, 5780 Å.)[8,11]; m. p. 96.5–97.5°, spec. rot. +2.9° (20°, *c* 2, $CHCl_3$, D line).[9]

Anal. Calcd. for $C_6H_7O_6(CH_3CO)_5$: C, 49.23; H, 5.68; CH_3CO, 12.8 cc. 0.1 *N* NaOH per 100 mg. Found: C, 49.16; H, 5.66; CH_3CO, 12.8 cc.

***keto*-D,L-Sorbose Pentaacetate.**[24]—Equal weights (1.0 g. of each) of *keto*-D-sorbose pentaacetate and *keto*-L-sorbose pentaacetate[8,9] were crystallized from methanol (15 cc.) and water (25 cc.); yield 1.8 g. (90%), m. p. 83–84° (unchanged on further crystallization), spec. rot. 0° (25°, *c* 2, abs. $CHCl_3$, D line).

Anal. Calcd. for $C_6H_7O_6(CH_3CO)_5$: C, 49.23; H, 5.68; CH_3CO, 12.8 cc. 0.1 *N* NaOH per 100 mg. Found: C, 49.16; H, 5.70; CH_3CO, 12.9 cc.

Oxime of *keto*-L-Sorbose Pentaacetate.[28]—An amount of 5 g. of *keto*-L-sorbose pentaacetate[8,9] was dissolved in 250 cc. of boiling water. Hydroxylamine hydrochloride (2.5 g.) and potassium acetate (5 g.) were added to the hot solution which was then allowed to cool slowly to room temperature. Upon cooling to 0° and scratching the sides of the flask, the product crystallized; yield 1.3 g., m. p. 113–114°, spec. rot. −42° (23°, *c* 3, abs. $CHCl_3$, D line). An additional 0.4 g. was obtained by extraction of the mother liquor with chloroform. The constants were unaltered after recrystallization from solution in acetone–ether by the addition of petroleum ether.

Anal. Calcd. for $C_6H_8O_6N(CH_3CO)_5$: C, 47.41; H, 5.72; N, 3.46; CH_3CO, 12.3 cc. 0.1 *N* NaOH per 100 mg. Calcd. for $C_6H_9O_6N(CH_3CO)_4$: C, 46.28; H, 5.83; N, 3.86; CH_3CO, 11.0 cc. Found: C, 47.40; H, 5.88; N, 3.68; CH_3CO (O-acetyl[29]), 12.1 cc.

D-Sorbose (VI) from *keto*-D-Sorbose Pentaacetate.[28]—An amount of 2.43 g. of *keto*-D-sorbose pentaacetate was added to 100 cc. of 0.6 *N* barium hydroxide solution, previously cooled to *ca.* 5°. With occasional shaking, the crystals dissolved in about thirty minutes. The solution was kept for one hour longer at *ca.* 5° and then was saturated with carbon dioxide and the precipitated barium carbonate was removed by filtration. A slight excess of 2 *N* sulfuric acid was added slowly and the barium sulfate removed by filtration through a bed of Super-Cel (Johns-Manville). The excess sulfuric acid was then removed exactly with barium hydrate and the filtered solution was concentrated under reduced pressure at 40° to a sirup which crystallized spontaneously. The crystalline mass was stirred with 10 cc. of ethanol for filtration; yield 0.90 g. (80%), m. p. 158–160°, spec. rot. +40.5° (26°, *c* 3, H_2O, D line). Pure material was obtained on one recrystallization from water by the addition of absolute ethanol; m. p. 160–162°, spec. rot. +43 (24°, *c* 3, H_2O, D line, no significant mutarotation). For D-sorbose, Alberda van Ekenstein and Blanksma[15] reported the constants: m. p. 165°, spec. rot. +43° (*c* 1, H_2O, D line). For the enantiomorphic L-sorbose, Schlubach and Vorwerk[9] have recorded the constants: m. p. 159–161°, spec. rot. −43° (20°, *c* 2, H_2O, D line). Pigman and Isbell[30] record a small, complex mutarotation for L-sorbose.

Mucyldimethane Tetraacetate (VII).[24]—To a chloroform (40 cc.) solution of 1,8-bisdiazomucyldimethane tetraacetate[18] (2.00 g.), in a separatory funnel, was added 8 cc. of 47% hydriodic acid. The mixture was shaken until cessation of nitrogen evolution, diluted with water (40 cc.) and the chloroform layer removed and washed successively with water, aqueous sodium thiosulfate and water. A white crystalline solid was obtained on solvent removal from the dried chloroform solution; yield 1.60 g., m. p. 200–204°. Pure material was obtained on recrystallization from acetone by the addition of absolute ethanol; yield 1.35 g. (78%), m. p. 204–206°. The substance gave a positive iodoform test (iodoform identified by m. p. and mixed m. p.).

Anal. Calcd. for $C_{16}H_{22}O_{10}$: C, 51.21; H, 5.91. Found: C, 51.25; H, 5.85.

Summary

1. An improved demercaptalation procedure for *aldehydo*-D-xylose tetraacetate (I) is described.

2. The tetraacetates of D-xylonyl chloride (III) and of 1-desoxy-1-diazo-*keto*-D-sorbose (IV) have been synthesized. Reaction of the latter with acetic acid led to the synthesis of *keto*-D-sorbose pentaacetate (V), from which D-sorbose (VI) was obtained on saponification.

3. An oxime of *keto*-L-sorbose pentaacetate has been obtained.

4. *keto*-D,L-Sorbose pentaacetate is described.

5. Hydriodic acid reduction of 1,8-bisdiazomucyldimethane tetraacetate yielded mucyldimethane tetraacetate (VII).

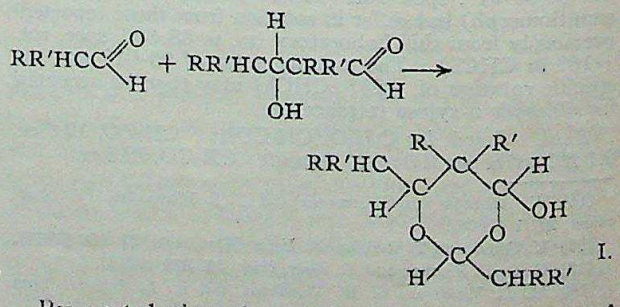
The Aldol Condensation. III. Aldol-aldehyde Addition Products and their Derivatives

BY ROBERT H. SAUNDERS AND M. J. MURRAY

Späth, Lorenz and Freund[1] and Hanschke[2] have recently independently reported the isolation of an addition product of acetaldehyde to aldol, together with the acetate and benzoate of this compound. While this work was still unknown to us, we reported an analogous compound formed by the reaction of isobutyraldehyde with its aldol.[3] Under the circumstances we are reporting the results of our research to date and are concluding our work on this phase of the problem.

The following equation shows the addition of aldehyde to its aldol to form a 1,3-dioxane derivative



I.

By acetylating the crude reaction mixtures of aldolized aldehydes related to acetaldehyde, propionaldehyde, *n*- and isobutyraldehydes we obtained the 6-acetoxy-1,3-dioxanes in about 70% yields. In one instance, namely, that from isobutyraldehyde, we also prepared the 6-methoxy-1,3-dioxane. Physical properties for

seven of these compounds are listed in Table I. The R, R′ substituents refer to groups in formula I, and X refers to the group attached to oxygen on position 6.

It is interesting to observe the action of aldolizing conditions on the aldol from isobutyraldehyde: namely, 2,2,4,4-tetramethylaldol. This aldol, of course, is incapable of further aldol condensation and in the presence of cold, dilute alkali immediately begins to dissociate into the aldehyde-aldol equilibrium mixture. However, also catalyzed by base, the isobutyraldehyde formed in this dissociation rapidly reacts with the aldol to produce 2,4-diisopropyl-5,5-dimethyl-6-hydroxy-1,3-dioxane (H) whose properties were described in a previous communication.[3] This reaction is accompanied by 1,3-dioxane formation between two molecules of the aldol, forming a white solid which is apparently the same material as the paraldol that deposits slowly from 2,2,4,4-tetramethylaldol samples.

The Raman spectra of the 1,3-dioxanes which we have prepared are shown in Table II. The dioxane from *n*-butyraldehyde was the only one encountered that could not be distilled without dissociation. Its spectrum is rather incomplete since the fluorescent material present, most of which was removed with charcoal, did not permit the long exposures needed to obtain good spectrograms of this compound. For the Raman spectrum of H see reference 3. The spectra of A and B will be found listed under the headings "acetaldol" and "propionaldol" in a previous communication.[4]

There are several interesting features of these spectra which it will be well to point out, the first of which concerns the symmetrical breathing frequency of a flexible ring structure such as is found in 1,3-dioxane. This frequency in 1,3-dioxane itself lies at 834 cm.$^{-1}$ and is very intense, certainly the strongest line in the spectrum.[5] As the symmetry of the ring is destroyed by the substitution of different groups, the intensity of this line decreases and finally in highly unsymmetrical compounds ceases to be significant for identification purposes. In the present group of compounds the ring frequency produces a fairly strong line only for the 1,3-dioxane from acetaldehyde and for its acetate.

The compounds which were made from isobutyraldehyde contain neopentyl skeletons. A neopentyl group will produce a highly symmetrical vibration, somewhat similar to the breathing frequency of a ring structure, which gives rise to an intense Raman line in the region from 750 to 800 cm.$^{-1}$. The neopentyl vibration in H, F and G produces a strong line at about 790 cm.$^{-1}$ in

each case; while this vibration for 2,2,4,4-tetramethylaldol, where the neopentyl group is not part of a ring system, drops to 770 cm.$^{-1}$. These two neopentyl lines were extremely useful in following the formation of H in the mixtures of isobutyraldehyde and 2,2,4,4-tetramethylaldol.[3]

The Raman lines in the 1750 cm.$^{-1}$ region for the acetates are due, of course, to the vibrations of the ester carbonyl group. It is interesting to note the similarity of the spectra of these acetates to the spectra of the parent 6-hydroxy-1,3-dioxanes.

Experimental

Preparation of the 6-Acetoxy-1,3-dioxanes.—The parent aldehyde was aldolized as described previously,[3] and the ether separated from the dried reaction product at the water pump. Equal volumes of this crude 1,3-dioxane, anhydrous pyridine, and acetic anhydride were mixed, and the reaction mixture allowed to stand overnight at room temperature. The acetic acid, pyridine, and excess acetic anhydride were then distilled off and the product fractionated under reduced pressure.

Preparation of G.—To 300 g. of 1% anhydrous methyl alcoholic hydrochloric acid was added 60 g. of H. This reaction mixture was sealed up in a 500-cc. flask for eighteen days. At the end of this time the reaction mixture was neutralized, diluted with water, and the organic layer fractionated under reduced pressure. Nineteen grams of the methyl ether was obtained; for physical properties see Table I.

The Aldolization of 2,2,4,4-Tetramethylaldol.—The aldolization of 14.4 g. of 2,2,4,4-tetramethylaldol was performed by the method previously described.[3] The crude product was washed well with water, dried, and freed of ether at the water pump. Distillation of this material produced 8.7 g. of H, and 3.5 g. of a white solid remained in the distilling flask. This white solid after two recrystallizations from petroleum ether melted at 105–107° which is the melting point found for the paraldol of 2,2,4,4-tetramethylaldol after recrystallization from the same solvent. This paraldol does not melt sharply and has a different melting point (within a range of 15°) when recrystallized from different solvents. This is probably due to the presence of several isomeric forms.

The apparatus and experimental technique for obtaining the Raman spectra are the same as were used in previous work.[3] The compounds studied gave very weak spectra so that long exposures were necessary.

Summary

1. The acetates of 2,4-diethyl-5-methyl-6-hydroxy-1,3-dioxane and 2,4-dipropyl-5-ethyl-6-hydroxy-1,3-dioxane, and the acetate and methyl ether of 2,4-diisopropyl-5,5-dimethyl-6-hydroxy-1,3-dioxane have been prepared and characterized.

2. The Raman spectra of the above compounds, of 2,4-dipropyl-5-ethyl-6-hydroxy-1,3-dioxane, and of 2,4-dimethyl-6-acetoxy-1,3-dioxane are reported.

3. It has been shown that the main product from the aldolization of 2,2,4,4-tetramethylaldol is 2,4-diisopropyl-5,5-dimethyl-6-hydroxy-1,3-dioxane.

A Study of the Haloform Reaction

BY RICHARD T. ARNOLD, ROBERT BUCKLES[1] AND JANET STOLTENBERG

Except for halogen-containing intermediates,[2,3] no neutral compounds have been isolated as products from the haloform reaction. In order to establish the structure of the methyl ketone (I) obtained from 5-methoxytetralin by means of the Friedel–Crafts reaction, the substance was treated with an aqueous methanol hypochlorite solution. To our surprise there was obtained, in addition to the small amount of expected carboxylic acid (II), a considerable quantity of a neutral, halogen-free solid whose analysis and molecular weight indicated the formula $C_{13}H_{16}O_3$. An 83% yield of this same compound was obtained if hypobromite solutions were employed. The method of preparation and the constitution of the starting materials permit only two reaonable structures for this formula, namely, III and IV.

It was at first supposed that the neutral substance was the ketol (IV) formed by hydrolysis of the phenacyl chloride which is presumably the first intermediate in the haloform reaction.[2] That this supposition was incorrect was indicated by the stability of the substance toward potassium permanganate, lead tetraacetate and periodic acid. Furthermore, no methane was liberated in the Zerewitinoff test.

Proof of the ester structure III was established by saponification to the acid II and the reconversion of II into III by treatment with diazomethane.

It seems surprising that methyl esters have not been reported previously as products of the haloform reaction since the procedure employed above is a typical one. We now believe that in aqueous methanol solution methyl esters are always formed but are so readily hydrolyzed that their isolation is difficult. In the experiment reported here, the temperature of the reaction mixture was not permitted to rise and the insoluble methyl ester crystallized from the solution as it was formed.

When the haloform reaction was carried out in aqueous dioxane solution (to prevent ester formation), a chlorine-containing acid (V) was formed as the sole product. That this substance was not formed during the haloform reaction but in-

stead resulted from a rapid chlorination of the expected acid II (by excess hypochlorite) during the isolation process was shown in two ways. First, only compound II resulted if the excess hypochlorite were destroyed with acetone before acidification of the reaction mixture, and, second, an independent experiment proved that II was chlorinated (to give V) at an exceedingly rapid rate in acidic hypochlorite solutions.

Molecules having the $-\overset{O}{\overset{\|}{C}}-CCl_3$ group often react in a manner analogous to that of acid chlorides. The work of Houben and Fischer[4] indicates that trichloromethyl ketones react more rapidly with alcohols than with water in the presence of an alkaline catalyst. This difference in reaction

$$R-\overset{O}{\overset{\|}{C}}-CCl_3 + R'OH \longrightarrow R-\overset{O}{\overset{\|}{C}}-OR' + CHCl_3$$

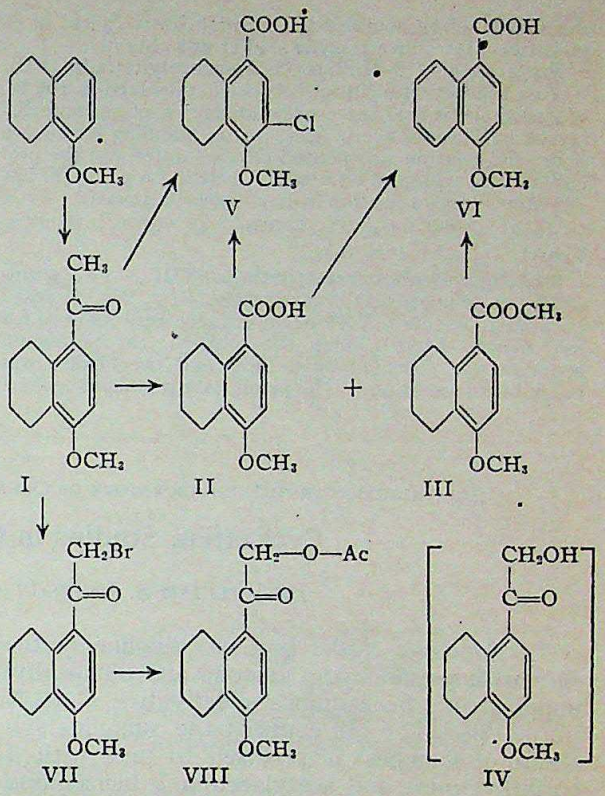
rate is remarkably similar to that observed in the Schotten–Baumann reaction of acid chlorides.[5]

The pseudo-halogen nature of the $-C-Cl_3$ group is also shown by the transformation of trichloroacetic acid esters into carbonates by reaction with alcohols.[6]

$$Cl_3-C\overset{O}{\overset{\|}{C}}-OR + R'OH \longrightarrow R'-O-\overset{O}{\overset{\|}{C}}-O-R + CHCl_3$$

An attempt to prepare IV was unsuccessful because of our inability to isolate a pure product from the hydrolysis of the acetate VIII.

The structure of the starting ketone employed in the haloform reaction was established by the dehydrogenation of III to 4-methoxy-1-naphthoic acid (VI). A reaction diagram is given below.



Experimental

5-Acetyl-8-methoxytetralin (I).—Into a 500-cc. three necked flask fitted with stirrer and reflux condenser there was placed a mixture of 200 cc. of redistilled nitrobenzene and 90 g. of aluminum chloride. While the temperature of this mixture was held at 0–5° by means of an ice-bath, 26 g. of acetic anhydride and 39 g. of 5-methoxytetralin were added at such a rate that the temperature did not exceed 5°. After four hours the reaction mixture was decomposed with ice and hydrochloric acid. The nitrobenzene was removed by steam distillation, and from the residue there was obtained 33.3 g. of ketone; b. p. 164–166° (8 mm.). The oxime prepared in the usual manner melted at 136–139° with decomposition.

Anal. Calcd. for $C_{13}H_{17}O_2N$: C, 71.2; H, 8.7. Found: C, 71.5; H, 7.8.

Preparation of 5-Carbomethoxy-8-methoxytetralin (III).—To a solution of 15 g. of calcium hypochlorate in 60 cc. of hot water was added a warm solution of 10.5 g. of potassium carbonate and 2 g. of potassium hydroxide in 30 cc. of water. After stirring thoroughly the mixture was filtered and the precipitate was washed with 12 cc. of water. One gram of the above-mentioned ketone was dissolved in 30 cc. of methanol and transferred to a separatory funnel. The hypochlorite solution was added slowly in small portions and following each addition the mixture was thoroughly shaken and cooled from time to time in an ice-bath. As soon as the hypochlorite addition was complete an oily solid formed. The solution was extracted with ether and the ether layer was evaporated. Crystallization of the residue first from aqueous methanol and finally from dilute acetic acid gave the methyl ester; m. p. 63–64°; yield 0.87 g. (80%).

Anal. Calcd. for $C_{13}H_{16}O_3$: C, 70.90; H, 7.26. Found: C, 70.96; H, 7.09.

From the basic solution there was obtained 0.1 g. of 8-methoxy-5-tetralincarboxylic acid; m. p. 215.5–216° after recrystallization from methanol.

Anal. Calcd. for $C_{12}H_{14}O_3$: C, 69.9; H, 6.8. Found: C, 70.5; H, 7.2.

This acid was also formed quantitatively by the saponification of the methyl ester.

4-Methoxy-1-naphthoic Acid.—Eight-tenths of a gram of 8-methoxy-5-tetralin-carboxylic acid was treated with excess diazomethane in ether and when the evolution of nitrogen ceased the ether was evaporated. The residue was heated with 0.25 g. of sulfur for two hours at 250°. Extraction of the residue with ether, filtration and evaporation of the ether produced a residue which was readily saponified with aqueous-alcoholic sodium hydroxide. Acidification of the basic solution gave 4-methoxy-1-naphthoic acid; m. p. 243.5–244° (after recrystallization from ethanol). This sample was identical with an authentic specimen.[7]

7-Chloro-8-methoxy-5-tetralincarboxylic Acid (V).—The hypochlorite solution was prepared as described above except that 6 g. of potassium hydroxide was used. The hypochlorite was added to a solution of 1 g. of the ketone (I) dissolved in 30 cc. of dioxane. The mixture was shaken continuously for ten minutes and extracted with ether. Acidification of the aqueous layer resulted in the precipitation of an acid which melted at 154–156° after recrystallization from aqueous ethanol. A qualitative test for chlorine was positive.

Anal. Calcd. $C_{12}H_{13}O_3Cl$: C, 59.9; H, 5.4. Found: C, 60.08; H, 5.44.

If in the above experiment the excess hypochlorite were

destroyed before acidification, a quantitative yield of 8-methoxy-3-tetralincarboxylic acid II was obtained.

Preparation of 8-Methoxy-5-bromoacetyltetralin (VII).—To a solution of 6.5 g. of ketone (I) dissolved in 100 cc. of glacial acetic acid there was added 5.1 g. of bromine dissolved in 25 cc. of acetic acid. After standing for twelve hours the solution was poured into ice-water and the precipitate was collected on a filter; weight 4.5 g.; m. p. 73–74° after recrystallization from aqueous acetic acid.

Anal. Calcd. for $C_{13}H_{15}O_2Br$: C, 55.1; H, 5.3. Found: C, 55.15; H, 5.51.

8-Methoxy-5-acetoxyacetyltetralin (VIII).—Two grams of the aforementioned bromoketone (VII), 2 g. of fused potassium acetate and 15 cc. of ethanol were refluxed for five hours. After cooling the solution, the potassium bromide was collected on a filter and the filtrate was poured into ice-water. The precipitate was dried and recrystallized first from petroleum ether (90–100°) and finally from dilute alcohol; m. p. 91–92°; yield 90%.

Anal. Calcd. for $C_{15}H_{18}O_4$: C, 68.7; H, 6.87. Found: C, 68.88; H, 6.79.

This compound reduced Fehling solution but could not be hydrolyzed to give a pure compound.

Summary

1. It has been shown that methyl esters may be obtained directly as products of the haloform reaction.

2. These esters probably result from the action of methanol on the trihalomethyl ketones which are intermediates in this reaction.

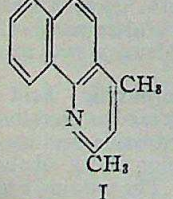
Cyclization Studies in the Benzoquinoline Series

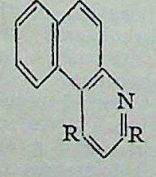
BY WILLIAM S. JOHNSON AND FREDERICK J. MATHEWS[1]

The Doebner–Miller type of quinoline synthesis[2a] with paraldehyde, acetone and β-naphthylamine gives a benzoquinoline derivative, $C_{15}H_{13}N$, m. p. 126–127°.[3] In contrast the quinoline synthesis of Combes[4] is reported to give with β-naphthylamine and acetylacetone a benzoquinoline of the same molecular formula, but m. p. 66–67°.[5] Both syntheses are known to be quite general for the production of quinoline derivatives. Thus from α-naphthylamine the Doebner–Miller and Combes' methods give bases[3,5] which are shown in the present work to be identical (formula I). The discrepancy regarding the benzoquinolines derived from β-naphthylamine presents a problem in proof of structures which is considered in this communication.

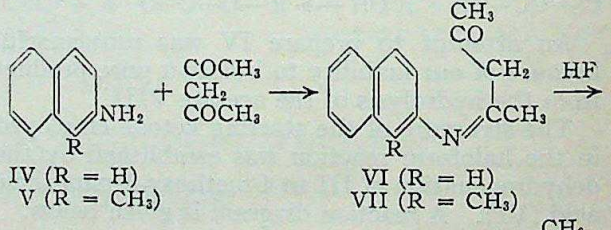
Previous studies suggest a similarity in mechanism—particularly at the cyclization step—between the Doebner–Miller and Skraup syntheses.[2] Since the latter is known[6] to give the angular base, benzo[f]quinoline (II) from β-naphthylamine, it would seem reasonable for Reed's 127° base to be 1,3-dimethylbenzo[f]quinoline (III). If the 127° base is III, the base reported by Combes could be 2,4-dimethylbenzo[g]quinoline (VIII) arising from the alternate—and indeed unexpected[7]—linear cyclization into the 3-position of the naphthalene nucleus. That these postulates are correct is shown below.



I

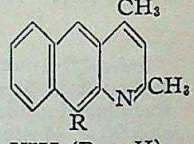


II (R = H)
III (R = CH_3)



IV (R = H)
V (R = CH_3)

VI (R = H)
VII (R = CH_3)



VIII (R = H)
IX (R = CH_3)

When the anil VI, which could be obtained in excellent yield from β-naphthylamine and acetylacetone, was treated with warm concentrated sulfuric acid according to the procedure of Combes,[5] only a small yield (4%) of basic material, m. p. 128.5–129° cor. (pure), was obtained. This substance proved to be identical with material which was prepared by the procedure of Reed.[3] The main product of the reaction was the monosulfonic acid (91% yield) of the expected base of Combes. The sulfonic acid (position of acid group unknown) could be hydrolyzed with dilute sulfuric acid at 220° to give the desired benzoquinoline. It was found, however, that under

(6) Skraup and Cobenzl, *Monatsh.*, **4**, 436 (1883).

(7) There is a general tendency for 2,1-cyclization to occur in the naphthalene nucleus. In the case of the Skraup reaction, for example, this tendency is so strong that a methyl group at position-1 prevents the reaction while a bromine atom or a nitro group is displaced to give 2,1 instead of 2,3 cyclization [Lellmann and Schmidt, *Ber.*, **20**, 3154 (1887); Marckwald, *Ann.*, **274**, 331 (1893); **279**, 1 (1894)].

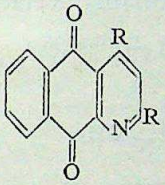
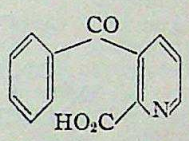
considerably milder cyclization conditions (two minutes below 60° instead of one-half hour at 100°) the sulfonation reaction could be largely eliminated and the base was produced directly from VI in yields up to 83%. The pure substance melted at 93–93.8° cor.[8] The balance of the material consisted of a small amount of the higher-melting isomer and of the sulfonic acid already mentioned. When the anil (VI) was treated with hydrogen fluoride,[9] the pure cyclized material (VIII) was produced in superior yield (96%) and to the exclusion of the angular isomer (III).[10]

It is noteworthy that hydrogen fluoride failed to cyclize the isomeric anil derived from α-naphthylamine.

In an effort to establish the structure, the 93° base was oxidized with potassium dichromate in acetic acid. A quinone (X) was produced which resembled anthraquinone in that it gave a deep colored vat with alkaline hydrosulfite and on reductive acetylation formed a crystalline hydroquinone diacetate. A number of attempts were



X (R = CH_3)
XI (R = H)



XII

made to cleave the quinone by alkali fusion,[11] but only intractable decomposition products were obtained. Acid permanganate, however, oxidized X rapidly in the cold to give a good yield of phthalic acid, the isolation of which, to be true, did not constitute a proof of structure. This facile oxidation, however, is in striking contrast to the behavior of anthraquinone, which is relatively stable. That the reactivity of the new quinone is due to the linear heterocyclic structure X was shown by an examination of the parent substance XI prepared by the unambiguous cyclization[12] of 3-benzoylpicolinic acid (XII).[13] This quinone closely resembled the one in question, responding comparably in the vat test, and in the easy oxidation to phthalic acid.

Evidence for the structures of the two benzoquinolines derived from β-naphthylamine also was supplied by a study of their absorption spectra. That of the 93° base is convincingly similar to that of anthracene (Fig. 1), while the absorption

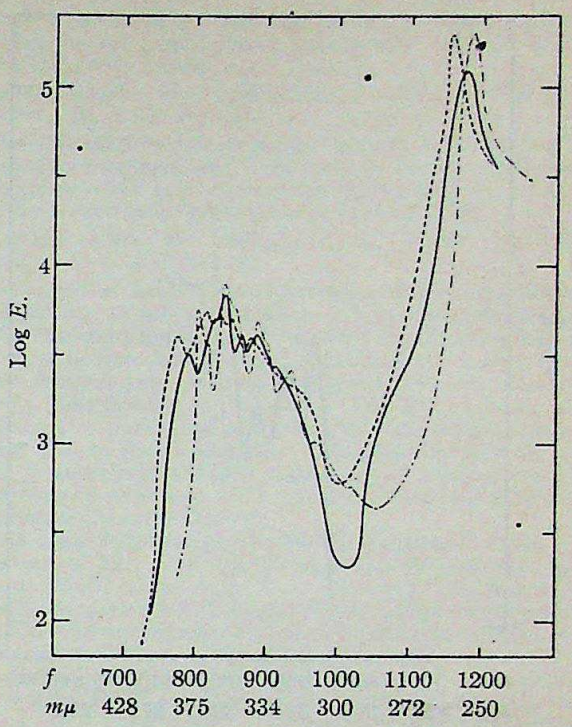


Fig. 1.— ——— 2,4-Dimethylbenzo[g]quinoline (VIII); - - - - - 2,4,10-trimethylbenzo[g]quinoline (IX); ·— · — · — anthracene.

of the 127° isomer resembles that of phenanthrene (Fig. 2). Even more striking is the comparison of the absorption of the latter base with that of

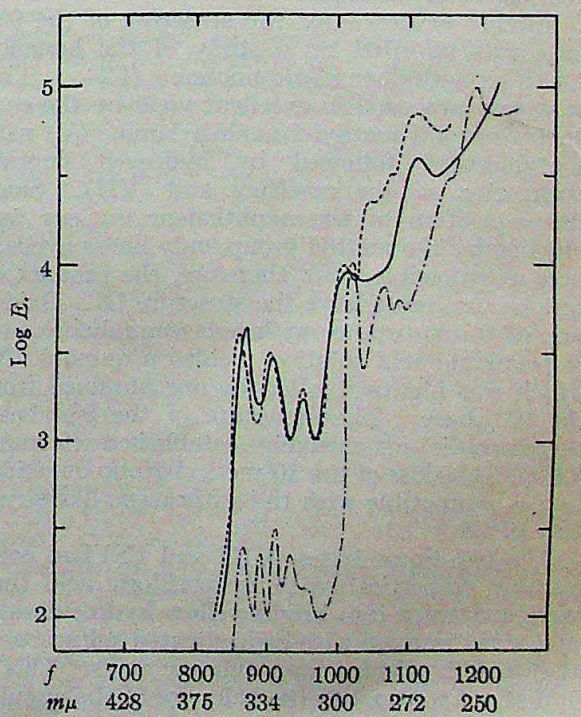

Fig. 2.— ———1,3-Dimethylbenzo[f]quinoline (III); - - - - 2,4-dimethylbenzo[h]quinoline (I); — · — · — phenanthrene.

(8) Our first preparations of Combes' base melted sharply at 74.5–75.5° cor. During the progress of the work some of this material changed into the polymorph, m. p. 93–93.8° cor., and since this occurrence only the latter has been encountered.

(9) Fieser and Hershberg, THIS JOURNAL, 61, 1272 (1939).

(10) An apparent tendency for hydrogen fluoride to favor linear cyclization of a different type has been noted previously by Fieser and Johnson, THIS JOURNAL, 61, 1647 (1939); Fieser and Daudt, *ibid.*, 63, 782 (1941), and Fieser and Heymann, *ibid.*, 63, 2333 (1941).

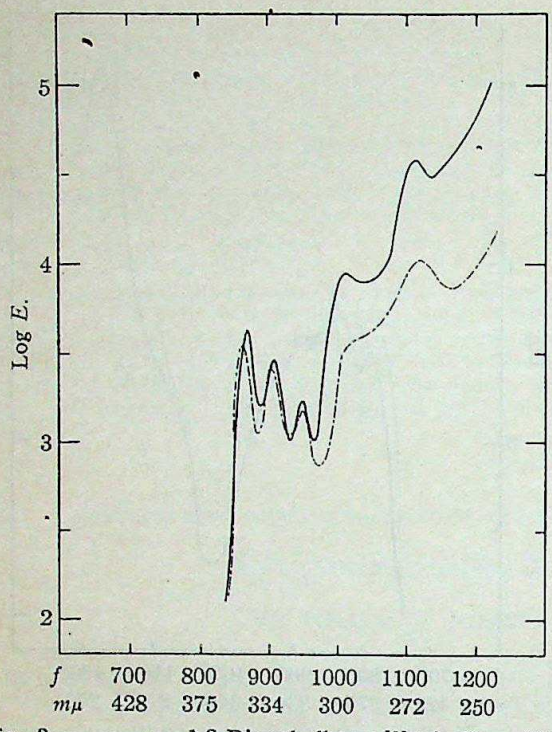

Fig. 3.— ——— 1,3-Dimethylbenzo[f]quinoline (III); — — — benzo[f]quinoline (II).

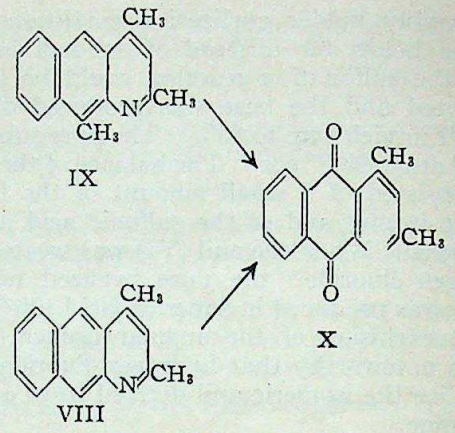
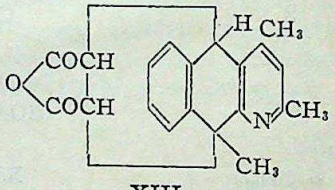
Skraup's benzo[f]quinoline (II)[14] (Fig. 3); the principal maxima appear at almost identical wave lengths. The absorption spectrum of 2,4-dimethylbenzo[h]quinoline (I) is included in Fig. 2 and bears a close relationship to those of the other angular analogs.

Further evidence for the structure of the 93° base was afforded by a study of the homolog 2,4,10-trimethylbenzo[g]quinoline (IX). This base was prepared in excellent yield by the condensation of 1-methyl-2-naphthylamine (V) with acetylacetone followed by hydrogen fluoride cyclization of the resulting anil (VII). Since the α-position of the naphthalene nucleus was blocked by the methyl group, only linear cyclization was possible, and, therefore, the product of ring closure must have the structure IX. Oxidation of this substance with potassium dichromate in propionic acid solution yielded a quinone (X) which was identical with the one obtained from the 93° base. The structure of the 93° base, therefore, is conclusively established (formula VIII). The loss of the 10-methyl group on oxidation is compatible with the anthracene-like structure of IX.[15]

The two linear bases (VIII and IX) had comparable properties: with hydrochloric acid they were converted into bright yellow hydrochlorides and when warmed with concentrated sulfuric acid they readily yielded monosulfonic acids. This is in distinct contrast to the behavior of the angular



bases which have colorless hydrochlorides and are sulfonated only under more drastic conditions.[3] This relative susceptibility of the linear and angular bases to sulfonation is reminiscent of the respective behavior of anthracene and phenanthrene. The new linear base (IX) also resembled anthracene in the reaction with maleic anhydride to form an addition product, probably XIII.[16]



XIII

The dimethyl base (VIII) also reacted readily with maleic anhydride, but the product was intractable. The angular bases, however, failed to react at all under the same conditions. The two linear bases were also closely comparable in respect to their absorption spectra (Fig. 1). A definite bathochromic shift may be noted in the maxima of the trimethyl derivative. This effect of the 10-methyl group is consistent with the observation that *meso* substituents exert such shifts in the absorption spectra of benzanthracene derivatives.[17]

Experimental Part[18]

4-(2-Naphthylimino)-pentanone-2 (VI).—The method of Combes[5] was modified by the introduction of Drierite into the reaction mixture. A mixture of 5.0 g. of β-naphthylamine, 6 cc. of acetylacetone and 10 g. of Drierite was heated on the steam-bath for three to four hours. The crude product obtained on elution with ether amounted to 7.55 g. (96% yield based on the amine), m. p. 89–96° with previous softening. One recrystallization from benzene–petroleum ether gave 6.5 g. (83% yield) of pure material, m. p. 98–99°. An additional 0.25 g., m. p. 96–98°, was obtained from the filtrate. A sample prepared for analysis formed tan flat needles and rods from ligroin, m. p. 98.5–99°.

trated sulfuric acid was heated on the steam-bath for one-half hour, cooled, and poured onto ice. The mixture was made alkaline, and a small amount (0.20 g.) of the angular 1,3-dimethylbenzo[f]quinoline (III) was obtained, m. p. 120–125°. Twice recrystallized from ligroin (90–100°) it melted at 128.5–129°, and showed no depression when mixed with an authentic specimen of the base prepared by the procedure of Reed.[3] Acidification of the alkaline solution yielded 5.8 g. (91%) of the yellow sulfonic acid of the linear base. It crystallized in small rods when a solution of the ammonium salt in dilute alcohol was boiled gently. The acid chars without melting when heated on a spatula; however, it is probably identical with the substance described by Combes[5] as shown by analysis.

Anal. Calcd. for $C_{15}H_{13}O_3NS$: C, 62.71; H, 4.56. Found: C, 62.94; H, 4.60.

2,4-Dimethylbenzo[g]quinoline (VIII): (a) By Hydrolysis of the Sulfonic Acid.—A suspension of 0.5 g. of the above sulfonic acid in 20 cc. of 10% (by volume) sulfuric acid was heated in a sealed tube at 220° for six hours. The mixture was made alkaline, and extracted with ether which gave 0.25 g. (70% yield) of the base, m. p. 63–70°. Once recrystallized from petroleum ether (60–68°) it melted at 71–72° (low-melting modification; see ref. 8). After the high-melting form was encountered in some later preparations, this material on recrystallization melted at 92–93°. Reaction temperatures above 220° caused considerable loss by charring while lower temperatures failed to effect complete hydrolysis.

(b) **Cyclization with Sulfuric Acid.**—The conditions for ring closure by this method appear to be very critical; it was not always possible to obtain yields as high as in the following experiment. To 85 cc. of chilled (2°) concentrated sulfuric acid was added with swirling 25.5 g. of 4-(2-naphthylimino)-pentanone-2 (VI). Better results were obtained when this operation did not exceed three minutes. The solution was then swirled in a flask at 60° (water-bath) for two minutes, cooled in an ice-bath and poured onto ice (300 g.). The insoluble yellow sulfate of the cyclized product was decomposed by making the mixture alkaline, and the base was taken up in ether. After treatment with Norit and drying, the ether was evaporated and the residue crystallized from ligroin (90–100°). This gave 19.6 g. (83.5% yield) of 2,4-dimethylbenzo[g]quinoline, m. p. 85–91° (high-melting form) with softening at 73°. One recrystallization gave 16.8 g. (71.5% yield) of material melting at 92–93°.

Evaporation of the filtrate from the first crystallization of VIII deposited a mixture of crystals from which could be separated mechanically about 0.5 g. (2% yield) of colorless clusters of needles, m. p. 121–125°, which consisted mainly of the angular isomer III; after two recrystallizations (90–100° ligroin) the m. p. was 128.5–129°, not depressed on mixing with authentic 1,3-dimethylbenzo-[f]quinoline. Attempts to cyclize the anil with dilute sulfuric acid resulted in hydrolysis.

(c) **Ring Closure with Hydrogen Fluoride.**—To 13.4 g. of the anil (VI) in a platinum vessel was added approximately 300 cc. of anhydrous hydrogen fluoride. After standing overnight at room temperature the residue was treated with 10% potassium carbonate solution, extracted with ether, treated with Norit, filtered, shaken with saturated salt solution and dried over anhydrous sodium sulfate. Evaporation of the ether yielded 11.75 g. (96%) of light tan crystals, m. p. 91–92.5°, not depressed on mixing with samples obtained by methods (a) and (b).

A sample of 2,4-dimethylbenzo[g]quinoline was purified for analysis by evaporative distillation at 130–140° (1 mm.). Recrystallization from acetone–ligroin gave colorless prismatic needles, m. p. 93–93.8°. Dilute solutions of the base exhibit a strong blue fluorescence. In dilute hydrochloric acid it gives an intense yellow solution of the salt.

Anal. Calcd. for $C_{15}H_{13}N$: C, 86.92; H, 6.32. Found: C, 87.05; H, 6.47.

2,4-Dimethylbenzo[g]quinoline hydrochloride was prepared by passing dry hydrogen chloride into an ether solution of the base. The salt on recrystallization from alcohol formed bright yellow microscopic crystals, m. p. 324–325° (dec.) (uncor.).

Anal. Calcd. for $C_{15}H_{14}ClN$: C, 73.91; H, 5.79 Found: C, 73.95; H, 5.76.

2,4-Dimethylbenzo[g]quinoline picrate was formed in alcohol and recrystallized from bromobenzene. It formed glistening yellow needles, m. p. about 271–273° (dec.) with previous darkening (introduced in bath at 250°).

Anal. Calcd. for $C_{21}H_{16}O_7N_4$: C, 57.80; H, 3.70. Found: C, 57.87; H, 3.46.

Reaction of 2,4-Dimethylbenzo[g]quinoline and Maleic Anhydride.—A solution of 0.4 g. of 2,4-dimethylbenzo(g)-quinoline and 1.5 g. of freshly distilled maleic anhydride in 10 cc. of benzene was allowed to stand for several hours at room temperature. The dark red precipitate amounted to 0.9 g. (air-dried), m. p. about 110–130° (dec.). All attempts to purify this material met with failure, apparently due to decomposition. This product may be the maleic anhydride addition compound by analogy to the homologous substance XIII which has been isolated in a pure state (described below).

2,4-Dimethylbenzo[g]quinoline-5,10-quinone (X).—A mixture of 16.3 g. of 2,4-dimethylbenzo[g]quinoline, 450 cc. of glacial acetic acid, 30 cc. of water and 23.5 g. of powdered potassium dichromate was boiled under reflux for one and one-quarter hours. The solution was cooled, poured into 500 cc. of saturated salt solution (to prevent emulsions) and extracted with benzene. Evaporation gave 8.9 g. (48% yield) of orange crystals of the quinone, m. p. 210.5–213.5° (dec.). A sample purified by sublimation at 180–190° (1 mm.) and recrystallization from benzene formed light orange needles, m. p. 215–216° (dec.). The quinone is photosensitive, turning bright red upon exposure to daylight for about two hours. It dissolves in alkaline sodium hydrosulfite solution to give a deep purple vat.

Anal. Calcd. for $C_{15}H_{11}O_2N$: C, 75.94; H, 4.67. Found: C, 75.80; H, 4.57.

5,10-Diacetoxy-2,4-dimethylbenzo[g]quinoline.—When the quinone (X) was treated by the customary procedure for reductive acetylation with zinc-dust, acetic anhydride and sodium acetate, only intractable oils were obtained. When sulfuric acid was used in place of the sodium acetate, the reduced diacetate was obtained.

To a solution of 0.50 g. of the quinone (X) in 15 cc. of acetic anhydride was added 0.4 cc. of concentrated sulfuric acid and 2 g. of zinc-dust. The pale orange solution presently turned bright yellow (due to the salt of the reduced diacetate; *cf.* the color of the hydrochloride of the base VIII), and was heated for one hour on the steam-bath. The filtered and cooled solution was poured onto ice, made alkaline, and extracted with benzene. The organic layer was extracted with a 3% solution of sodium hydrosulfite in 5% sodium hydroxide until all the quinone was removed as followed by the color of the vat, treated with Norit, and evaporated. The residue was sublimed at 165–180° (3 mm.) and recrystallized from benzene–ligroin (90–100°) to give yellow needles, m. p. 198–199°; yield 0.25 g. (37%). 5,10-Diacetoxy-2,4-dimethylbenzo[g]quinoline forms bright yellow solutions with dilute mineral acids, and does not give a vat test. It is relatively stable to light, but decomposes on long standing.

Anal. Calcd. for $C_{19}H_{17}O_4N$: C, 70.57; H, 5.30. Found: C, 70.68; H, 5.18.

Oxidation of 2,4-Dimethylbenzo[g]quinoline-5,10-quinone.—To a solution of 0.100 g. of the quinone (X) in 10 cc. of 20% (by volume) sulfuric acid was added dropwise a saturated solution of potassium permanganate until the latter was decolorized only slowly. The manganese dioxide was decomposed with sodium bisulfite and the solution extracted with ether. Evaporation of the dried ether layer gave 0.055 g. of almost colorless material m. p. 170–175°. Sublimation gave 0.025 g. of phthalic anhydride, m. p. 121–128°. After purification it melted at 126–128° and on mixing did not depress the m. p. of an authentic

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

specimen. The free acid had the m. p. 190–192°, not depressed on mixing with authentic phthalic acid. The neutral equivalent was 84.5 (calcd. 83.1).

Oxidation of Benzo[g]quinoline-5,10-quinone.—Benzo[g]quinoline-5,10-quinone (XI) was prepared from 3-benzoylpicolinic acid (XII) by the action of sulfuric acid.[12] The picolinic acid was obtained by the Friedel and Crafts reaction of quinolinic anhydride and benzene.[13] The quinone which was obtained in 6% yield was sublimed at 170–190° (1 mm.) and recrystallized from toluene. It formed pale greenish-yellow needles, m. p. 279–280° (uncor.) (literature[12] m. p. 280°), and gave a brilliant purple vat with alkaline sodium hydrosulfite solution.

For the oxidation of the quinone (50 mg.) the procedure already described for the oxidation of the dimethyl homolog (X) was used. The reaction proceeded similarly in every respect, and phthalic acid (25 mg.) was likewise isolated.

1-Methyl-2-naphthylamine (V) has been prepared previously[19] in 50% yield by the Bucherer reaction on 1-methyl-2-naphthol. In the present work the yield was improved considerably.

A mixture of 7.8 g. of 1-methyl-2-naphthol[20] (m. p. 107–109°); 10 g. of sodium bisulfite, 40 cc. of concentrated ammonium hydroxide solution, and 10 cc. of water was heated in a sealed Pyrex tube at 200 to 205° for forty-eight hours. The mixture was then diluted with water, made strongly alkaline with sodium hydroxide and extracted with ether. If the ether layer was evaporated, the residue could not be purified satisfactorily by recrystallization since an apparently homogeneous substance, m. p. 91–93° contaminated the product. This contaminant was shown to consist of a molecular complex of amine and unchanged naphthol which could not be separated with alkali. The amine could be liberated as the hydrochloride by treating an ether solution of the complex with dry hydrogen chloride. Thus it was found expedient to apply this treatment to the original dried ether layer. The amine hydrochloride was filtered, washed with ether, dissolved in hot water and decomposed with sodium hydroxide. The liberated amine was extracted with ether and dried. Evaporation of the solvent gave a crude product m. p. 46–50°; yield 7.2 g. or 93%. Once recrystallized from petroleum ether (60–68°) it formed a colorless product, m. p. 49–50° (literature[19] m. p. 50–51°), amounting to 5.5 g. (71% yield).

4-(1-Methyl-2-naphthylimino)-pentanone-2 (VII).—The procedure already described for the homolog VI was used, except that a large excess of acetylacetone was employed since the ketone is more accessible than the amine in this case. From 14.0 g. of 1-methyl-2-naphthylamine (m. p. 49–50°) and 20 cc. of acetylacetone with 28 g. of Drierite, there was obtained 22.0 g. of crude anil (VII), m. p. 87–92°. Recrystallization from ligroin (90–100°) gave 15.2 g. of material, m. p. 92–93.5°, and a second crop amounting to 3.2 g., m. p. 90–92°; thus the yield of pure anil was 87%. A sample twice recrystallized from petroleum ether (60–68°) formed light tan prisms, m. p. 93–94.8°.

Anal. Calcd. for $C_{16}H_{17}ON$: C, 80.31; H, 7.16. Found: C, 80.37; H, 7.21.

2,4,10-Trimethylbenzo[g]quinoline (IX).—The cyclization of the above anil (VII) was carried out according to both procedures (b) and (c) for the preparation of 2,4-dimethylbenzo[g]quinoline already described. The sulfuric acid method (b) gave good yields (up to 93%) of the cyclized base, but suffered from the same type of uncertainty already mentioned in the case of the lower homolog. Consistently excellent yields of the new quinoline derivative were realized when the hydrogen fluoride method (c) was employed. Thus from 5.0 g. of 4-(1-methyl-2-naphthylimino)-pentanone-2 (m. p. 91–93°) was obtained 4.42 g. (96% yield) of 2,4,10-trimethylbenzo[g]-quinoline, m. p. 122–125°. Material purified by evaporative distillation at 130–140° (1 mm.) and recrystallization from acetone–petroleum ether formed colorless prisms, m. p. 126.2–127°. Like the lower homolog its solutions exhibit a strong fluorescence, and with dilute hydrochloric acid it gives a bright yellow salt.

Anal. Calcd. for $C_{16}H_{15}N$: C, 86.84; H, 6.83. Found: C, 86.75; H, 6.71.

2,4,10-Trimethylbenzo[g]quinoline hydrochloride was prepared as described above for the homologous substance. The orange-yellow salt crystallized from alcohol in microscopic crystals, m. p. 295–296° (dec.) (uncor.).

Anal. Calcd. for $C_{16}H_{16}ClN$: C, 74.55; H, 6.26. Found: C, 74.75; H, 6.02.

2,4,10-Trimethylbenzo[g]quinoline picrate crystallized in yellow rods from the solvent pair nitromethane–tetrachloroethane. The m. p. was 253–255° (dec.) with previous darkening (introduced in bath at 240°).

Anal. Calcd. for $C_{22}H_{18}O_7N_4$: C, 58.66; H, 4.03. Found: C, 58.72; H, 4.16.

2,4,10-Trimethylbenzo[g]quinoline-x-sulfonic acid was prepared according to the procedure already described for the homolog. From 15.0 g. of the anil (VII) was obtained 17.4 g. (92% yield) of the acid. On slow hydrolysis of the ammonium salt the pure acid crystallized in small orange-yellow rods. It is hygroscopic, and more soluble than the lower homolog.

Anal. Calcd. for $C_{16}H_{15}O_3NS$: C, 63.77; H, 5.02. Found: C, 63.41; H, 4.98.

Reaction of 2,4,10-Trimethylbenzo[g]quinoline with Maleic Anhydride.—A solution of 0.30 g. of the base and 0.75 g. of freshly distilled maleic anhydride in 6 cc. of benzene was boiled under reflux for six hours. After cooling the solution was diluted with 15 cc. of benzene, dry hydrogen chloride passed in, and the precipitated hydrochloride filtered. This product was colorless, indicating that the addition was complete (*cf.* the intense yellow color of the salt of the starting base). The adduct was regenerated by boiling for ten minutes with acetone and powdered sodium acetate, filtering and evaporating the solvent; yield 0.33 g. The residue was purified by recrystallization from ether (poor recovery). It formed colorless microscopic crystals, m. p. 203.5–204.5°. Attempts to prepare the dibasic acid in a pure state were discouraged by difficulties attributable to the amphoteric nature of the substance.

Anal. Calcd. for $C_{20}H_{17}O_3N$: C, 75.22; H, 5.37. Found: C, 74.90; H, 5.26.

When the angular bases (I and III) were submitted to the reaction conditions above they were recovered unchanged.

Potassium Dichromate Oxidation of 2,4,10-Trimethylbenzo[g]quinoline.—A solution of 2.0 g. of the benzoquinoline and 5.4 g. of potassium dichromate in 40 cc. of propionic acid and 5 cc. of water was boiled under reflux for two hours. The cooled, green solution was poured into 300 cc. of water and extracted with benzene. The quinone was extracted from the benzene solution with a 1 to 1 mixture of 5% sodium hydrosulfite and 10% sodium hydroxide solution. The quinone was regenerated from the purple vat by passing air through the aqueous solution for several hours. Thus was obtained 0.1 g. (about 5% of the theoretical) of crude quinone, m. p. 180–195°. The reduced diacetate was prepared by the procedure already described. Sublimation and recrystallization gave material, m. p. 196–198°, identical in appearance with the reduced diacetate obtained from 2,4-dimethylbenzo[g]quinoline quinone. A mixture of the two samples showed no m. p. depression.

2,4-Dimethylbenzo[h]quinoline (I) was prepared from α-naphthylamine and acetylacetone according to previous procedures.[5,21] The use of Drierite (see above) was found to increase the yield (99%) of the anil which we were not able to obtain homogeneous. Fusion of the material occurred over a wide range below 100° even after several recrystallizations (*cf.* v. Braun, *et al.*,[21] who give the m. p.

(19) Scholl and Neuberger, *Monatsh.*, **33**, 507 (1912); Shimomura and Cohen, *J. Chem. Soc.*, 740 (1921).

(20) Robinson and Weygand, *J. Chem. Soc.*, 386 (1941).

(21) v. Braun, Gmelin and Petzold, *Ber.*, **57**, 382 (1924).

165°). The crude anil, however, could be cyclized with sulfuric acid in good yields (80–90%). The benzoquinoline twice recrystallized from petroleum ether (40–60°) formed colorless needles, m. p. 51.5–53°. Material of the same m. p. was obtained laboriously in about 2% yield using the procedure of Reed.[3] The mixed m. p. showed no depression. It was surprising to find that hydrogen fluoride failed to cyclize noticeably 4-(1-naphthylimino)-pentanone-2; hydrolysis to α-naphthylamine took place instead.

Absorption Spectra.—A Hilger quartz spectrograph equipped with a Hilger photometer was used in conjunction with a hydrogen discharge tube as the light source. Ethanol, specially dried over magnesium ethoxide[22] and distilled in an all-glass apparatus, was used as the solvent.

The analytical samples of the benzoquinolines were used. Benzo[f]quinoline (Eastman Kodak Company) was recrystallized from 60–68° petroleum ether, m. p. 90.5–91.5°. Anthracene was sublimed and recrystallized from chloroform and ethanol, m. p. 214.5–215.5°. A pure sample of phenanthrene was prepared by dehydrogenation of pure 9,10-dihydrophenanthrene[23] over 30% palladium-charcoal,[24] followed by recrystallization from ethanol, m. p. 98–99°.

The linear compounds were determined at four concentrations: *M*/4000, *M*/10,000, *M*/40,000 and *M*/200,000. For anthracene a determination was made also at *M*/400,000. The angular substances were determined at *M*/2000, *M*/10,000, *M*/50,000 and *M*/200,000. In the figures the abscissas are plotted in fresnel (*f*) units in accordance with the suggestion of Brode.[25] The log *E* values observed for anthracene and phenanthrene do not check those of Capper and Marsh,[26] but in the case of anthracene are in agreement with those of Heertjes and Waterman.[27]

The principal maxima are given below. The wave lengths are in ångström units, the intensity in log *E* (in parentheses), and * indicates inflections.

Anthracene.—3740 (3.75), 3700* (3.55), 3560 (3.9), 3505* (3.75), 3375 (3.70), 3340* (3.58), 3200 (3.43), 3090 (3.05), 2940 (2.75), 2530 (5.30).

2,4-Dimethylbenzo[g]quinoline.—3800 (3.45), 3640 (3.70), 3575 (3.85), 3470 (3.62), 3380 (3.62), 3290 (3.45), 2565 (5.10).

2,4,10-Trimethylbenzo[g]quinoline.—3870 (3.6), 3695 (3.75), 3600 (3.7), 3530 (3.7), 3420 (3.6), 2590 (5.3).

Summary

The preparation and proof of structure of some benzoquinoline derivatives is considered. Particular attention is given to the cyclization of the anil from β-naphthylamine and acetylacetone, which, surprisingly, takes place so as to give a linear benzoquinoline. The latter represents a class of compounds about which little has been known. Some of the properties of this type of substance are considered.

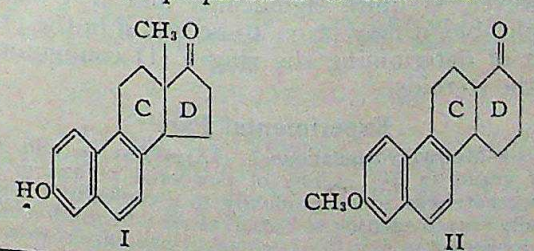
Introduction of the Angular Methyl Group. II.[1] *cis*- and *trans*-8-Methylhydrindanone-1[2]

BY WILLIAM S. JOHNSON

The purpose of this communication is to describe a method for converting decalone-1 (III) into the angularly methylated hydrindanones (IX and X). This process affords a means of arriving at the structure defined by rings C and D (compare formula I) of a number of the steroid hormones, and obviously serves as a model synthesis for the preparation of hormones of the equilenin (I) type from chrysene derivatives like II.[3]



Considerable attention already has been devoted to 8-methylhydrindanone-1[4–11] but with one exception[11] all of the syntheses have led to one and the same isomer of this compound which, however, can exist in two racemic forms described by *cis* (IX) and *trans* (X) fusion of the rings. The present synthesis affords a means of obtaining each of these diastereoisomers, which is fortunate particularly in view of the fact that the ring C/D

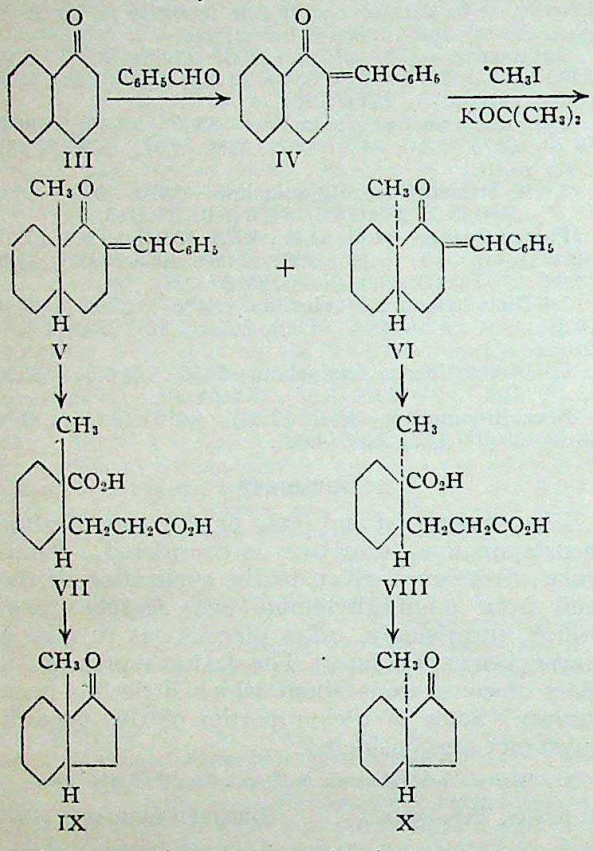
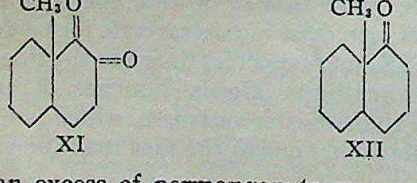
configuration of the steroids has not yet been established unequivocably.



In a previous communication[1] was described a practicable preparation of the two stereoisomeric forms of 2-benzal-9-methyldecalone-1 from decalone-1 (III → VI). In the present work these benzal derivatives were found to be very susceptible to oxidative degradation by potassium permanganate in acetone solution. With the amount of oxidizing agent calculated to produce the α-diketone XI a mixture of starting material and acidic substances was obtained. None of XI was found even when the reaction was conducted at 0°. This suggests that under the conditions employed, the diketone, if formed, is more sensitive to oxidation than the benzalketone.



When an excess of permanganate was employed the benzal derivatives V and VI were converted into the dibasic acids VII and VIII, respectively, and benzoic acid. For the purpose of preparing the hydrindones it was found unnecessary to isolate these acids. Thus by distillation from a small amount of barium oxide[12] the crude acidic fractions from the oxidation gave the 8-methylhydrindanones IX and X isolated as the semicarbazones in over-all yields of 35 and 55%, respectively. The pure ketones were obtained by steam distillation of these derivatives in the presence of oxalic acid.

From the benzal derivative, m. p. 104°, which formerly[1] was converted to the 9-methyldecalone-1 (XII) of *cis* (probable[8]) configuration, was obtained the well-known[4-11] *cis*-8-methylhydrindanone-1. This relationship between the two homologous ketones is consistent with the previous demonstration[8] that they belong to the same stereochemical series. From the isomeric benzal derivative, m. p. 94°, was produced the stereoisomeric 8-methylhydrindanone-1 (configuration provisionally *trans*) which has been obtained through a different synthesis by Bachmann and Kushner.[11] Their description of the new ketone (which was published since the completion of the present work), is in good agreement with the current findings. A comparison of the two stereoisomeric ketones and derivatives is found in Table I.

[a] All melting points are corrected. [b] The comparison of melting and boiling points with those which have been reported previously may be found in the experimental part of this paper. [c] Probable configuration. [d] Double melting point.

The difference which has been observed between members of the *cis* and *trans* series with respect to reactivity of the carbonyl group[1] is consistently carried over to the hydrindanones as shown by the fact that the so-called *trans* substance forms the semicarbazone with marked rapidity relative to its stereoisomer. As with the 9-methyldecalones ordinary molecular models fail to show any pronounced difference in degree of hindrance of the carbonyl group. The chemical distinction, however, is quite significant, and if generally applicable, it may prove to be useful in the problem of determining the ring C/D configuration of the steroids.

Experimental Part[13]

cis-8-Methylhydrindanone-1 (IX).—Twelve and one-half grams (a 5% excess) of powdered potassium permanganate was added gradually to a cooled and mechanically stirred solution of 7.20 g. of *cis*-2-benzal-9-methyl-

(12) The pyrolytic cyclization of the acids VII and VIII was used rather than the Dieckmann method principally because of the simplicity of manipulation. The latter method should be useful, however, particularly when applied to larger molecules. *Cf.* Bachmann, Cole and Wilds, THIS JOURNAL, **62**, 824 (1940).

decalone-1[1] (m. p. 99–102°) in 250 cc. of acetone. The rate of addition was controlled so that the temperature was maintained between 2 and 4°. After the addition was complete, stirring was continued for about one hour at 0°; then the solvent was evaporated in a stream of air and replaced by water. This mixture was chilled (ice–salt bath) and stirred mechanically while dilute sulfuric acid (20 cc. of concentrated acid in 20 cc. of water) was added followed by 20 cc. of a saturated solution of sodium bisulfite. The colorless mixture was extracted thoroughly with several portions of ether, and the latter solution was in turn extracted with portions of saturated sodium bicarbonate solution. Evaporation of the ether yielded 0.88 g. of a semicrystalline neutral fraction which consisted mainly of starting material. Acidification of the combined aqueous extracts yielded an oily mixture of the dicarboxylic acid VII and benzoic acid. In one experiment the benzoic acid was removed by steam distillation, leaving *cis*-β-(2-carboxy-2-methylcyclohexyl)-propionic acid (VII) as an oil which solidified on standing, m. p. 93–97°. As reported by Burnop and Linstead, reference 9 (footnote p. 721), recrystallization was difficult. The m. p. of once recrystallized material was 99.5–103°. The pure substance is reported to melt at 108–109°.[9] The mixture of organic acids was extracted with ether, washed with water, saturated salt solution and dried over anhydrous sodium sulfate. Evaporation of the ether left 7 to 8 g. of crude acid fraction which was mixed with 0.35 g. of barium oxide and pyrolyzed according to previous procedures[5,7] in a two-bulb flask at 300–320° for one to two hours. The colorless distillate which had partially solidified (benzoic acid) was dissolved in ether and extracted with a saturated solution of sodium bicarbonate which on acidification yielded benzoic acid. The ether solution was washed with saturated salt solution, dried over anhydrous potassium carbonate and the solvent was removed through a short Vigreux column. The residue which had a strong camphor-like odor was dissolved in 15 to 20 cc. of methanol, 3.0 g. of semicarbazide hydrochloride and 3.0 cc. of pyridine were added, and the mixture refluxed for one hour during which the semicarbazone gradually precipitated. After the addition of a little water and cooling 1.97 g. of material m. p. 221–222.5° (dec.) was obtained. An additional 0.10 g., m. p. 208–215°, was obtained from the mother liquors, making the total yield 35%. A sample of the semicarbazone recrystallized to constant m. p. from methanol formed small colorless blades, m. p. 224.5–225.5° (dec.) (reported m. ps. range from 213°[4,11] to 224–225°[11]).

The free ketone was obtained easily in practically quantitative yield by distillation of an aqueous solution of oxalic acid containing a suspension of the semicarbazone, m. p. 221–222.5° (dec.). The distillate contained the oily colorless ketone which solidified on standing in ice. Ether extraction followed by distillation gave *cis*-8-methylhydrindanone-1 of constant boiling point, 106° (20 mm.); m. p. 34.5–36° (reported m. ps. range from 33–34°[5] to 39.5°[10]). In agreement with the observation of Elliott and Linstead[8] the semicarbazone formed readily only on heating.

The **oxime** of *cis*-8-methylhydrindanone-1 was prepared in methanol with hydroxylamine hydrochloride and pyridine. The crude product was sublimed at 65–70° (0.1 mm.) and recrystallized twice from aqueous methanol. The colorless crystals melted at 87–88°. Bachmann and Kushner[11] give m. p. 85.5–87°.

Anal. Calcd. for $C_{10}H_{17}ON$: C, 71.81; H, 10.25. Found: C, 71.60; H, 9.92.

The **2,4-dinitrophenylhydrazone** of IX formed short orange needles from methanol, m. p. 140.5–141°.

Anal. Calcd. for $C_{16}H_{20}O_4N_4$: C, 57.82; H, 6.07. Found: C, 57.87; H, 6.19.

trans-**8-Methylhydrindanone-1** (X) was prepared by essentially the same procedure which is described above for the *cis* isomer. For the oxidation of 16.56 g. of *trans*-2-benzal-9-methyldecalone-1 (m. p. 92–93.5°) 250 cc. of acetone and 31.6 g. (a 15% excess) of potassium permanganate were used. The larger excess of oxidizing agent seemed to improve the reaction; only a negligible amount of neutral material remained. After the addition of the sulfuric acid (50 cc. concentrated acid and 50 cc. water) and the sodium bisulfite solution (50 cc.) the dibasic acid VIII and benzoic acid remained as a colorless precipitate which was filtered, dissolved in sodium bicarbonate solution, filtered, and reprecipitated with hydrochloric acid. The filtrate from this operation was combined with the original filtrate from the oxidation step and worked up by extraction as in the previously described procedure. (This method of working up the organic acids in two fractions seemed desirable because of the low solubility of the dibasic acid VIII in non-polar solvents.) The additional oily acidic material thus obtained was combined with the above solid fraction, and 0.8 g. of barium oxide was added for the pyrolysis. In this preparation the crude distillate from the pyrolysis was treated directly, without removal of the benzoic acid, with 50 cc. of ethanol, 7 g. of semicarbazide hydrochloride and 15 cc. of pyridine. The insoluble semicarbazone began to precipitate after two minutes' heating on the steam-bath. After one hour the mixture was cooled, filtered and washed thoroughly with water; yield 7.39 g. of colorless crystals, m. p. 243–244° (dec.). From the mother liquors was obtained an additional 0.16 g. of good material, m. p. 239–242° (dec.), making the total yield 55%. Hydrolysis of the semicarbazone as described above gave *trans*-8-methylhydrindanone-1 of constant b. p. 109° (20 mm.), $n^{26}D$ 1.4800, d^{26}_4 0.9793, M_D (found) 44.16, M_D (calcd.) 43.99. Bachmann and Kushner[11] report, b. p. 108–109° (20 mm.), $n^{25.8}D$ 1.4807. The ketone had the characteristic camphor-like odor and reformed the semicarbazone readily at room temperature.

Anal. Calcd. for $C_{10}H_{16}O$: C, 78.89; H, 10.60. Found: C, 78.78; H, 10.66.

The **semicarbazone** of *trans*-8-methylhydrindanone-1 on recrystallization from ethanol formed colorless plates, m. p. 242–243° (dec.) (reported, 234°[11]).

Anal. Calcd. for $C_{11}H_{19}ON_3$: C, 63.13; H, 9.15. Found: C, 62.87, H, 9.01.

The **oxime** was purified by sublimation at 70–80° (0.1 mm.) and recrystallization from aqueous methanol. It formed small colorless plates, m. p. 115–115.5° (reported, 113–115.5°[11]).

Anal. Calcd. for $C_{10}H_{17}ON$: C, 71.81; H, 10.25. Found: C, 72.30; H, 10.21.

The **2,4-dinitrophenylhydrazone** formed orange blades from methanol–ethyl acetate. It melted sharply at 146.5–147° and resolidified as the temperature was raised, remelting at 153.5–154°.

Anal. Calcd. for $C_{16}H_{20}O_4N_4$: C, 57.82; H, 6.07. Found: C, 58.16; H, 6.00.

trans-β-**(2-Carboxy-2-methylcyclohexyl)-propionic Acid (VIII).**—A sample of the solid reprecipitated acid mixture obtained in the above oxidation was triturated with benzene in which the dicarboxylic acid VIII is relatively insoluble. The latter was filtered, washed with benzene and recrystallized to constant m. p. from aqueous methanol and then once from ethyl acetate. It formed colorless pointed blades, m. p. 179–180°.

Anal. Calcd. for $C_{11}H_{18}O_4$: C, 61.66; H, 8.47. Found: C, 61.80; H, 8.41.

Summary

A method is described for obtaining *cis*- and *trans*-8-methylhydrindanone-1 from decalone-1.

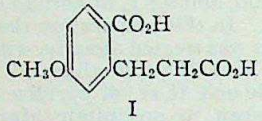
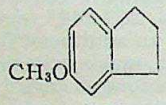
Derivatives of 5-Methoxyhydrindene and 6-Methoxytetralin. Synthesis of β-(2-Carboxy-5-methoxyphenyl)-propionic Acid[1]

BY WILLIAM S. JOHNSON, JOHN M. ANDERSON AND WESLEY E. SHELBERG

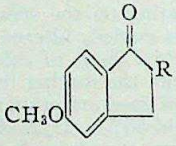
For the synthesis of β-(2-carboxy-5-methoxyphenyl)-propionic acid (I) which was desired as an intermediate in some projected syntheses of steroid types, the readily available[2] 5-methoxyhydrindene (II) and the similarly accessible[3] 6-methoxytetralin (VI) were chosen as promising starting materials.



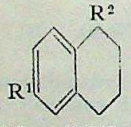
I



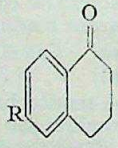
II



III (R = H)
IV (R = Br)
V (R = CN)



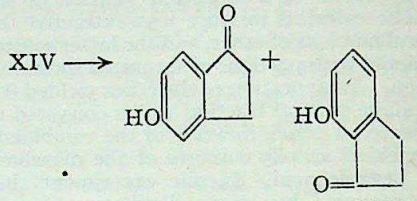
VI (R^1 = OCH_3, R^2 = H)
VII (R^1 = H, R^2 = $OCOCH_3$)
VIII (R^1 = OCH_3, R^2 = $OCOCH_3$)
IX (R^1 = OCH_3, R^2 = OH)



X (R = OCH_3)
XI (R = H)

Since it has been shown[4] that 6-methoxytetralin (VI) is converted by oxidation with chromic oxide into 6-methoxytetralone-1 (X) in yields up to 70%,[3b] it was hoped that a similar selective oxidation would take place in the case of the five-membered ring homolog II to produce 5-methoxyhydrindone-1 (III). This indeed was realized, and conditions were found whereby the pure ketone (III) was obtained in 75–80% yields. The identity of the substance was confirmed by comparison with material prepared by a conventional synthesis involving no new compounds, but describing a new series of reactions[5]

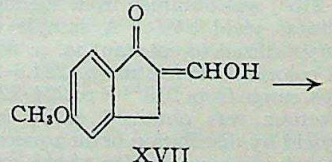
m-HOC_6H_4CHO (XII) ⟶
m-$HOC_6H_4CH{=}CHCO_2H$ (XIII) ⟶
m-$HOC_6H_4CH_2CH_2CO_2H$ (XIV)



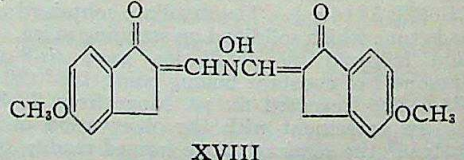
XV (85%) XVI (13%)

The cyclization of *m*-hydroxyhydrocinnamic acid (XIV) with hydrogen fluoride[6] gave a 98% yield of a mixture of isomeric ketones easily and quantitatively separated by steam distillation. The non-volatile 5-hydroxyhydrindone-1 (XV) was formed in preponderance (yield 85%), and methylation afforded the ether III, identical with the oxidation product of II described above.

It was planned to degrade 5-methoxyhydrindone-1 to the desired acid (I) by a series of reactions employed by Lapworth[7] to open the ketonic ring of camphor to obtain homocamphoric acid. This method has been used also by Bardhan[8] to open ring D of estrone, and by Robinson and Rydon[9] to cleave the analogous ring of a synthetic product related to equilenin. The Claisen condensation of III with ethyl formate gave 2-hydroxymethylene - 5 - methoxyhydrindone - 1 (XVII) in 98% yield. This in glacial acetic acid



XVII



XVIII

condensed with hydroxylamine to give—instead of the expected[7,8,9] nitrile (V)—a 90% yield of an insoluble orange compound, $C_{22}H_{19}O_5N$, probably bis - (5 - methoxy - 1 - keto - 2 - hydrindylidenemethyl)-hydroxylamine (XVIII).[10] The condensation product has an acidic hydrogen, and on

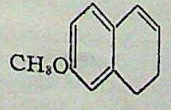
(10) During a study of the condensation of hydroxylamine with a number of hydroxymethylene ketones under various conditions we have come to the conclusion that the product obtained by Robinson and Rydon (reference 9) and presumed by them to be a nitrile, probably was a dimolecular condensation product like XVIII. The formation and alkaline cleavage of compounds of this type will be considered in a subsequent communication.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

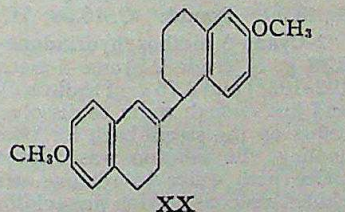
Digitized by Arya Samaj Foundation Chennai and eGangotri

dissolving in alkali gives an intense purple color which is gradually dispelled on warming. Prolonged heating of XVIII with one equivalent of hydroxylamine in alkaline solution was accompanied by the evolution of ammonia and the formation of β-(2-carboxy-5-methoxyphenyl)-propionic acid (I) in 61% yield. Lower yields were obtained in the absence of hydroxylamine. The structure of the acid was confirmed by distillation with barium oxide to regenerate 5-methoxyhydrindone-1. The mechanism of the degradation of XVIII to the dicarboxylic acid (I) may involve the nitrile (V) as an intermediate,[10] although we have not yet been able to prepare V from either XVIII or the hydroxymethylene derivative XVII. The nitrile could be obtained, however, in 73% yield from 2-bromo-5-methoxyhydrindone-1 (IV), and on alkaline hydrolysis afforded an 88% yield of the acid (I).

Preliminary attempts to prepare β-(2-carboxy-5-methoxyphenyl)-propionic acid by direct oxidation of 6-methoxytetralin (VI) or of the tetralone derivative X using acid permanganate[11] or chromic acid were so unpromising that this method of attack was abandoned. A more favorable approach was found in the oxidation of VI with lead tetraacetate. Since it has been shown[12] that this reagent reacts with tetralin to give 1-acetoxytetralin (VII), it was expected that the 6-methoxy derivative (VI) also would be acetoxylated. This indeed was realized, the reaction proceeding at room temperature, and a monoacetoxy derivative was obtained in 62% yield. Since the methoxyl group of VI activates the hydrogen atoms on the carbon atom in the *para* position toward chromic acid oxidation,[4] it was presumed that lead tetraacetate had attacked the same position to produce 1-acetoxy-6-methoxytetralin (VIII). This substance exhibited a remarkable tendency to lose acetic acid, also probably due to the activating effect of the *p*-methoxyl substituent. The decomposition was catalyzed by mineral acid, and 7-methoxy-1,2-dihydronaphthalene (XIX) was thus obtained in 87% yield as a liquid, b. p. 95° (2–3 mm.). A



XIX



XX

solid, m. p. 73–74°, presumed to have the structure XIX has been described by Long and Burger.[13]

Their substance was prepared by the action of hydrobromic acid on 1-hydroxy-6-methoxytetralin (IX).[14] The structural similarity between XIX and anethole, which is known to dimerize in the presence of mineral acids,[15] suggested that XIX would not be stable in such a medium. Indeed when our liquid compound was treated with hydrobromic acid it was converted into a solid dimer, m. p. 75.5–76.5°, apparently identical with the previously reported substance. By analogy to the anethole dimer of known structure, the present substance may be formulated tentatively as XX.

Oxidation of XIX with cold permanganate in acetone solution gave β-(2-carboxy-5-methoxyphenyl)-propionic acid (I) in 40% yield. The identity of this product established the structure of XIX and, in turn, that of the acetoxylation product VII.

Experimental Part[15a]

5-Methoxyhydrindone-1 (III). (a) **By the Oxidation of 5-Methoxyhydrindene (II).**—A solution of chromic anhydride (28 g.) in 14 cc. of water and 80 cc. of glacial acetic acid was added slowly with mechanical stirring to a chilled solution of 26.2 g. of 5-methoxyhydrindene (prepared[16] from hydrindene according to A. H. Cook and Linstead[2]) in 160 cc. of glacial acetic acid. The temperature was maintained between 5 and 10° during the addition (one hour). The mixture was kept cool for five hours and then allowed to come to room temperature. After standing overnight most of the acetic acid was removed at 40° under diminished pressure, water was added, and the oil extracted with ether. The combined extracts were washed cautiously with 10% potassium carbonate solution until all of the acid was removed, then with concentrated sodium chloride solution, and finally dried over anhydrous potassium carbonate. The product on evaporation of the ether distilled at 130–132° (2–3 mm.), giving a yellowish oil which presently solidified, m. p. 95–108°; yield 22.3 g. (78%). A single crystallization from dilute methanol gave 20.0 g. of long colorless prismatic rods, m. p. 108–110°. A sample was recrystallized from benzene to a constant m. p. 109.8–110.5° (literature m. p. 110°[5a] and 108°[5b]). This material as well as the semicarbazone, m. p. 240–241° (dec.) (literature m. p. 239°[5a]) showed no depression of m. p. on mixing with the specimens prepared as described below.

(b) **By the Cyclization of *m*-Hydroxyhydrocinnamic Acid (XIV).**—*m*-Hydroxycinnamic acid (XIII) was prepared in 91% yield from *m*-hydroxybenzaldehyde by heating the latter (20.9 g.) with malonic acid (31.2 g.) in pyridine (32 cc.) and piperidine (8 drops) for four and one-half hours on the steam-bath. Acidification with dilute hydrochloric acid yielded 25.5 g. of XIII, m. p. 192–194°. Material once recrystallized from dilute methanol solution had the m. p. 194–195° (literature m. p. 191°[5a,17] and 193°[18]). This was reduced in methanol solution with platinum oxide to give a quantitative yield of *m*-hydroxy-

(11) The permanganate oxidation of tetralin to *o*-carboxyhydrocinnamic acid was reported by Bamberger and Kitschelt, *Ber.*, **23**, 1561 (1890). Later, however, v. Braun and Deutsch, *ibid.*, **45**, 1267 (1912), produced evidence indicating that the previous work had been carried out on impure tetralin containing some dihydronaphthalene which was actually the principal source of the dicarboxylic acid.

(12) Criegee, *Ann.*, **481**, 263 (1930).

(13) Long and Burger, *J. Org. Chem.*, **6**, 852 (1941).

(14) Salzer, *Z. physiol. Chem.*, **274**, 39 (1942), reported material b. p. 103° (1 mm.) from the dehydration of IX. The reactions of this material indicated that it was, at least in part, 7-methoxy-1,2-dihydronaphthalene, but no analytical data were given. Compare German Patent 708,114 [*Chem. Abs.*, **37**, 2748 (1943)] and U. S. Patent 2,223,664 [*Chem. Abs.*, **35**, 1808 (1941).]

(15) Goodall and Haworth, *J. Chem. Soc.*, 2482 (1930).

(15a) All melting points are corrected.

(16) The preparation of 5-methoxyhydrindene was carried out by Mr. E. Goldstein who also performed some of the preliminary oxidation experiments.

hydrocinnamic acid (XIV), m. p. about 99°. The pure acid, m. p. 111.8–112.5° (literature m. p. 111°[17]) was obtained by distillation under diminished pressure and crystallization from benzene.

For the cyclization 3.31 g. of pure XIV was treated in a platinum vessel with approximately 100 g. of anhydrous hydrogen fluoride.[6] On standing overnight the yellow solution evaporated, leaving a colorless crystalline mass which was submitted to steam distillation. 7-Hydroxyhydrindone-1 (XVI) crystallized from the distillate which was saturated with sodium chloride and extracted with ether. This extract after drying over anhydrous sodium sulfate and evaporation yielded 0.40 g. (13%) of almost colorless material, m. p. 109–111°. Recrystallized from methanol–petroleum ether, it formed colorless prisms, m. p. 110.5–111.5° (literature m. p. 111°[19,5]) and gave an intense violet color with ferric chloride.[19,5] Practically pure crystalline 5-hydroxyhydrindone-1 (XV) remained in the distilling flask from the steam distillation, and amounted to 2.50 g. (85% yield), m. p. 184–185°. Recrystallized from dilute alcohol (Norit) it formed almost colorless prisms, m. p. 184–185.5° (literature m. p. 182°[5a] and 183°[19]); semicarbazone, m. p. 222–222.5° (dec.) (introduced in bath at 215°) (literature m. p. 223°[19]). The **acetate** of XV crystallized from ether–petroleum ether in colorless plates, m. p. 92.8–93.2°.

Anal. Calcd. for $C_{11}H_{10}O_3$: C, 69.46; H, 5.30. Found: C, 69.66; H, 5.55.

When the cyclization was performed on distilled but unrecrystallized *m*-hydroxyhydrocinnamic acid (yield 90–95%) the total yield of ketones was 94% instead of 98%.

Crude 5-hydroxyhydrindone-1 (11 g.) prepared as above was converted into the methyl ether III by the action of dimethyl sulfate in alkaline solution. The yield of crude III was 11.6 g. (97%), m. p. about 110° with previous softening. Recrystallized from benzene it melted at 110–110.5°; semicarbazone m. p. 240–241° (dec.) (*cf.* the product prepared in (a) above). The **2,4-dinitrophenylhydrazone** formed red needles from chloroform, m. p. 282–284° (dec.) (uncor.).

Anal. Calcd. for $C_{16}H_{14}O_5N_4$: N, 16.37. Found: N, 16.45.

The ***p*-nitrophenylhydrazone** crystallized from dilute alcohol in small orange needles, m. p. 209–211.5° (dec.) (introduced in bath at 200°).

Anal. Calcd. for $C_{16}H_{15}O_3N_3$: N, 14.14. Found: N, 14.25, 14.31.

2-Hydroxymethylene-5-methoxyhydrindone-1 (XVII).[20]—A solution of sodium methoxide prepared from 0.74 g. (0.032 mole) of sodium and 10 cc. of methanol was evaporated to dryness at 200° under reduced pressure. The colorless cake was broken up, and a solution of 2.38 g. (0.032 mole) of ethyl formate in 16 cc. of dry benzene was added, and the system evacuated and filled with nitrogen. To the cooled mixture was added with swirling, a solution of 2.60 g. (0.016 mole) of 5-methoxyhydrindone-1 in 20 cc. of dry benzene. A precipitate having a pink tinge gradually formed, and after four to five hours slightly below room temperature it was hydrolyzed with cold water, and a few cc. of ether was added to minimize emulsion formation. The organic layer was washed once with water and with dilute sodium hydroxide. The aqueous portions were combined, washed with ether, and acidified with ice and hydrochloric acid. Almost pure 2-hydroxymethylene-5-methoxyhydrindone-1 precipitated; yield 2.98 g. (98%), m. p. 136.5–138°. Recrystallized from benzene it formed almost colorless plates, m. p. 138–138.5° (dec.), which gave an intense purple color with ferric chloride.

Anal. Calcd. for $C_{11}H_{10}O_3$: C, 69.46; H, 5.30. Found: C, 69.65; H, 5.53.

The **bis-(2,4-dinitrophenylhydrazone)** of XVII crystallized from bromobenzene in short, orange needles, m. p. 223–226° (dec.) (introduced in bath at 220°).

Anal. Calcd. for $C_{23}H_{18}O_9N_8$: N, 20.36. Found: N, 20.40.

2-Hydroxymethylene-5-methoxyhydrindone-1, on melting, turns dark red and slowly gives off a gas. This decomposition represents the elimination of formic acid between two molecules of XVII to form a condensation product of the type described by Ruhemann and Levy.[21] The product, probably **2-(5-methoxy-1-keto-2-hydrindylidenemethyl)-5-methoxyhydrindone-1**, was obtained after heating for one hour at 140–150°. It crystallized from benzene–petroleum ether or from glacial acetic acid in orange prisms, m. p. 213–215° (dec.) (introduced in bath at 205°).

Anal. Calcd. for $C_{21}H_{18}O_4$: C, 75.43; H, 5.43. Found: C, 75.82; H, 5.51.

Bis-(5-methoxy-1-keto-2-hydrindylidenemethyl)-hydroxylamine (XVIII).—A solution of 1.42 g. (0.0075 mole) of 2-hydroxymethylene-5-methoxyhydrindone-1 in 20 cc. of glacial acetic acid was treated with 0.59 g. (0.0085 mole) of powdered hydroxylamine hydrochloride. Although the latter is sparingly soluble, the reaction started presently as indicated by coloring of the solution followed by the formation of a red precipitate. The mixture was stirred or shaken mechanically for twenty-four hours, and the product filtered and triturated with water which caused the color to change from red to orange. The yield of dry material amounted to 1.27 g. (90%), m. p. 190–204° (dec.) (introduced in bath at 180°). It crystallized from pyridine in the form of orange needles, m. p. 216–218° (dec.) (introduced in bath at 214°). The same m. p. was observed in an evacuated tube.

Anal. Calcd. for $C_{22}H_{19}O_5N$: C, 70.01; H, 5.07; N, 3.71. Found: C, 69.93; H, 5.14; N, 3.62.

The condensation product XVIII is sparingly soluble in the common organic solvents. It dissolves in dilute alkali to give an intense violet color like that of permanganate solution.

2-Bromo-5-methoxyhydrindone-1 (IV).—A solution of 5-methoxyhydrindone-1 (1.68 g.) in 200 cc. of anhydrous ether was treated with 0.60 cc. of bromine according to the procedure of Wilds[22] for the bromination of 1-keto-1,2,3,4-tetrahydrophenanthrene. A purer product was obtained when the reaction mixture was allowed to stand overnight after the addition of the bromine. The crude material amounted to 2.38 g. (95% yield), m. p. 102–105°. A sample recrystallized for analysis from benzene formed colorless prisms, m. p. 107.8–108.5°.

Anal. Calcd. for $C_{10}H_9O_2Br$: C, 49.81; H, 3.77. Found: C, 49.93; H, 3.77.

2-Bromo-5-methoxyhydrindone-1 2,4-dinitrophenylhydrazone formed red needles from chloroform, m. p. 202.5–204.5° (dec.) (introduced in bath at 195°).

Anal. Calcd. for $C_{16}H_{13}O_5N_4Br$: C, 45.62; H, 3.12; N, 13.30. Found: C, 45.58; H, 3.11; N, 13.48.

2-Cyano-5-methoxyhydrindone-1 (V).—A solution of 2.38 g. of crude 2-bromo-5-methoxyhydrindone-1 (m. p. 102–105°) and 4.76 g. of sodium cyanide in 70 cc. of alcohol and just enough water to dissolve the salt, was allowed to reflux on the steam-bath for twenty-five minutes. After cooling, the solution was diluted with water, extracted twice with ether to remove neutral material, and the chilled aqueous portion was acidified with cold hydrochloric acid. The oily cyano ketone which separated was extracted with chloroform, and this solution was clarified with Norit, then extracted with small portions of 5% potassium hydroxide solution until a test portion no longer gave a precipitate on acidification. Acidification of the combined cold aqueous layers gave 1.34 g. (73%) of 2-cyano-5-methoxyhydrindone-1 which soon solidified, m. p. 90–92.5°. The pure material crystallized from alcohol in tan plates, m. p. 96–96.5°; ferric chloride test negative.

1-Acetoxy-6-methoxytetralin (VIII).—A suspension of 100 g. of lead tetraacetate[23] in 150 cc. of glacial acetic acid (previously distilled from permanganate) containing 33 g. of 6-methoxytetralin[3] was stirred at room temperature for sixteen hours. The reaction, at first slightly exothermic, was controlled by external cooling. The excess oxidizing agent was decomposed with a small amount of glycerol[24] (using the starch-iodide test) and most of the solvent removed under reduced pressure. The oil obtained on dilution with water was extracted with ether, washed with water followed by successive portions of 10% sodium carbonate solution to remove the acetic acid. Two washings with 2% sodium hydroxide solution removed a small amount of dark material (phenolic ?). The ether solution was then washed with water, saturated sodium chloride solution, and dried over anhydrous potassium carbonate. The oil obtained on evaporation was roughly fractionated through a short Vigreux column, and the pale yellow portion, b. p. 132–139° (1–2 mm.), was 1-acetoxy-6-methoxytetralin; yield 27.9 g. (62%). The analytical sample boiled at 118.5° (0.5 mm.); $n^{25}D$ 1.5348.

Anal. Calcd. for $C_{13}H_{16}O_3$: C, 70.89; H, 7.32. Found: C, 71.21; H, 7.19.

This ester is quite unstable, having a pronounced tendency to lose acetic acid to form 7-methoxy-1,2-dihydronaphthalene (XIX). Even on standing, the substance gradually darkens and develops the odor of acetic acid. Since the decomposition is catalyzed by mineral acid, all glassware to come in contact with the ester must be freed of traces of acid by washing with alkali.

7-Methoxy-1,2-dihydronaphthalene (XIX).—When 1-acetoxy-6-methoxytetralin (9.4 g.) was heated at 120° (22 mm.) with a crystal of potassium acid sulfate the elimination of acetic acid was complete in a few minutes. The remaining product distilled at 85–86° (about 1 mm.); yield 5.9 g. (87%). Redistilled material had the b. p. 94–95° (2–3 mm.); 75–76° (0.3–0.4 mm.), $n^{26.5}D$ 1.5837, $d_4^{26.5}$ 1.0561, M_D (found) 50.75, M_D (calcd.) 48.37.

Anal. Calcd. for $C_{11}H_{12}O$: C, 82.46; H, 7.55. Found: C, 82.48; H, 7.48.

The exaltation of the molecular refractivity of XIX is in close agreement with that predicted from data on similar compounds.[25] The exaltation for 1,2-dihydronaphthalene is 1.47. The additional influence of the methoxyl group *para* to the olefinic bond may be estimated from the increase (0.60) in the exaltation produced in the case of styrene by introduction of a *p*-methoxyl group. The expected exaltation for 7-methoxy-1,2-dihydronaphthalene therefore would be 2.07. The observed value is 2.38.

Dimeric 7-Methoxy-1,2-dihydronaphthalene (possibly formula XX).—Four g. of XIX was treated with 40 cc. of 48% hydrobromic acid as described by Long and Burger[12] for 1-hydroxy-6-methoxytetralin. The fraction b. p. about 230° (0.5–1 mm.) amounted to 3.3 g. Recrystallization from 40–60° petroleum ether gave 2.8 g. (70% yield) of material, m. p. 73–76°. A sample purified by recrystallization from methanol formed colorless needles, m. p. 75.5–76.5°. Long and Burger give the m. p. 73–74°.

Anal. Calcd. for $C_{22}H_{24}O_2$: C, 82.46; H, 7.55; mol. wt., 320. Found: C, 82.30; H, 7.53; mol. wt., 333 (Rast).

β-(2-Carboxy-5-methoxyphenyl)-propionic Acid (I). (a) From bis-(5-Methoxy-1-keto-2-hydrindylidenemethyl)-hydroxylamine (XVIII).—A solution of 0.500 g. (0.0013 mole) of uncrystallized XVIII and 0.092 g. (0.0013 mole) of hydroxylamine hydrochloride in 85 cc. of 2% aqueous sodium hydroxide was boiled under reflux. The deep purple color gradually faded, and usually within forty minutes the solution was light-red. Ammonia was slowly evolved as the heating was continued for four days. The filtered solution was acidified and the precipitated acid extracted with ether from which it was recovered by extraction with 5% sodium bicarbonate solution. Acidification of the combined aqueous extracts yielded 0.360 g. (61%) of yellowish β-(2-carboxy-5-methoxyphenyl)-propionic acid, m. p. 194–199° with previous softening. A pure sample of the acid was obtained by sublimation under reduced pressure and crystallization from alcohol. It formed colorless needles, m. p. 203.5–204°.

Anal. Calcd. for $C_{11}H_{12}O_5$: C, 58.92; H, 5.40. Found: C, 58.94; H, 5.44.

(b) By Hydrolysis of 2-Cyano-5-methoxyhydrindone-1 (V).—A solution of 1.07 g. (0.006 mole) of the crude nitrile in 170 cc. of 5% aqueous potassium hydroxide was boiled under reflux until ammonia was no longer evolved (forty-eight hours). The dibasic acid was isolated from the alkaline solution just as described in (a). The yield of colorless material was 1.13 g. (88%), m. p. 201–202.5°; after sublimation under reduced pressure and recrystallization from water it formed colorless needles, m. p. 201.5–203.7°.

(c) By Oxidation of 7-Methoxy-1,2-dihydronaphthalene (XIX).—Powdered potassium permanganate (3.62 g.) was added in portions with stirring to a solution of 1.38 g. of XIX in 30 cc. of acetone. During the addition (twenty minutes) the temperature was maintained between 0 and 3°, then the mixture was stirred at room temperature for about forty minutes. The acetone was removed, dilute sulfuric acid added followed by sodium sulfite to dissolve the manganese dioxide, and the residue extracted with ether. This solution was extracted with 5% sodium bicarbonate solution which on acidification yielded 0.78 g. (40%) of the dibasic acid (I), m. p. 195–199° with previous softening. A sample purified by clarification of a solution of the sodium salt with Norit, followed by recrystallization from alcohol had the m. p. 201–203.5°.

The samples of β-(2-carboxy-5-methoxyphenyl)-propionic acid prepared by the three methods above showed no melting point depressions on mixing.

Cyclization of β-(2-Carboxy-5-methoxyphenyl)-propionic Acid.—Each of the products obtained by the three methods described above was submitted to the following treatment: about 0.2 g. of the acid mixed with a few mg. of barium oxide was distilled slowly in a two-bulb flask. The distillate was dissolved in warm dilute alcohol containing about 2% of sodium bicarbonate. On cooling, crystals of 5-methoxyhydrindone-1 separated, m. p. 108–110°, no depression on mixing with an authentic sample.

Summary

During a search for methods of obtaining β-(2-carboxy-5-methoxyphenyl)-propionic acid several transformations in the 6-methoxytetralin and 5-methoxyhydrindene series have been correlated.

5-Methoxyhydrindone-1 is obtained in good yield by oxidation of 5-methoxyhydrindene. The structure of the ketone was confirmed by com-

(23) A slight modification in the procedure (Fieser, "Experiments in Organic Chemistry," D. C. Heath and Co., Boston, Mass., 2nd ed., 1941, p. 436) for the preparation of lead tetraacetate seemed to be advantageous. When the reaction temperature was kept lower (between 40 and 50°) very little darkening occurred, and the crude product was pale yellow. A single recrystallization without the use of Norit gave an excellent yield of colorless material.

(24) Fieser, "Experiments in Organic Chemistry," 1941, p. 438.

parison with material prepared by a conventional synthesis involving the cyclization of *m*-hydroxyhydrocinnamic acid. Condensation of 2-hydroxymethylene-5-methoxyhydrindone-1 with hydroxylamine hydrochloride in acetic acid yields, instead of the expected nitrile, a dimolecular condensation product which is probably bis-(5-methoxy - 1 - keto - 2 - hydrindylidenemethyl) - hydroxylamine. Alkaline hydrolysis of the latter in the presence of hydroxylamine gives β-(2-carboxy-5-methoxyphenyl)-propionic acid. This acid is also obtained on alkaline cleavage of 2-cyano-5-methoxyhydrindone-1 which can be prepared from 5-methoxyhydrindone-1 through the 2-bromo derivative.

Oxidation of 6-methoxytetralin with lead tetraacetate gives the 1-acetoxy derivative in 62% yield. The latter readily loses the elements of acetic acid to form 7-methoxy-1,2-dihydronaphthalene which forms a crystalline dimer in the presence of hydrobromic acid. Oxidation of the monomeric substance gives β-(2-carboxy-5-methoxyphenyl)-propionic acid.

Morpholinomethyl Derivatives of Urea and Substituted Ureas[1]

BY WELCOME I. WEAVER,[2] J. K. SIMONS[2] AND WILMER E. BALDWIN

The aminomethylation of active hydrogen compounds by primary or secondary amines and formaldehyde has received considerable attention. The work with active methylene compounds, the Mannich reaction, has been reviewed recently,[3] while that with nitrogen compounds has been reported in a number of investigations of amines,[4] imides,[5] amides[6] and thiourea.[7] Einhorn and Spröngerts[8] described the reaction products of diethylaminomethanol and piperidinomethanol with urea. Later Einhorn[9] patented the reaction products of these alcohols with isovalerylurea. More recently there has appeared a patent[10] on the use of several bis-(dialkylaminomethyl)-ureas including bis-(morpholinomethyl)-urea.

The object of the present work was to prepare morpholinomethyl derivatives of urea and a number of substituted ureas and to investigate their behavior under conditions which would bring about cleavage, *e. g.*, reduction, treatment with acid anhydrides, picric acid or alkali.

Monomorpholinomethyl- and bis-(morpholinomethyl)-urea were prepared in yields of 85–95% by the reaction of urea with one or two equivalents of morpholinomethanol in aqueous solution or with paraformaldehyde and morpholine in dioxane. The reaction of dimethylol urea and morpholine gave the bis derivative in a yield of 60%. Methylene-bis-morpholine and urea produced monomorpholinomethylurea in a yield of 33%.

Hydrolysis of these compounds in hot alkaline solution yielded morpholine quantitatively. Zinc and hydrochloric acid reduction of either compound produced N-methylmorpholine. Catalytic reduction of monomorpholinomethylurea under non-hydrolyzing conditions described in the experimental part yielded urea and the calculated anount of N-methylmorpholine.

Monomorpholinomethylurea treated with an excess of acetic anhydride yielded N-acetylmorpholine and a white solid which was provisionally identified by analysis as polymeric dimethylene urea $(—CH_2NCONCH_2—)_x$. Butyric anhydride and monomorpholinomethylurea produced a similar product.

The reaction of picric acid and the morpholinomethylureas in ethanol or water solution formed impure products. Recrystallization progressively changed the melting points until they were near that of morpholine picrate. The hydrolysis indicated by this result is similar to the reported behavior of the morpholinomethyl derivatives of ketones and phenylacetonitrile.[11] It was found that the picrates of both mono- and bis-(morpholino-methyl)-urea could be prepared in glacial acetic acid.

Monomorpholinomethyl derivatives of 18 different substituted ureas were prepared. The N-morpholinomethyl-N′-acetylurea was more stable to hydrolysis than any other urea derivative studied. It formed a picrate stable in water, ethanol and glacial acetic acid, which could be recrystallized without decomposition. Acetic or butyric anhydrides reacted to form N-acetoxymethyl-N′-acetylurea and N-butyroxymethyl-N′-acetylurea, respectively. The acylmorpholine was formed simultaneously.

Monomorpholinomethylthiourea was prepared from thiourea and one equivalent of the aminomethanol. Succinimide and phthalimide yielded N-(morpholinomethyl)-succinimide and N-(morpholinomethyl)-phthalimide. The N-morpholinomethyl derivatives of benzenesulfonamide and *p*-toluenesulfonamide were prepared.

The symmetrical structure suggested by Einhorn[9] for the piperidinomethyl derivative of isovalerylurea has been assigned to bis-(morpholinomethyl)-urea and to the monomorpholinomethyl derivatives of the substituted ureas. Morpholinomethanol reacts only with an amido group ($—NH_2$) of a urea where that group is not substituted. Thus symmetrical diphenyl- and dibutylurea failed to react with morpholinomethanol under the same experimental conditions as phenyl- and butylurea. Normal butylurea yielded only a monomorpholinomethyl derivative even though it reacted with an excess of the aminomethanol. Urea formed only bis-(morpholinomethyl)-urea where two, three or four equivalents of morpholinomethanol were allowed to react with urea.

Dimethylol urea, which is the symmetrical derivative, reacted with morpholine to form a bis-(morpholinomethyl)-urea which was identical with the product formed from two (or more) moles of morpholinomethanol.

N-Carbamylmorpholine is an example of a urea in which both hydrogens of one amido group are substituted. It readily formed a monomorpholinomethyl derivative which must have the symmetrical structure.

Experimental Part

General and Preparations of Materials.—Morpholinomethanol was prepared according to the general procedure of Henry.[4] The unpurified product was used directly. Some of the substituted ureas were commercially available, others were prepared by reported methods.[12] β-Benzoyloxyethylurea, a new substituted urea, was prepared as follows: β-benzoyloxyethylamine hydrochloride[13] from benzoyl chloride and ethanolamine hydrochloride was heated with an equivalent of urea at 130–140°; the product was isolated by washing with water and purified by recrystallizing from ethanol. The melting point was 122–124°; yield, 36%.

Anal. Calcd. for $C_{10}H_{12}N_2O_3$: N, 13.5. Found: N, 13.6.

All melting points were determined with an Anschütz thermometer and were not corrected for stem immersion.

Monomorpholinomethylurea.—A mixture of urea (0.5 mole) and an aqueous solution of morpholinomethanol (0.5 mole) was heated to 80–90°. After the vigorous exothermic reaction took place, the mass was cooled to precipitate a white crystalline solid; yield of crude product was 92%. It was obtained in needle crystals, m. p. 162–163°, by recrystallization from a mixture of ethanol and acetone.

Combination of equivalent quantities of urea, morpholine and paraformaldehyde in boiling dioxane gave the same product in 84% yield. Interaction of methylene-bis-morpholine[5e] and urea in boiling dioxane yielded only 33% of the theoretical monomorpholinomethylurea.

(12) (a) Davis and Blanchard, THIS JOURNAL, 51, 1790 (1929); (b) "Organic Syntheses," Vol. III, John Wiley and Sons, Inc., New York, N. Y., 1923, pp. 95–97; (c) Rudqvist, *Arch. Pharm.*, 236, 452 (1898); (d) Harvey and Caplan, U. S. Patent 2,247,495.

(13) Mannich, *Arch. Pharm.*, 272. 341 (1934).

Bis-(morpholinomethyl)-urea.—Urea (0.25 mole) and two equivalents of aqueous morpholinomethanol were heated until the mixture boiled. On cooling there was obtained a 95% yield of crude product which was purified by crystallization from a mixture of ethanol and acetone. It was obtained in platelets melting at 163–164°. The mixed melting point with monomorpholinomethylurea was slightly lower, 157–159°.

Interaction of urea with two equivalents each of paraformaldehyde and morpholine in boiling dioxane gave the bis derivative in 90% yield. By evaporation of a mildly refluxed solution of dimethylol urea (0.063 mole) and morpholine (0.2 mole) in 50 cc. of water a crude product was obtained, which yielded 60% of the theoretical quantity of bis-(morpholinomethyl)-urea.

Morpholinomethyl Derivatives of Substituted Ureas.—These compounds were prepared from the substituted urea by interaction with one equivalent of morpholinomethanol in aqueous solution (see Table I for several exceptions). In a few cases sufficient ethanol was added so that a homogeneous solution was obtained as the mixture was brought to a boil. The morpholinomethyl derivatives usually crystallized on cooling; a few were obtained by concentrating the solution *in vacuo* and then cooling, while others crystallized after standing for several days in a cold room (0°).

The morpholinomethyl derivatives of *s*-hexylurea and *as*-dimethylurea crystallized at 0° but melted below room temperature and were not purified. The derivative of *as*-diethylurea failed to crystallize after six months.

The preparative and analytical data for the morpholinomethyl derivatives of urea and substituted ureas are listed in Table I.

Symmetrical Disubstituted Ureas and Morpholinomethanol.—*sym*-Diphenylurea (0.1 mole) was refluxed for five minutes with one equivalent of morpholinomethanol in 50 cc. of ethanol. Ninety-five per cent. of the original weight of diphenylurea was recovered unchanged and no evidence of reaction was observed.

sym-Di-*n*-butylurea was heated with one and with two equivalents of morpholinomethanol in dilute ethanol solution. Only unreacted dibutylurea was recovered from the mixture.

Experiments with urea and 2, 3 and 4 equivalents of morpholinomethanol yielded only bis-(morpholinomethyl)-urea in yields of 95, 78 and 63%, respectively. Formation of no other product was indicated.

n-Butylurea and different excess amounts of morpholinomethanol yielded only the mono derivative.

Morpholinomethanol with Thiourea, Imides and Sulfonamides.—These compounds combined readily with morpholinomethanol in dioxane, water or aqueous alcohol by refluxing for thirty minutes. The data are summarized in Table II.

Hydrolysis of Monomorpholinomethylurea.—Monomorpholinomethylurea (0.05 mole) in 100 cc. of 10% sodium hydroxide was steam distilled. The distillate was acidified and concentrated. The concentrated solution by treatment with benzenesulfonyl chloride and 20% alkali yielded 11.7 g. of N-benzenesulfonylmorpholine (m. p. 118–119°). This accounted for 97% of the calculated amount of morpholine present.

Reductions of Monomorpholinomethylurea.—Zinc dust (4 equivalents) was added in small portions to a mildly refluxing hydrochloric acid solution (10%) of the urea derivative. After complete solution of the zinc, the reaction was made alkaline and steam distilled. Organic base in the distillate was determined by titration and identified as methylmorpholine by conversion to picrate, m. p. 224–226°. Morpholine was proved to be absent by testing with benzenesulfonyl chloride; yield of methylmorpholine, 79%. By the same procedure bis-(morpholinomethyl)-urea and morpholinomethanol gave, respectively, 70 and 57% yields of methylmorpholine.

In order to eliminate the probability that morpholinomethanol was first formed by hydrolysis and then reduced, the hydrogenation of monomorpholinomethylurea was

attempted under conditions where hydrolysis was unlikely.

Catalytic Reduction of Monomorpholinomethylurea.—Monomorpholinomethylurea (0.0094 mole) in absolute ethanol was hydrogenated at room temperature and atmospheric pressure using a platinum catalyst (0.1056 g.).[14] One molecular equivalent of hydrogen was absorbed. A quantitative yield of methylmorpholine was isolated as its picrate (m. p. 224–226°). Urea was identified as the other hydrogenolysis product by formation of characteristic crystals of urea nitrate.

Exactly similar results were obtained by hydrogenation in glacial acetic acid.

Acid Anhydride and Monomorpholinomethylurea.—Monomorpholinomethylurea did not react with cold (0–5°) acetic anhydride. At steam-bath temperature reaction took place and an insoluble solid was formed. This product was washed in turn with alkali, alcohol and ether to obtain material, m. p. 235–236°, with fairly reproducible nitrogen values. Found: N, 33.29, 33.21, 33.94. Acetylmorpholine was obtained in 62% yield from the acetic anhydride mother liquors.

Monomorpholinomethylurea and butyric anhydride at steam-bath temperatures yielded the same white insoluble solid, m. p. 233–236°. The mixture of this compound with the preceding product melted at 235–236°. Found: N, 33.69, 33.94. The identity of this solid product is not known, but it may be some urea-formaldehyde condensation product, *e. g.*, $(-CH_2NCONCH_2-)_x$; calcd.: N, 33.3.

N-Acetoxymethyl-N′-acetylurea.—Morpholinomethylacetylurea (0.05 mole) and acetic anhydride (0.39 mole) were heated on the steam-bath for three hours. Solution occurred slowly and cooling yielded a white crystalline product. Crystallization from ethyl acetate yielded 5.5 g. (64%) of material with m. p. 144.6–145.2°. Its saponification equivalent indicated that under the conditions used[15] the acetylurea part of the molecule was saponified also. This conclusion was substantiated by a blank with acetylurea.

Anal. Calcd. for $C_6H_{10}N_2O_4$: N, 16.09; saponification equivalent, 87. Found: N, 16.07; saponification equivalent, 87.

(14) Thanks are owed R. P. Mariella, Carnegie Institute of Technology, who prepared the catalyst and carried out the hydrogenation.

Distillation of the acetic anhydride mother liquors yielded 4.6 g. (72%) of acetylmorpholine, b. p. 230–240°.

N-Butyroxymethyl-N′-acetylurea.—Morpholinomethylurea (0.05 mole) and butyric anhydride (0.31 mole) were heated on the steam-bath for two and one-half hours. A clear solution formed within five minutes and on cooling yielded 8.5 g. (84%) of plate-like crystals which, crystallized from ethyl acetate, melted at 116.8–117°.

Anal. Calcd. for $C_8H_{14}N_2O_4$: N, 13.85; saponification equivalent, 101. Found: N, 13.80; saponification equivalent, 100.

Picrates of Morpholinomethyl Derivatives.—Mono- and bis-(morpholinomethyl)-urea formed unstable picrates (m. p. 140–160°) from alcohol and water solutions. In contrast to these results stable picrates were prepared from glacial acetic acid solutions in a yield expected for a one to one molecular combination from mono- and bis-(morpholinomethyl)-urea. They melted at 162.0–163.3° and 163–164°.

Morpholinomethyl derivatives of alkylureas did not form picrates in glacial acetic acid solutions. In alcohol and water solutions unstable picrates were obtained which on purifying yielded morpholine picrate (m. p. 148.8–149.2°).

Stable picrates of morpholinomethyl derivatives of acetylurea (m. p. 195°), phenylurea (156–158°), phthalimide (205°), and succiuimide (188–189°) were prepared in either water, alcohol or glacial acetic acid solutions.

Summary

Mono- and bis-(morpholinomethyl)-urea were prepared and described. These compounds were cleaved by hydrolysis, reduction, and acetic anhydride to yield morpholine, methylmorpholine and acetylmorpholine.

Morpholinomethyl derivatives of 18 substituted ureas were prepared and characterized; N-morpholinomethyl-N′-acetylurea underwent reaction with acetic anhydride, yielding N-acetoxymethyl-N′-acetylurea and acetylmorpholine. Butyric anhydride gave the analogous butyroxymethyl derivative.

The morpholinomethyl derivatives of thiourea, succinimide, phthalimide, benzene- and *p*-toluenesulfonamide were prepared and characterized.

Kinetics of Reactions between Iodine and Histidine

BY CHOH HAO LI

Imidazole compounds react readily with iodine.[1] The imidazole containing amino acid, histidine, however, has not hitherto been iodinated. Bauer and Strauss[2] were not able to halogenate the histidine with ICl, but their results[3] with globin indicate the possibility of iodohistidine formation. On the other hand, Pauly[1b] succeeded in preparing benzoyldiiodo-histidine and tetraiodo-histidine anhydride. The fact that histidine cannot be iodinated in the free state but both its anhydride and its benzoyl derivative smoothly take up one mole of iodine (on the two C atoms of the imidazole ring) in a slightly alkaline solution has recently been confirmed by Bauer, Strauss and Maschmann.[4]

When histidine and iodine are allowed to react in a nearly neutral solution, the disappearance of iodine follows the rate law

$$dx/dt = (a - x)(b - 2x) \qquad (1)$$

where a and b are the initial concentrations of histidine and titatable iodine, respectively; k_2 is the specific rate constant and x is the concentration of diiodo-histidine which is formed according to the reaction: histidine + 2 I_2 → di-iodohistidine + 2HI. The rate law (1) is identical with that found in the formation of diiodotyrosine.[5] Table I gives the values of k_2 in a typical run for successive time intervals by means of the integrated form of equation (1). The concentrations are in moles per liter and time in minutes. The bimolecular rate law is further verified when one varies the initial concentrations of iodine and histidine. The specific rate is not changed by the addition of neutral salts.

TABLE I

A TYPICAL KINETIC EXPERIMENT AT 25°

$b = 2a = 5.26 \times 10^{-3}m$, $(I^-) = 3.15 \times 10^{-2}m$, *p*H 7.21 citrate–phosphate buffer $(HPO_4^-) = 3.50 \times 10^{-2}m$.

t, min.	$(b)\ 10^3$	$(x)\ 10^3$	k_2
0	(5.26)		
5.0	4.50	(0.38)	(6.4)

30.0	2.65	1.30	6.1
50.0	2.00	1.63	6.3
			Av. 6.2

The Rate as a Function of *p*H.—The dependence of specific rate on *p*H of the environment is similar to that found for the iodine-phenol reaction,[5] *i. e.*, the reaction becomes slower as the acidity of the solution increases. Data, summarized in Table II, give a relationship

$$k_2 = 0.10 + (5 \times 10^{-8}/(H^+)) \qquad (2)$$

in citrate buffers containing $(I^-) = 3.15 \times 10^{-2}$.

TABLE II

EFFECT OF *p*H ON THE RATE AT 25°

Citrate buffer $(I^-) = 3.15 \times 10^{-2} m$

*p*H	k_2	k_2 calcd.
6.00	0.05	0.06
6.56	.25	.28
6.94	.50	.54
7.07	.72	.70
7.21	1.00	.90

The Rate as a Function of (I^-).—In a constant *p*H solution, the rate decreases as the (I^-) increases. This is evident from the results shown in Table III. The last column of Table III is calculated by the equation

$$k_2 = \frac{4.0 \times 10^{-3}}{(I^-)} + \frac{6.0 \times 10^{-4}}{(I^-)^2} \qquad (3)$$

The agreement between the observed and calculated k_2 appears satisfactory.

TABLE III

EFFECT OF (I^-) ON THE RATE AT 25°

Citrate buffer, *p*H 7.07

$(I^-)\ 10^2$	k_2	k_2 calcd.
3.15	0.72	0.73
3.80	.52	.52
5.00	.33	.32
7.10	.19	.17
10.00	.10	.10

From the preceding studies of diiodo-tyrosine formation,[5] it may be assumed that free iodine and hypoiodous acid react with the histidine. The rate law becomes

$$\frac{-\mathrm{d(histidine)}}{dt} = k_2'\,(\text{histidine})(I_2) + k_2''\,(\text{histidine})(\mathrm{HOI}) \qquad (4)$$

Since the concentrations of iodine and hypoiodous acid are determined by the equilibria (5) and (6)

$$I_2 + I^- \rightleftarrows I_3^- \qquad (5)$$

$$I_2 + H_2O \rightleftarrows HOI + H^+ + I^- \qquad (6)$$

it follows that

$$-\frac{\mathrm{d(histidine)}}{dt} = \left[\frac{k_2'}{K_5(I^-)} + \frac{k_2''K_6}{K_5}\frac{1}{(H^+)(I^-)^2}\right](\text{histidine})(I_3^-) \qquad (7)$$

therefore

$$k_2 = \frac{k_2'}{K_5(I^-)} + \frac{k_2''K_6}{K_5}\frac{1}{(H^+)(I^-)^2} \qquad (8)$$

Thus, in a constant *p*H with variations of (I^-) the specific rate may be represented by the expression

$$k_2 = \frac{A}{(I^-)} + \frac{B}{(I^-)^2} \qquad (9)$$

where $A = k_2'/K_5$ and $B = k_2''K_6/K_5(H^+)$. This expression is in accordance with the empirical equation (3). By comparison of equations (3) and (9) together with the equilibrium constants,[6,7] $K_5 = 715$, $K_6 = 3 \times 10^{-13}$ at 25°, we have obtained $k_2' = 2.9$ and $k_2'' = 1.2 \times 10^5$.

When the reaction occurs in a constant (I^-) with variations of (H^+), equation (8) may be written as

$$k_2 = C + (D/(H^+)) \qquad (10)$$

where $C = k_2'/K_5\,(I^-)$ and $D = k_2''\,K_6/K_5\,(I^-)^2$. This is identical with the empirical equation (2). From equations (2), (10), and equilibrium constants K_5, K_6, the specific rate k_2' and k_2'' are computed to be 2.3 and 1.18×10^5, respectively. These values agree very well with those obtained with a different set of data as described.

Therefore, the reaction of iodine and histidine in citrate buffer follows the course expressed by

$$-\mathrm{d(histidine)}/dt = 2.5(\text{histidine})(I_2) + 1.2 \times 10^5(\text{histidine})(\mathrm{HOI}) \qquad (11)$$

It is evident that hypoiodous acid is far more reactive as an iodinating agent than free iodine. This conclusion is consistent with that obtained in the study of the iodination of phenols.[5]

Catalytic Effect of $(HPO_4^=)$ on the Rate.—When a phosphate buffer instead of the citrate buffer of the same *p*H was used, the specific rate was greatly increased. Since the rate is not accelerated by the addition of neutral salt, the effect of phosphate buffer must be specific.

When a phosphate buffer of the same *p*H was added gradually to the citrate buffer, the rate appeared to increase according to the concentration of $(HPO_4^=)$. The data in Table IV bear out these conclusions. A similar catalytic effect of phosphate buffer was observed in the kinetic studies of diiodo-tyrosine formation.[8]

TABLE IV

EFFECT OF $(HPO_4^=)$ ON THE RATE AT 25°, $(I^-) = 3.15 \times 10^2$

*p*H of buffer	$(HPO_4^=)\ 10^2$	k_2
7.21	0.00	1.0
	1.75	3.2
	3.50	6.2
	5.25	8.4
	7.00	11.1

	1.10	.55
	2.20	1.0
	3.30	1.2
	4.40	1.6

Discussion

The fact that the kinetic data herein reported are analogous to those secured in the iodination of tyrosine indicates that iodine reacts with the imidazole ring of the histidine molecule to form diiodo-histidine

(6) W. C. Bray and Mackay, THIS JOURNAL, 32, 914 (1910).

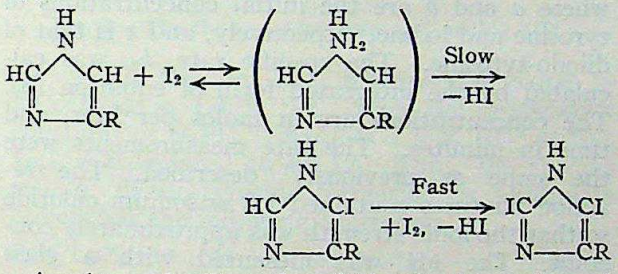
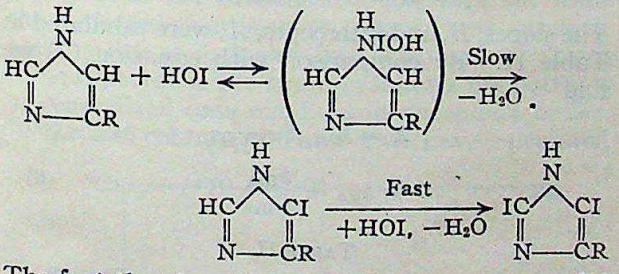
Preliminary experiments in which diiodo-histidine was isolated, indicated that this is indeed the case. Bauer and Strauss[3] have postulated that one iodine atom is attached to the amino group of the imidazole ring. Our experiments do not support this assumption.

The kinetic data here reported show that the rate-determining step requires a reaction of the first order with respect to both histidine and iodine although the net reactions use up two moles of iodine. Since most aromatic substitution reactions are usually explained by the rearrangement mechanism,[5,9] a similar scheme may be applied to the present case

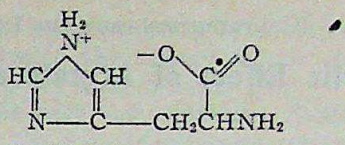


As shown in Equation (11), the formation of diiodo-histidine is also achieved through another path in which the hypoiodous acid is the iodinating agent



The fact that hypoiodous acid is a more powerful iodinating agent than iodine may be partly attributed to the greater tendency to form *undissociated* water molecule as compared with the formation of ionizing hydrogen iodide when free iodine acts as an iodinating agent.

In acid solution the occurrence of $>NH_2^+$ ion prevents the formation of the $>NHI_2$ or $>NHIOH$ complex and in turn the rate becomes slower. A similar explanation may be offered of the ease of isolation of the tetraiodo-histidine anhydride as observed by Pauly and others. In free histidine, it is probable that there exists a dipolar ion



which is absent in histidine anhydride.

The iodination of tyrosine is much faster than that of histidine and this may be partly due to the occurrence of such a dipolar ion in the histidine molecule. Table V summarizes the specific rates of diiodo-histidine and diiodo-tyrosine formation under comparative conditions. At *p*H 6.0, for instance, k_2 for histidine is about one hundredth of that for tyrosine. It is of interest to note that in the iodination of certain proteins, such as insulin[10] and pituitary lactogenic hormone,[11] the I_2 reacts only with the tyrosine residue although the protein contains both tyrosine and histidine. If the iodine is in excess and the solution is allowed to react longer, the histidine residue in the protein may take up iodine as well as the phenolic groups of the molecule.

TABLE V

COMPARISON OF THE RATE OF DIIODO-HISTIDINE AND DIIODO-TYROSINE FORMATION AT 25°

*p*H	Buffers	$(I^-)\ 10^2$	k_2 Tyrosine	k_2 Histidine
7.21	Citrate	3.15	27.0	1.0
7.21	Phosphate[a]	3.15	(310)	16.0
7.00	Phosphate[b]	10.00	7.4	0.34
6.00	Citrate	3.15	3.9	.05

[a] $(HPO_4^-) = 0.125\ m$. [b] $(HPO_4^-) = 3.06 \times 10^{-2}\ m$ containing 0.90 m $NaNO_3$.

Experimental

The crystalline l-histidine monohydrochloride (Eastman Kodak Co.) was used without further purification. Citrate and phosphate buffers were made according to Clark.[12] A weighed amount of histidine in 20 cc. of buffer was mixed with 20 cc. of iodine buffer solution containing the known concentration of potassium iodide in a glass-stoppered flask at 25.0 ± 0.02° thermostat, after both histidine and iodine solutions had attained the temperature of the thermostat. The time of mixing was taken as 0 time. The disappearance of iodine during the reaction was followed at known time intervals by pipetting 5 cc. of solution into 10 cc. of 1.0 m hydrochloric acid, which stopped the reaction. The excess of iodine was titrated with 0.010 N thiosulfate solution using starch solution as indicator.

Summary

The reaction between iodine and histidine to form diiodo-histidine is evident from the kinetic data; the kinetics of its formation is similar to that found in diiodo-tyrosine formation. At 25° in citrate buffer the rate of diiodo-histidine formation follows the expression: rate = 2.5 (histidine) $(I_2) + 1.2 \times 10^5$ (histidine) (HOI).

Catalytic Effect of Acetate and Phosphate Buffers on the Iodination of Tyrosine

BY CHOH HAO LI

In the reactions between iodine and tyrosine[1] it was observed that the rate is accelerated by the phosphate buffer. It was further noted that such an effect is not due to the increase of ionic strength. It is now possible to show that the specific rate, k_2, in phosphate buffer corresponds to the sum of a series of catalytic effects represented by the equation

$$k_2 = k_{OH}(OH^-) + k_{HA}(HPO_4^-) + k_{H_2A}(H_2PO_4^-) \quad (1)$$

where k_{OH}, k_{HA} and k_{H_2A} are the catalytic coefficients of hydroxide, dibasic and monobasic phosphate ions, respectively. In view of the equilibria

$$H_2PO_4^- \rightleftharpoons H^+ + HPO_4^-$$
$$H_2O \rightleftharpoons H^+ + OH^-$$

equation (1) may be written

$$k_2 = k_{OH} K_W \frac{1}{(H^+)} + (HPO_4^-)\left[k_{HA} + \frac{k_{H_2A}}{K_{H_2A}}(H^+)\right] \quad (2)$$

where K_{H_2A} is the dissociation constant of $H_2PO_4^-$.

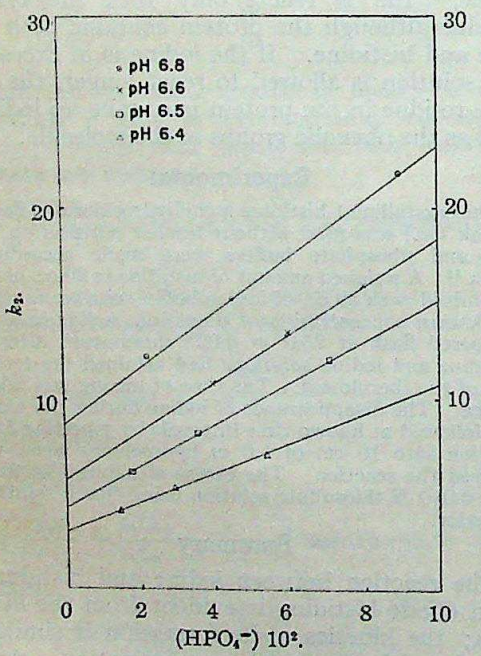

Fig. 1.—Specific rate, k_2, as the function of (HPO_4^-) at 25°.

Catalytic Activity of Phosphate Buffer.—Table I presents a summary of the specific rates obtained in different pH of different concentrations of phosphate at 25°. It may be recalled that the iodination of tyrosine[1] follows a bimolecular reaction rate

$$dx/dt = k_2(a - x)(b - 2x) \quad (3)$$

TABLE I

THE EFFECT OF HPO_4^- ON THE RATE AT 25°, $(I^-) = 6.3 \times 10^{-2}$

pH	$(HPO_4^-)\ 10^2$	k_2	k_2 calcd.
6.80	2.23	12.2	11.5
6.80	4.47	15.4	16.9
6.80	8.95	22.0	21.1
6.60	4.02	10.8	10.7
6.60	6.03	13.6	14.0
6.60	8.06	16.0	17.4
6.50	1.79	6.2	6.4
6.50	3.58	8.2	9.5
6.50	7.16	12.31	15.6
6.40	1.50	4.2	5.1
6.40	3.00	5.4	7.8
6.40	5.40	7.2	11.8

where a and b are the initial concentrations of tyrosine and iodine, respectively, and x is that of diiodo-tyrosine. The specific rate, k_2, was calculated by the integrated form of equation (3). The concentrations are in moles per liter, and time in minutes. The rate measurements were the same as previously[1] described. The reaction mixtures contained 1.0 m sodium chloride so that the ionic strength was approximately constant. The pH was measured with a glass electrode.

As shown in Fig. 1, a plot of (HPO_4^-) against the specific rate reveals a linear function

$$k_2 = A + B(HPO_4^-) \quad (4)$$

The slopes, B, and intercepts, A, were tabulated in Table II. By comparison with equation (2) we find

$$A = k_{OH} K_W \frac{1}{(H^+)} \quad (5)$$

$$B = k_{HA} + \frac{k_{H_2A}}{K_{H_2A}}(H^+) \quad (6)$$

TABLE II

THE VALUES OF A AND B IN PHOSPHATE BUFFER

pH	A	B
6.80	8.8	130
6.60	5.8	110
6.50	4.3	105
6.40	3.0	85

In Fig. 2 we have drawn the relation[2] between A and $1/(H^+)$ from the slope of this curve and $K_W = 1.2 \times 10^{-14}$ we have computed the catalytic coefficient of hydroxide ion, k_{OH}, to be 1.0×10^8.

Similarly Fig. 3 presents the plot of B *versus* (H^+); it appears that equation (6) holds very well. From the intercept of the curve in Fig. 3

(1) C. H. Li, THIS JOURNAL, 64, 1147 (1942).

(2) We have assumed that $a_{H^+} = (H^+)$ throughout in this paper.

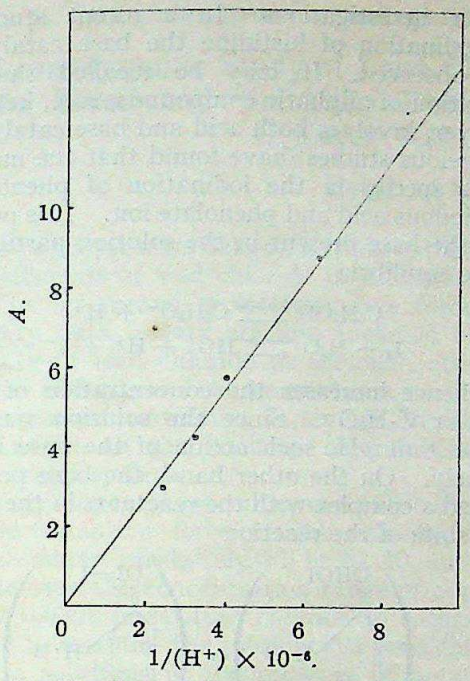

Fig. 2.—The change of intercepts, A, with $1/(H^+)$.

we obtain $k_{HA} = 150$, whereas the slope $= k_{H_2A}/K_{H_2A} = 1.6 \times 10^8$. Since the dissociation constant[3] of $H_2PO_4^-$, $K_{H_2A} = 7.5 \times 10^{-8}$ at 25°, k_{H_2A} is calculated to be 12. Thus, the specific rate of diiodo-tyrosine formation in phosphate buffers has the following expression

$$k_2 = 1.0 \times 10^8 (OH^-) + 150 (HPO_4^-) + 12 (H_2PO_4^-) \quad (7)$$

Hence it may be said that the catalytic effect of dibasic phosphate ion is about 10 times more active than the monobasic phosphate ion while the hydroxide ion is most potent in its catalytic activity due to its highly basic character. This is to be expected if the reaction follows the patterns of generalized base catalysis in phosphate buffer. In the last column of Table I we have calculated the specific rate using equation 7; there is a closer agreement between the observed and calculated values in higher pH than at lower pH.

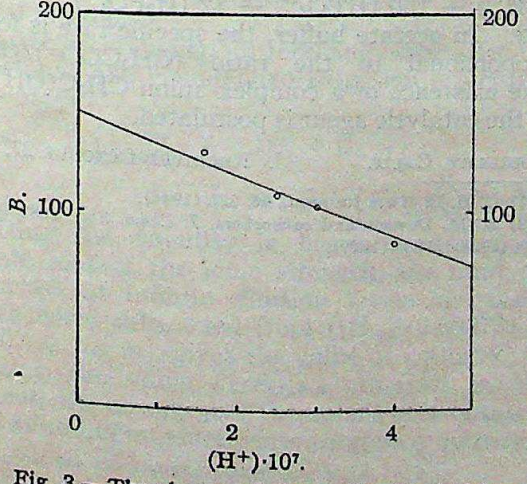

Fig. 3.—The change of slopes, B, with (H^+).

Catalytic Activity of Acetate Buffers.—In acetate buffer, the acetate ion itself does not seem to involve the catalytic mechanism. This is surprising because one would expect that the catalytic coefficient of acetate ion should be of the same magnitude as that for monobasic phosphate. Table III summarizes the kinetic data studied in acetate buffers with different concentrations. The relations between the concentration of acetate ion and specific rate do not conform to similar equations given for the phosphate buffer.

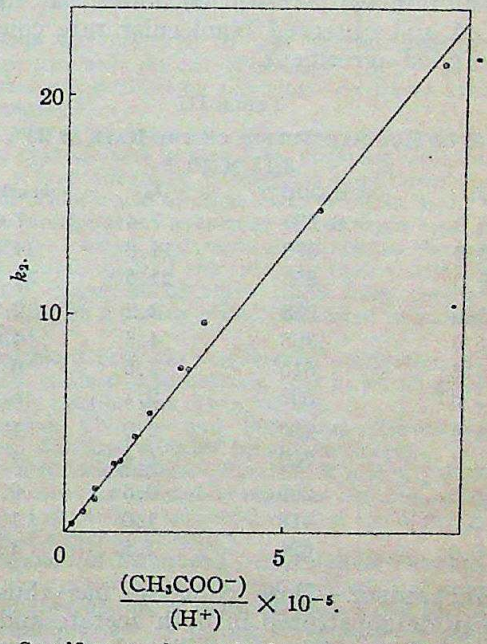

Fig. 4.—Specific rate, k_2, as the function of $(CH_3COO^-)/(H^+)$ at 25°.

As given in Fig. 4 it is possible to show that the specific rate is a function of $(CH_3COO^-)/(H^+)$

$$k = C(CH_3COO^-)/(H^+) \quad (8)$$

where C is a constant. This result may be explained if the acetate buffers are assumed to contain the complex acetate ion $CH_3C(OH)O_2^-$ formed by combination[4] of the simple ion with the hydroxide ion. The relation between the concentrations of these entities is given by $K_c = (CH_3C(OH)O_2^-)/(CH_3COO^-)(OH^-)$, where K_c is the complex constant. The catalytic coefficient for the complex anion being denoted by k_c, equation (8) becomes

$$K_2 = K_w K_c k_c \frac{(CH_3COO^-)}{(H^+)} \quad (9)$$

(3) A. Kossiakoff and D. Harker, THIS JOURNAL, 60, 2047 (1938).

(4) In dilute acetic acid solution we may have some acetic acid hydrate

$$CH_3COOH + H_2O \rightleftharpoons CH_3C(OH)_3 \rightleftharpoons CH_3C(OH)O_2^- + 2H^+$$

The formation of the complex acetate ion may not be unreasonable.

CC-0. Jangamwadi Math Collection. Digitized by eGangotri

Digitized by Arya Samaj Foundation Chennai and eGangotri

From Fig. 4 the slope of the curve gives $K_wK_ck_c = 2.5 \times 10^{-5}$. Since the magnitude of the complex anion constant K_c is unknown, it is not possible to assign a value to the catalytic coefficient[5] k_c. However, it may be expected that the complex anion, $CH_3C(OH)O_2^=$, is more basic than the simple hydroxide ion; this in turn suggests that the catalytic coefficient of the complex anion would be greater than that of hydroxide ion. It is of interest to note that Dawson and Spivey[6] have suggested the formation of the complex ion ($CH_3COOH \cdot CH_3COO^-$) as an active catalytic species in the reaction of iodine and acetone in acetate buffer.

Table III includes the specific rate calculated by equation (9). It will be noted that the calculated and observed binolecular rate constants are in good agreement.

TABLE III

EFFECT OF ACETATE BUFFER ON THE RATE AT 25°, $(I^-) = 3.15 \times 10^{-2}$

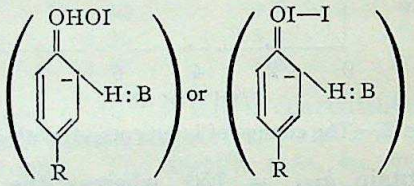
pH	(CH_3COO^-)	k_2	k_2 calcd.
6.0	0.280	7.4	7.0
6.0	.570	14.8	14.3
6.0	.850	21.5	21.2
5.6	.268	3.2	2.7
5.6	.398	4.5	4.0
5.6	.645	7.5	6.5
5.6	.805	9.7	8.1
5.4	.250	2.0	1.6
5.4	.760	5.4	4.8
5.0	.209	0.6	0.5
5.0	.418	1.0	1.1
5.0	.626	1.5	1.6

Mechanism.—Base catalysis has thus been clearly demonstrated in both acetate and phosphate buffers. The possibility that the catalysis may belong to the generalized base type needs further investigations. In a recent study[7] of the iodination of histidine the base catalysis is also observed. It may be recalled that the iodination of aliphatic compounds, *e. g.*, ketones,[8] however, involves both acid and base catalysis.

Previous studies[1] have found that the most reactive species in the iodination of phenols are hypoiodous acid and phenolate ion. It is possible that the base present in the solution participates in the equilibria

$$C_6H_5OH \rightleftharpoons C_6H_5O^- + H^+$$
$$I_2 + H_2O \rightleftharpoons HOI + H^+ + I^-$$

and hence increases the concentration of either HOI or $C_6H_5O^-$. Since the solution was kept at constant pH, such action of the base is very unlikely. On the other hand, the base probably formed a complex with the reactants in the transition state of the reaction



where :B denotes the base. Thus the removal of hydrogen atom from the ring is assisted by :B and in turn enhances the rate of the iodine atom entering into the ortho position. It is obvious that the catalytic coefficients of :B depend on its basicity. In the present investigation we have obtained an order of the catalytic effect: $CH_3C(OH)O_2^= > OH^- > HPO_4^= > H_2PO_4^-$, which approximately follows the order of their basicity.

Summary

1. The catalytic effect of phosphate and acetate buffers in the reactions between iodine and tyrosine has been investigated at 25°. In phosphate buffer, the specific rate is $k_2 = 1.0 \times 10^8 (OH^-) + 150 (HPO_4^=) + 12 (H_2PO_4^-)$.

2. In acetate buffer, the specific rate is found proportional to the ratio $(CH_3COO^-)/(H^+)$. The existence of a complex anion $CH_3C(OH)O_2^=$ as the catalytic agent is postulated.

BERKELEY, CALIF. RECEIVED OCTOBER 27, 1943

(5) We may assume that K_c is very small and has a magnitude of 10^{-10}. This is not unreasonable if we compare the following equilibria

$$OP(OH)_2O^- \rightleftharpoons OP(OH)O_2^= + H^+$$
$$OC(OH)_2 \rightleftharpoons OC(OH)O_2^- + H^+$$
$$H_3CC(OH)_2O^- \rightleftharpoons H_3CC(OH)O_2^= + H^+$$

Since we know the dissociation constants of monobasic phosphate and carbonic acid of about 10^{-3}, the assumption of taking 10^{-10} as K_c for the complex anion $CH_3C(OH)_2O^-$ may be justified. Thus, if $K_c = 10^{-10}$, k_c is computed to be 2.5×10^{10}; it is far greater than the catalytic coefficient for hydroxide ion as obtained in phosphate buffer.

[A CONTRIBUTION FROM THE DEPARTMENT OF CHEMISTRY OF THE OHIO STATE UNIVERSITY]

A Thermodynamic Study of Lead Chloride in Dioxane–Water by Means of Electromotive Force and Solubility Data at 25°; The Acetone-, Ethanol-, Dioxane-, Glycerol–Water–Lead Chloride Systems[1a]

BY M. V. NOBLE AND A. B. GARRETT

This paper presents data on a study of the activity coefficients of lead chloride in dioxane–water solutions by means of electromotive force and solubility data. Data are also included on the solubility of lead chloride in acetone-, ethanol-, dioxane- and glycerol–water mixtures.

The general procedure is similar to that of other work[1] on the thallous chloride–ethylene glycol–water system.

The experimental procedure was (1) to measure the electromotive force of the cell Ag/AgCl/dioxane–water/$PbCl_2$/(Hg)Pb in 20, 40, and 60% dioxane over the concentration range of approximately 0.0004 molal lead chloride to saturation, and (2) to measure the solubility of lead chloride in these solutions in the presence of potassium chloride.

The cell data are used to evaluate the activity coefficients of lead chloride below the saturation point, and the solubility data are used for this evaluation above saturation. Solubility measurements in alcohol–water, acetone–water, and glycerol–water mixtures supplement the dioxane–water data and give an interesting picture of the effect of dielectric constant *versus* the solvent character upon the solubility of lead chloride.

The activity coefficients are evaluated by the method of Carmody.[2]

In a cell without liquid junction

$$E = E_0 - \frac{RT}{NF} \ln a_{AB_2} \text{ or} \qquad (1)$$

$$E_0 - E_{obs.} = \frac{3RT}{Nf} \ln (4a_{\pm}) = \frac{3RT}{Nf} \ln 4(\gamma_{\pm} m_{\pm}) \qquad (2)$$

where $E_{obs.}$ is the measured e. m. f., E_0 is the standard potential and the other quantities have their usual meaning.[1]

After rearranging, introducing values for the constants, and changing to Briggsian logarithms, we obtain

$$-\log \gamma_{\pm} = \left[\frac{E_{obs.}}{0.08873} + 0.2007 + \log m\right] - \frac{E_0}{0.08873} \qquad (3)$$

Plotting the quantity in brackets against the square root of the ionic strength, the limit approached at infinite dilution gives $E_0/0.08873$ which when subtracted from $[(E_{obs.}/0.08873) + 0.2007 + \log m]$, gives the value of $(-\log \gamma_{\pm})$.

Using the value $(1/m)_{\mu=0}$ obtained in this manner, the accuracy of the values of γ obtained from solubility measurements are greatly increased.

III. Experimental Procedure

Conductivity water was used to prepare the solvent mixtures. Dioxane was purified[3,4] by refluxing it for two days with concentrated hydrochloric acid and then for two days over metallic sodium. The purified dioxane was stored over sodium until time to be used, at which time it was redistilled from the sodium and stored under nitrogen.

Glycerol was prepared by distilling at reduced pressure Merck C. P. grade glycerol; only the middle portion was used.

Acetone was prepared for use by fractionating C. P. grade acetone as in the case of glycerol.

Alcohol was purified by refluxing over silver oxide and fractionating.[5]

The solvent mixtures were all prepared on weight basis.

Lead chloride was prepared by dropping Coleman and Bell C. P. lead nitrate (1 *N* solution) simultaneously with 1 *N* hydrochloric acid solution into a two-liter flask. During the precipitation a current of nitrogen was passed through the solution to exclude air and to stir the mixture. The precipitate of lead chloride was then washed by decantation, recrystallized three times from conductivity water, dried on a porous plate, and stored in a desiccator until used.

Hydrochloric acid was prepared by distillation of Grasselli C. P. grade of hydrochloric acid in an all-glass still; the middle fraction was taken for use.

Potassium Chloride and Potassium Nitrate.—Baker Analyzed was used without futher purification.

Diphenylthiocarbazone.—Eastman Kodak Co. diphenylthiocarbazone was purified by repeated extraction between water and chloroform as recommended by Wilkins, Willoughby, Kramer and Smith.[6]

Preparation of Electrodes.—Silver–silver chloride electrodes were prepared by different methods,[7-12] several of which involve plating of platinum with silver and subsequent chloridization, or baking silver oxide on platinum followed by chloridization. Due to several chemical and mechanical difficulties involved, it was decided to investigate the possibility of simply chloridizing pure silver wire as described in previous work.[12] This gave a firm white coating of silver chloride in a solution free from impurities such as are present in a silver plating bath (particularly the cyanide ion). These electrodes gave the required potential reproducible to 0.1 mv. against a calomel half-cell. Electrodes were prepared in this manner only a short time in advance of making up the cell and were stored in distilled water until ready for use.

Preparation of Amalgam.—The amalgam was prepared thermally[13] by dissolving enough freshly cleaned Baker Reagent stick lead in carefully purified mercury to make a 6% amalgam. The amalgam was run through a capillary tube and stored in a sealed Pyrex tube under nitrogen pressure until used.

Preparation of Cells.—The cell was a modification of the one used by Carmody.[1,2]

Purification of Nitrogen.—Tank nitrogen was purified by successively passing it through soda lime, calcium chloride, reduced copper at 700°, calcium sulfate, alkaline pyrogallol, and a solution of the same composition as that in the cell. All work was done in an atmosphere of nitrogen.

Measurement of e. m. f.—The e. m. f. of the cells was measured with a Leeds and Northrup type K-2 potentiometer. The standard cell used was checked at regular intervals against another cell certified by the National Bureau of Standards which was kept for that purpose only. The galvanometer used was a Type R (Leeds and Northrup) with a sensitivity of 3×10^{-9} ampere per millimeter with scale at one meter. All leads were shielded.

Preparation of Solubility Samples.—These were prepared by the method described in earlier work.[1,14]

Sampling and Analysis.—After equilibration, the samples were sedimented for a day in the 25° bath, and were then filtered by means of nitrogen pressure through a Jena glass filter into a dry flask. The sample was weighed, density determinations were then made and the weighed sample analyzed by the chromate method given by Scott[15] (test analyses by this method gave results reproducible to two parts in one thousand) or by the colorimetric method of Craig and Vinal.[16]

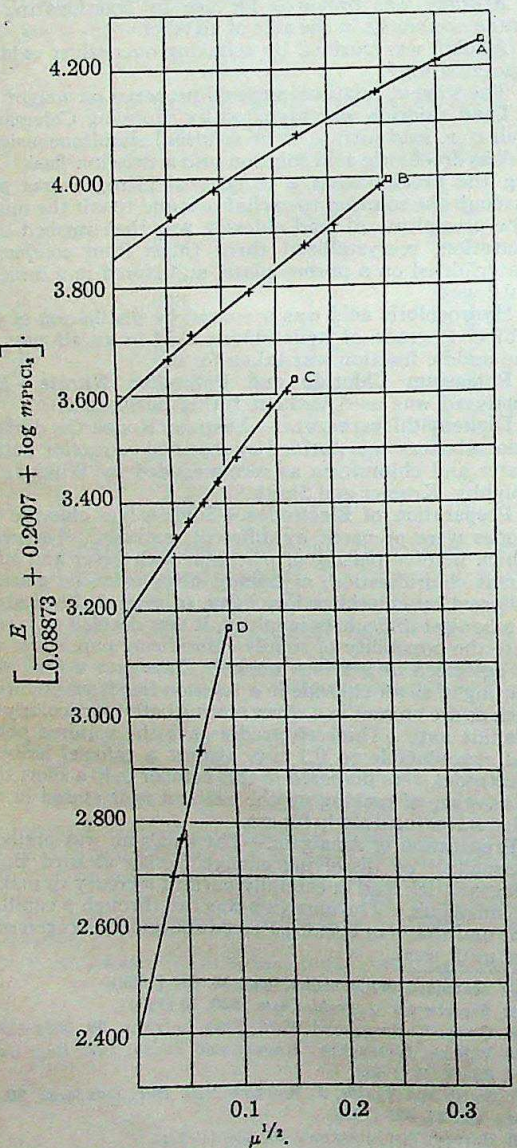

Fig. 1.—A, Water; B, 20% dioxane; C, 40% dioxane; D, 60% dioxane.

The Data

A. Electromotive Force Data; Activity Coefficients to Saturation (at 25 ± 0.02°).—The apparatus and techniques of the cell measurements were first studied in the lead chloride–water system previously reported by other investigators;[2,17] the values of E and γ obtained were in agreement with their data. The mixed solvent system was then investigated.

The activity coefficients of lead chloride were calculated from cell data in 20, 40 and 60% dioxane–water mixtures which are given in Table I.

TABLE I

ACTIVITY COEFFICIENTS OF LEAD CHLORIDE FROM E. M. F. DATA

(18) Early work on these cells was discouraging due to the difficulty experienced in reproducing the data. However, this was almost entirely eliminated as a result of the observation that even small traces of oxygen will apparently cause rapid oxidation of the organic solvent in the presence of the solute. Consequently, standard solutions prepared and stored under nitrogen were discarded and the general policy adopted was to prepare the lead chloride–dioxane–water solutions just before it was to be used.

[a] All concentrations are expressed as moles of solute for 1000 g. of solvent.

Considering the error in extrapolation to $\mu = 0$ and the reproducibility of the data, the maximum probable error is in the order of ±0.005.

From the value of $\gamma_{\pm}$ at saturation and $(1/m_{\pm})_{\mu \text{ at sat.}}$, the value of $(1/m_{\pm})_{\mu=0}$ could be evaluated for use in evaluating γ from the solubility data.

B. Solubility Data in Potassium Chloride and in Potassium Nitrate Solutions.—The data in potassium chloride solutions are summarized in Table II. All solubility values are expressed in moles per 1000 g. of solvent. A plot of the solubility of lead chloride as a function of added chloride ion is shown in Fig. 2. The common ion effect, complex formation and relative degree of dissociation may be noted in this graph.

An indication of the degree of dissociation of lead chloride in these solvents is given by extrapolating the solubility curve to $m_{Cl^-} = 0$ to obtain the amount of undissociated lead chloride.[19] This value divided by the total amount of lead chloride in solution (solubility in the pure solvent) gives the per cent. of dissociated lead chloride; these values range for 5% in water through 6, 9 and 20% in the three mixtures studied. The data in water solubility are those obtained by Deacon in solutions of sodium chloride.[20] Fromherz[21] claims that absorption spectra data indicate the following relative ion concentrations in a saturated aqueous solution of lead chloride: 48%$PbCl^+$, 48%Pb^{++} and 4%$PbCl_2$. His conclusions are compatible with the above calculations.

TABLE III

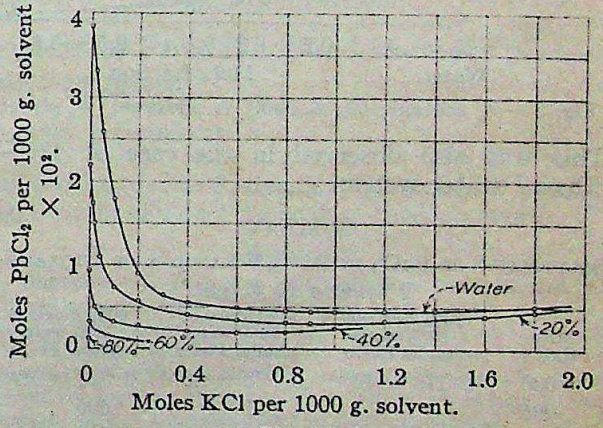

Fig. 2.

Values of γ at rounded values of m_{PbCl_2} are given in Table III.

The solubility of lead chloride as a function of added potassium nitrate (at 25°) is summarized in Table IV. The increased ionic strength due to the presence of potassium nitrate has the obvious and expected effect of increasing the solubility of lead chloride.

The limiting slopes of $-\log \gamma_{\pm}$ *vs.* $\sqrt{\mu}$ are 1.69, 2.73 and 8.00 for the three mixtures studied; they are all larger than the theoretical slopes calculated from the limiting law, $-\log \gamma = C\sqrt{\mu}$.

[a] All concentrations are expressed as moles of solute per 1000 g. of solvent.

Other situations where the experimental slopes are greater than the theoretical slopes have been observed in the $CdBr_2$–water system,[22] in which it is well known the cadmium bromide is a weak electrolyte; furthermore, it is observed in mixed solvent systems,[23] and in liquid ammonia system.[24] It may safely be concluded that the deviation from the limiting law can be accounted for primarily by the increased association at these low values of the dielectric constant. The changing a values should be considered but are probably of secondary importance.

Solubility Products.—The thermodynamic solubility products of lead chloride have been calculated in water, 20, 40 and 60% dioxane from the relationship $K_{s.p.} = 4(m\gamma)^3$, and are given in Table V.

WITH MICHAEL ERCHACK, STANLEY MILLER AND HENRY FLOYD

C. The Solubility of Lead Chloride in Dioxane–Water, Ethanol–Water, Acetone–Water, Glycerol–Water and Ethylene Glycol–Water Solutions.—Preliminary treatment of the lead chloride–dioxane–water data indicated that a plot of the log of the solubility of lead chloride *vs.* log D along with the data of Dunning and Shutt[25] taken in solutions of glycine and water of high dielectric constant, gave a break at the water point. This behavior led us to become interested in the behavior of other solvent pairs to obtain at least qualitative information about the specific solvent effect *versus* the dielectric constant effect. Consequently, solubility data were obtained in several

[a] Carmody, ref. 2.

The plot of solubility *vs.* mole fraction (Fig. 3) gives an interesting comparison of relative solvation effects in mole for mole of solvent.

It appears that the number and the character of polar groups on the solvent which is used with water is a factor that determines the direction of the solubility effect. Within the particular solvent pair the dielectric constant of the mixture plays an important role, but a minor one compared with the "solvent character" effect. This is in accord with the conclusions of Kraus.[27]

(26) The data on the lead chloride–ethylene glycol–water system were published in THIS JOURNAL, **65**, 293 (1943). The data are tabulated here in weight per cent. rather than mole per cent. for the sake of condensing the tables. The data are shown in Fig. 3 as mole fraction which serves as a better basis of comparison of solvation effects.

Summary

1. The electromotive force of the cell $Pb(Hg)/PbCl_2/AgCl/Ag$ has been measured at several concentrations in 20, 40, and 60% dioxane–water mixtures.

2. The solubility of lead chloride has been determined in dioxane–water mixtures with added potassium chloride and potassium nitrate. The solubility has also been determined in alcohol–water, glycerol–water and acetone–water mixtures with no added salt present.

3. From these data the activity coefficients of lead chloride are calculated over a wide range of concentrations. The divergence in the slope of $-\log \gamma$ *vs.* $\sqrt{\mu}$ is attributed to association.

4. The solubility product constants are calculated for the 20, 40, and 60% mixtures of dioxane and water and for pure water.

5. The data in the various mixed solvent pairs are discussed.

The Dipole Moments of Friedelin, Cerin, Isomers of Friedelinol and Isomers of 3-α-Naphthyl-1-chloro-1-propene[1,2]

BY JOHN J. LANDER AND W. J. SVIRBELY

The presence of specific functional groups in friedelin, cerin and high and low melting friedelinol have been decided upon on the basis of chemical evidence.[3] While dipole moment determinations would not be able to locate the positions of the functional groups in these cases, nevertheless such measurements could be regarded as a check on the accepted structures since their magnitudes should be of about the same order as those usually attributed to those same functional groups. This investigation was undertaken to check the structures of the above compounds. Dipole moments were also determined for two compounds which were suspected of being *cis–trans* isomers of 3-α-naphthyl-1-chloro-1-propene to decide whether such isomerism was possible on the basis of their moments.

Materials

Benzene.—J. T. Baker thiophene-free benzene was refluxed over mercuric acetate, dried with calcium chloride, refluxed over sodium and fractionally distilled over sodium, collecting the middle fraction (b. p. 78.1° uncor.). Subsequent distillations of benzene solutions were made to recover the benzene for reuse. The benzene was stored over sodium wire in a glass bottle and used as required.

Friedelin.—Slightly impure friedelin was recrystallized twice from pyridine (m. p. 254–260°). This may be compared with the melting range of 256–262° for the pure material.

Low-melting Friedelinol.—Slightly impure compound was recrystallized twice from dioxane. The melting point range, 278–282°, was the same as for the pure material.

High-melting Friedelinol.—This compound was prepared by hydrogenating some of the pure friedelin in dioxane solution over a copper–chromium oxide catalyst at 200° and 2000 lb. pressure. The crude material was recrystallized once from dioxane. The melting point range, 299–301°, may be compared to the range 301–304° for the pure material.

Cerin.—Pure cerin was used,[4] m. p. 248–251°.

(4) Impure friedelin, impure low-melting friedelinol, and pure cerin were supplied us through the courtesy of Dr. N. L. Drake and his collaborators.

3-α-Naphthyl-1-chloro-1-propene.—Two compounds, one a liquid and the other a solid, both having the same chemical analysis, were furnished us by Mr. T. H. Harris and Dr. Colin M. Mackall of the George Washington University. Since elaborate purification procedures had already been used[8] in their preparation, the compounds were used as received.

Experimental Procedure

The heterodyne beat apparatus and the dielectric cell used in this work have been referred to in an earlier publication.[5] The solutions were made up in the following manner. One hundred ml. of benzene was pipetted into a series of glass-stoppered flasks. Three of the flasks were weighed empty and reweighed with the benzene. The average weight of the benzene was used throughout the series. The pipet was capable of delivering 100 ml. of benzene to within ±0.01 g. Samples of the solute were weighed and transferred into the flasks containing the benzene. Since time was required for the material to go into solution, the flasks were usually allowed to stand on a warm surface (approx. 40°) overnight. The solubilities of the first four compounds were very slight (low-melting friedelinol, the most soluble one, was soluble to the extent of 0.404 g. per 100 ml. of benzene). The dielectric constants of these solutions as well as that of the benzene used in their preparation were obtained.

Densities were measured using a modified Ostwald-Sprengel pycnometer having a volume of about 24 ml. Duplicate density measurements were made on benzene and on three or four of the solutions scattered over the concentration range. Duplicate checks were obtained to ±0.005%. The densities of the solutions which were not measured were read from the linear plot of density *vs.* N_2 for the particular series of solutions being studied.

Experimental Results

Part of our experimental results are given in Table I which lists the mole fractions of the

(5) Davis, Bridge and Svirbely, THIS JOURNAL, 65, 85 (1943).

solute, N_2, the densities of the solutions, d, the dielectric constants of the solutions, ϵ, the molar polarizations, P_2, and the extrapolated value of P_∞ obtained separately for each run from the extrapolation of the polarization data. The values of P_2 were calculated in the usual method using, however, the extrapolated value of ϵ_0 in case it appears in Table I. In all other cases the experimental value of ϵ_0 was used in all calculations.

The molar refractions MR_D were calculated in all cases from the atomic and the molar refractions given in Landolt–Börnstein. The values of $P_E + P_A$ given in the third column of Table II were taken equal to 1.05 MR_D. The value of MR_D for the last compound in Table II was also calculated from the density and the refractive index of the pure liquid and was in very good agreement with the value obtained from the atomic refractions. The fourth column of Table II gives the polarizations P_∞ obtained by averaging the results of the P_∞ values obtained for each run given in Table I. The fifth column of Table II gives the dipole moments calculated in the usual manner along with the probable errors in the values listed.

TABLE II

Compound	Formula	$P_E + P_A$	P_∞		$\mu \times 10^{18}$
Friedelin	$C_{30}H_{50}O$	136.2	295	(32°)	2.80 ± 0.03

H. M. Friedelinol	$C_{30}H_{52}O$	137.2	200	(50°)	1.81 ± .05
Cerin	$C_{30}H_{50}O_2$	137.9	248	(50°)	2.39 ± .05
Solid	$C_{13}H_{11}Cl$	65.7	98.8	(32°)	1.27 ± .02
Liquid	$C_{13}H_{11}Cl$	65.7	111	(32°)	1.47 ± .02

Discussion of Results

The effect on the polarization of the solute (P_2) of errors in measurement of N_2, ϵ, d and P_1 has already been treated in a quantitative manner[5] and indicates that errors of 0.1% in all of these quantities except N_1 would result in the possibility of large errors in P_2 for solutions where these values are measured at concentrations below about 0.005 N_2. Since the measurements on solutions of friedelin and its related compounds reported here were made at concentrations of 0.0008 N_2 or smaller and since the change in dielectric constant in going from the pure solvent to the most concentrated solution was so small, it may well be questioned whether our results have any physical significance whatsoever.

On examining the quantities ϵ, P_1 and d in order for the effect of errors in them on the μ value in the light of the experimental data obtained, it appeared that errors in extremely dilute solutions were not as great as those assumed for calculation previously[5] and consequently these results have significance, although the precision of the moments calculated is necessarily not as good as that for moments calculated from measurements in more concentrated solutions.

The dielectric constants of the different samples of pure benzene given in Table I varied at the most ±0.009 from an average value of 2.2489. In any particular run, however, all solutions were made up from the same sample of benzene and the utmost precautions were taken to keep the circuit characteristics as constant as possible. Plots of dielectric constant against N_2 for a series of solutions indicated that the data were consistent to better than 0.1%. The question as to whether these day by day variations in the dielectric constant of the solvent affected the value of μ is easily answered. In Table III the measured

TABLE III

$N_2 \times 10^4$	ϵ (Meas.)	P_2	ϵ (Assumed)	P_2 (Based on assumed ϵ's)
0.00000	2.2502	$P_1 = 26.560$	2.2581	$P_1 = 26.679$
1.2117	2.2516	299	2.2595	299
2.1728	2.2528	302	2.2607	303
3.1011	2.2539	301	2.2617	301
4.0923	2.2553	304	2.2632	304

values of ϵ_0 and ϵ obtained from a run on friedelin are given in column two. A value of ϵ_0 is assumed in column four. The deviation between the assumed ϵ_0 and the measured ϵ_0 is about 0.4%. The difference between the measured ϵ_0 and assumed ϵ_0 is added to each in column two to obtain the ϵ values in column four. Reference to the polarization values in columns three and five of Table III shows quite definitely that the absolute values of ϵ_0 have little or no effect on the calculated polarization values provided that the slope of the resulting ϵ *vs.* N_2 curve is not affected. One concludes that in a given solvent the P_2 and ultimately the μ values of the solute depend on the change in ϵ with concentration and if the change in ϵ will be the same for the measured ϵ as it is for the true value of ϵ then the P_2 values will be the same and consequently μ will be the same. Evidently if we are dealing with the same solvent, then the day to day values of ϵ_0 will not materially affect the μ value of a solute dissolved in it, providing the ϵ values of the solutions vary correspondingly.

On plotting the values of ϵ against N_2 a linear relationship was obtained in every run for all of the compounds studied. The extrapolation of the resulting straight lines to $N_2 = 0$ gave in some cases values of ϵ_0 which agreed with the experimental values while in other cases they were either higher or lower than the experimental ϵ_0's. If it is assumed that there is a correct value for ϵ_0 relative to the best straight line which can be drawn for the ϵ *vs.* N_2 data and that this correct value is actually the extrapolated value at $N_2 = 0$, then the following conclusions may be drawn. First, if the measured value of ϵ_0 is smaller than the extrapolated value, the P_2 *vs.* N_2 curve will exhibit an upward trend as the dilution progresses. Second, if it is the same as the extrapolated value, then a positive and negative scattering of points due to experimental error will result. Third, if it is larger than the extrapolated value, then a definite downward trend will exist in the curve. This follows from the equation used for the cal-

CC-0. Mumukshu Bhawan Varanasi Collection. Digitized by eGangotri

Digitized by Arya Samaj Foundation Chennai and eGangotri

culation of P_2, namely, $P_2 = [P_{12} - P_1(1 - N_2)]/N_2$ where it can be seen that P_2 results from a subtraction of P_1 from P_{12} and consequently if P_1 is smaller than it should be, then P_2 will be greater and *vice versa*. As dilution progresses, however, the error in P_2 is magnified due to a division of difference which decreases rather slowly by a rapidly decreasing N_2. In Table IV we illustrate the above argument using the data of run no. 1 on low-melting friedelinol which showed an upward trend and using the data of run no. 1 on high-melting friedelinol which showed a downward trend when the experimental data were used in both cases to calculate P_1. If the extrapolated ϵ_0 value is used to calculate P_1, then the corresponding P_2 values change. These are given for the above cases in column four of Table IV. It becomes quite evident that on using[6] the extrapolated ϵ_0 value, the marked curvatures are eliminated and the spottiness of points occurs which has been shown to be due to *non-systematic experimental errors*.[5] The variations in ϵ_0 (exp.) and ϵ_0 (extrapolated) need not be very large in such dilute solutions to cause abrupt changes in curvature in the polarization curves. The values given in Table IV represent deviations of less than 0.03%.

TABLE IV

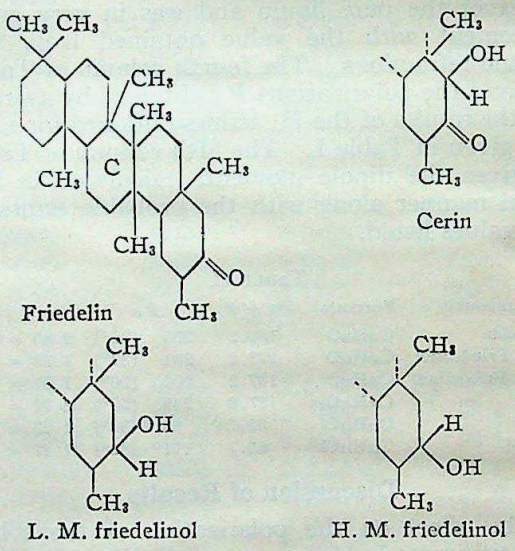
EFFECT OF CORRECTED DIELECTRIC CONSTANT OF THE PURE SOLVENT ON POLARIZATION VALUES

ϵ (meas.)	P_2	ϵ_0 (extrap.)	P_2
Low-Melting Friedelinol, Run no. 1			
$\epsilon_0 = 2.2473$	$P_1 = 26.518$	2.2478	$P_1 = 26.526$
2.2484	281		211
2.2491	241		207
2.2496	227		203
2.2502	223		205
2.2513	215		203
2.2526	215		206
High-Melting Friedelinol, Run no. 1			
$\epsilon_0 = 2.2090$	$P_1 = 26.548$	2.2085	$P_1 = 26.541$
2.2091	137		193
2.2095	142		189
2.2099	159		180
2.2109	174		187

All the polarization data given in Table I were calculated using ϵ_0 (extrapolated) if the ϵ_0 (extrapolated) and ϵ_0 (experimental) values differed.

Errors in the measurement of density because of the subtraction involved in the calculation will be relative to one another just as were those of ϵ and thus any variation of the density curve between separate runs will show up as a change in μ. Here again the absolute value obtained for the density is not important if the same assumption is made as was made previously for ϵ, *i. e.*, that the change in the density as measured would be the same as that for the absolute value. The slope in the density curve would not be expected to vary much even if widely varying values for d_0 were obtained for the same solvent.

The structures of friedelin, the friedelinols and cerin are believed[3] to be either the following



or some modification of these structures where the functional groups are, however, located near the end of the molecule, definitely not in ring C. The moment found for friedelin, $\mu = 2.8\ D$, may be compared to that of cyclohexanone which is given variously in the literature[7] as 2.75, 2.8, 2.90 and 3.00 D. The moments found for the isomers of friedelinol, $\mu = 1.8\ D$ may be compared to that of cyclohexanol which is given[7] as 1.69, 1.82 and 1.9 D. The moment found for cerin, $\mu = 2.39\ D$, could not be compared with a compound having similar functional groups since apparently none have been measured.

Thus we conclude that the moments of the compounds given above offer independent evidence for the structures which have been assigned to them. Furthermore, the residues of the structures (besides the functional groups) involved in each case affect slightly if at all the characteristic moments of the functional groups.

The solid and liquid forms of $C_{13}H_{11}Cl$ were thought to be *cis–trans* isomers.[8] While the

(6) There appeared recently a paper by Halverstadt and Kumler, THIS JOURNAL, 64, 2988 (1942), in which they discuss errors which would lead to marked rises in the polarization curves. They also develop methods of treating the data which would eliminate such rises. In this paper and in an earlier one, ref. 5, it was found necessary to explain apparent decreases as well as increases in the polarization curves at high dilutions. The method used by us in getting an extrapolated ϵ_0, while developed independently, is essentially the same as the one proposed by H. and K. However our conclusions differ inasmuch as we believe that both the apparent rise and the apparent fall in the polarization curves are due to experimental error in getting the true dielectric constant of the solvent. The value of ϵ_0 obtained by extrapolation of the ϵ *versus* N_2 curve may be either higher, lower or equal to the measured value of ϵ_0. When the experimental and extrapolated values of ϵ_0 were the same, then in the cases we investigated, the polarization curves behaved linearly; in case they differed then abnormal behavior occurred.

chemical evidence was inconclusive, nevertheless it appeared as though the solid form might be the *trans*-isomer and the liquid form the *cis*-isomer. The moments found for the two compounds, namely, 1.27 *D* for the solid and 1.47 *D* for the liquid, support the assumption of *cis–trans* isomerism.

Acknowledgment.—We wish to acknowledge the assistance of Dr. Peter Oesper in the experimental work on the $C_{13}H_{11}Cl$ compounds.

Summary

1. The precision of the calculated P_2 values and consequently of the dipole moment of a solute in a given solvent does not materially depend on the absolute values of the dielectric constants and densities.

2. Marked upswings and downswings in the polarization curves at high dilution are shown to be due to experimental error in measuring ϵ_0. It is suggested that an extrapolated ϵ_0 value obtained from an ϵ *vs.* N_2 plot be accepted as the dielectric constant of the pure solvent.

3. The dipole moments of friedelin, low and high-melting friedelinol, cerin and the solid and liquid forms of 3-α-naphthyl-1-chloro-1-propene have been determined.

4. The observed dipole moments of these compounds are compatible with their postulated structures.

The Kinetics of the Antioxygenic Synergism of Quinones with Ascorbic Acid in Fat Systems[1]

BY VINCENT P. CALKINS[2] AND H. A. MATTILL

In a study of the well-recognized capacity of ascorbic acid, under certain conditions, to act as an inhibitor of fat oxidation, Golumbic and Mattill[3] demonstrated that by itself it was a relatively ineffective antioxidant, but that in fats and oils containing tocopherols, it greatly enhanced the stabilizing action of these naturally occurring inhibitors. This reinforcing action of ascorbic acid was shown to extend to other fat stabilizers of phenolic character, including quinols and hydroxy chromans, and appeared to be accomplished by a delaying of the quinol ⇄ quinone oxidation that is fundamentally responsible for their stabilizing capacity. Isler[4] had earlier demonstrated that ascorbic acid markedly protected tocopherol from oxidation.

The oxidation potentials of the antioxygenic quinols[5] are appreciably higher than that of ascorbic acid. Since fat peroxides oxidize quinols, their oxidation potentials are still higher, but despite this considerable difference in potential between ascorbic acid and the fat peroxides, ascorbic acid added to fats is neither appreciably oxidized during their induction period nor does it sensibly prolong this period unless quinones, hydroquinones or other phenolic inhibitors are present.

This investigation is a kinetic study of the role of these intermediary agents in the antioxygenic action of ascorbic acid.

The systems used comprised the ethyl esters of lard fatty acids with and without ascorbic acid, with and without quinone; since quinone is antioxygenic because it is reduced to hydroquinone, the hydroquinone-lard ethyl esters system was also studied.

The ethyl esters of lard fatty acids were prepared according to the method of Olcott and Mattill[6] and were stored in the icebox under nitrogen. The induction period of each system was measured by the oxygen absorption method in oxygen at 75°; from time to time during its progress, determinations were made of hydroquinone, ascorbic acid, dehydroascorbic acid and glycolic acid, and these results were plotted against time.

Hydroquinone was determined by the α,α′-dipyridyl color reaction[7]; a calibration curve (Klett-Summerson photoelectric colorimeter, Filter 52) showed that the logarithmic reading was a linear function of the amount of hydroquinone present and obeyed Beer's law. Peroxides, except in a very low concentration, interfere with this determination.

Ascorbic acid and dehydroascorbic acid were determined by the method of Bessey,[8] slightly modified to fit the existing conditions. A calibration curve prepared from readings made on solutions of known concentration was linear and obeyed Beer's law. In the assay of dehydroascorbic acid, particular care was taken to remove

the last traces of hydrogen sulfide because of the interference of sulfhydryl compounds.[9]

To determine total ascorbic and dehydroascorbic acids, both dissolved and undissolved, in the ester mixture, the entire contents of the test flask was extracted with a mixture of benzene and 3% metaphosphoric acid in a separatory funnel. The acid layer was analyzed for ascorbic and dehydroascorbic acids. For the occasional determination of dissolved ascorbic and dehydroascorbic acids in the ester mixture, a portion of this was weighed out, made up to a definite volume with benzene and centrifuged to remove any undissolved acids. The supernatant liquid was then extracted with 3% metaphosphoric acid solution, the benzene fraction retaining any hydroquinone or quinone present, the metaphosphoric acid solution containing the ascorbic acid and its oxidation products. This solution was buffered with citrate to *p*H 3.5–3.6 and was centrifuged again to remove remaining traces of benzene. Absence of any emulsion was absolutely necessary for the successful use of the modified method for determining ascorbic acid; the second centrifugation aided the process of separation without danger of emulsification.

Glycolic acid was estimated by a new method[10] based on a color reaction with 2,7-dihydroxynaphthalene in concentrated sulfuric acid.

The average induction period of the esters was one to two hours, but since this varied with the freshness of the sample, a blank was always run simultaneously with the protected fat, thus permitting a comparison between the various runs on the basis of an antioxygenic index. Figure 1 shows the rate of disappearance of hydroquinone (0.02% in 20 cc. of esters) during the induction period, which in this case was nineteen hours as against one hour for the unstabilized fat. When plotted logarithmically, this curve suggests an order of reaction lying between 0 and 1. Half of the hydroquinone was oxidized in the first five hours; oxidation of the remainder required fourteen hours. As has appeared in other connections,[11,12] the length of the induction period is a function of the concentration of quinol; at its close, all the hydroquinone was in the form of quinone for, on reduction, all that had originally been introduced could be recovered. When very pure quinone was added to the ethyl esters, the original content of quinol, 1.2 μg per gram of quinone, was increased to 6.5 μg during fifteen minutes warming in air or under nitrogen. Quinone apparently acts as a hydrogen acceptor, and the hydrogen may come from the fat as a result of the formation of further double bonds (oxidation).[13]

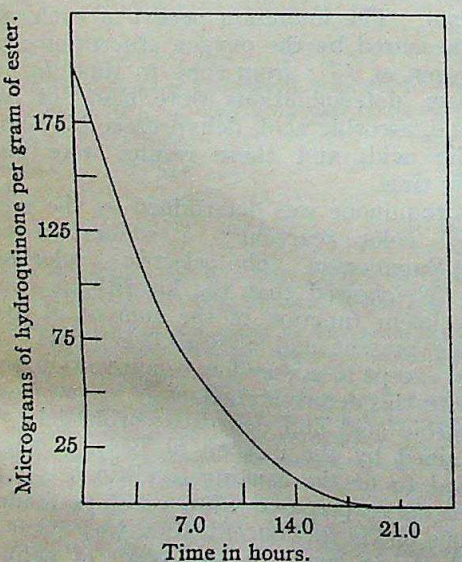

Fig. 1.—Disappearance of hydroquinone during the induction period of ethyl esters of lard fatty acids.

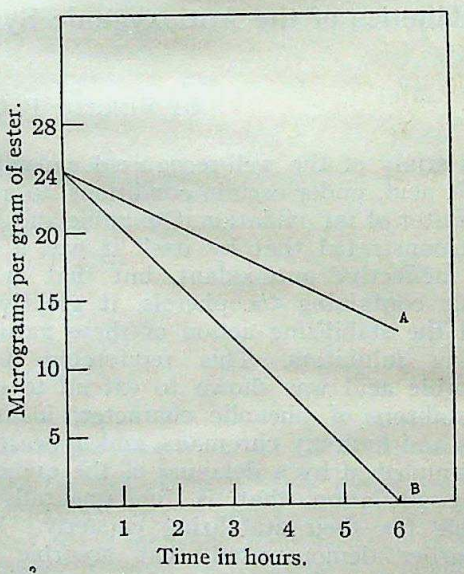

Fig. 2.—Disappearance of ascorbic acid (0.0024%) in ethyl esters: A, ascorbic acid alone; B, ascorbic acid and 0.02% quinone.

The disappearance of ascorbic acid (0.0024%), both dissolved and undissolved, during the oxidation of the ethyl esters is shown in Fig. 2. Both in the presence (Curve B) and in the absence (Curve A) of quinone, this follows a zero order reaction; the oxidation of ascorbic acid is independent of its concentration, as represented by the equation

$$-\mathrm{d}c/\mathrm{d}t = k$$

Upon integration this equation assumes the form

$$K = (C_0 - C_t)/(t_2 - t_0)$$

and from the slope of curve A, K_A is found to be 2.5×10^{-9} mole per liter per second. Similar

calculation for curve B gives a figure for K_B, 5.2×10^{-9} mole per liter per second. The rate of oxidation of ascorbic acid in the ethyl esters is thus approximately twice as great in the presence of quinone as in its absence. Traces of ascorbic acid were found in solution in the esters when it was present by itself (A), but never when quinone was also present (B). Apparently in the presence of quinone, ascorbic acid is oxidized as quickly as it goes into solution, but this does not necessarily imply that the interaction of quinone and ascorbic acid is solely a solution phenomenon. The significance of these two constants K_A and K_B will be discussed later.

The effect of the increased rate of oxidation of ascorbic acid in the presence of quinone is clearly demonstrated in Fig. 3. Curve E represents the peroxide formation in lard ethyl esters alone; curve D shows the slightly decreased rate of peroxide formation in esters containing 0.0024% of ascorbic acid. Curve C represents peroxide formation in the ester system containing 0.02% quinone in addition to 0.0024% ascorbic acid. Comparison of these curves shows the powerful synergistic action of ascorbic acid with quinone in the stabilization of the esters.

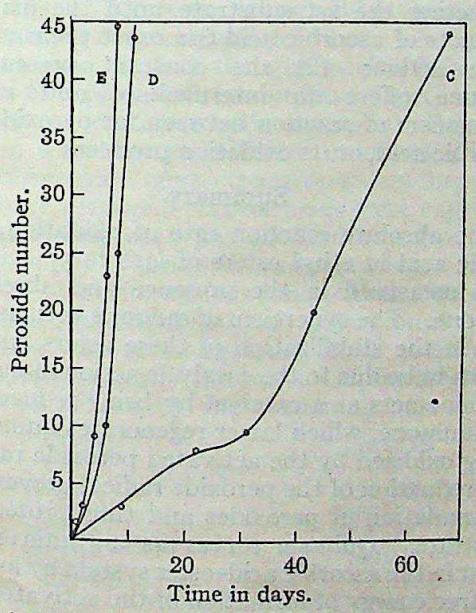

Fig. 3.—Peroxide formation in the ethyl esters containing: E, no additions; D, 0.0024% ascorbic acid; C, 0.0024% ascorbic acid and 0.02% quinone.

The actual mechanism of this synergistic action is suggested by Fig. 4, where the curves represent the course of the oxidation of ascorbic acid in the quinone–ester system as studied by the tests available. Each curve is a composite of a series of determinations and shows the mean path followed by the various substances involved.

Curve C (ascorbic acid) shows that the ascorbic acid had completely disappeared in less than six hours although the induction period lasted for nearly seventy hours. Curve A shows the gradual appearance and subsidence of dehydroascorbic acid, that is, a typical curve for the primary resultant of a consecutive reaction. Part of the oxidized dehydroascorbic acid is found in the form of glycolic acid as shown by Curve B. The glycolic acid content seems to remain relatively constant throughout the course of the induction period.

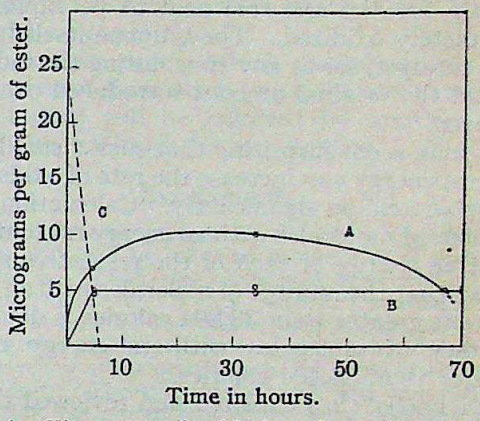

Fig. 4.—The course of oxidation of ascorbic acid in fat ethyl esters, in the presence of quinone: A, total dehydroascorbic acid; B, glycolic acid; C, total ascorbic acid.

Discussion

The significance of the two velocity constants, K_A and K_B, is best demonstrated by substituting their respective values in an equation developed by Eyring,[14] Gershinowitz[15] and others where K_1

$$K_1 = \frac{kTe^{-\frac{\Delta F^*}{RT}}}{h}$$

is the specific rate constant, ΔF^* is the free energy of formation of the activated state, T is the absolute temperature, R is the universal gas constant and k and h are the Boltzmann and Planck constants, respectively. This expression shows that the rate of a reaction is determined by a free energy change which usually is not the same as the free energy change for the total reaction. Use is made of an activated complex, and it is shown that the rate of a chemical reaction is determined by the concentration of the reacting systems in a certain fraction of the total phase space available, multiplied by the velocity with which the systems are passing through this space. ΔF^* cannot be the same as ΔF unless the energy of formation of the activated state is equal to the energy of the reaction.

By applying this equation to the velocity constants of both the ascorbic acid–lard ethyl esters and the ascorbic acid–quinone–lard ethyl esters systems, the respective ΔF^* of each system can be determined. By rearrangement of the equation and substitution of numerical values, ΔF^* values are obtained: $\Delta F_1^* = 34{,}404$ calories per mole per liter; $\Delta F_2^* = 33{,}894$ calories per mole per

liter; where ΔF_1^* and ΔF_2^* are the free energies of formation of the activated states of the ascorbic acid–lard ethyl ester system and the ascorbic acid–quinone–lard ethyl ester system, respectively.

The difference between the two ΔF^* values, 510 calories per mole per liter, indicates that the addition of quinone to the ascorbic acid–lard ethyl ester system lowers the free energy level sufficiently for the ascorbic acid to be rapidly and completely oxidized. The quinone itself behaves as a catalyst, for at any time during the induction period the original amount introduced can be recovered.

It may seem surprising that such a small difference in energy can increase the rate of oxidation of ascorbic acid so significantly. Calculation of the number of molecules with an energy content above the free energy of each of the respective systems shows that the number of molecules with an energy content greater than 33,894 calories is double the number of molecules with an energy content greater than 34,404 calories.

Michaelis[16] has explored and reviewed the role of semiquinones as intermediate steps of reversible organic oxidation–reduction. The oxidation of organic compounds is frequently sluggish, even when an oxidant of thermodynamically sufficient oxidative power is applied, because it must, as a rule, go through two univalent steps; the intermediate step generally involves climbing over an energy hill; catalysts and enzymes concerned with oxidation–reduction processes convert the substance to be oxidized into some form or compound, in which the intermediate radical has a stronger resonance and so a greater stability than the original form.

These results with ascorbic acid and quinone can be interpreted on this basis, and the following hypothetical mechanism would explain them. The oxidation of ascorbic acid must go through two univalent steps, and to go through the intermediate step means climbing over a larger energy hill when quinone is absent than when it is present. In its presence, the oxidation of ascorbic acid can readily pass through its intermediate step since the free energy of formation of the activated complex, ascorbic acid + quinone, is less than that of the formation of the activated complex, ascorbic acid + peroxide radical. The compulsory univalent oxidation of ascorbic acid is favored more by the presence of quinone than by the presence of fat peroxide radical.

Quinone may act as a catalyst by being reduced to a semiquinone which latter is oxidized back to quinone by the activated peroxide radical, thus protecting the substrate. Necessarily, the free energy of formation of the activated complex of the semiquinone with the peroxide radical must be less than the free energy of formation of the activated complex of ascorbic acid with the peroxide radical. Otherwise, quinone could not act as an intermediary agent. Since only a trace of semiquinone, tested as quinol, could be found throughout the reaction, its rate of oxidation must be very high, significantly higher than that of ascorbic acid, and its free energy value correspondingly less.

In the ascorbic acid–quinone–ester system, the early and complete disappearance of ascorbic acid relative to the long induction period of the fat suggests that the real antioxidant involved is an oxidation product of ascorbic acid. This may be dehydroascorbic, 2,3-diketogulonic, threonic, glycolic, or oxalic acid, or a combination of all of them. The oxidation of ascorbic acid proceeded beyond dehydroascorbic acid and at least to glycolic acid.

The ascorbic acid–ester system differs from the quinone–ascorbic acid–ester system in two important aspects: (1) the presence of quinone permits the rapid oxidation of ascorbic acid, thus protecting the fat substrate until the oxidation products of ascorbic acid can exert their antioxygenic action; (2) the constant presence of quinone offers an intermediate and indirect mechanism of reaction between fat peroxides and ascorbic acid, or its oxidation products.

Summary

The absolute reaction rate of oxidation of ascorbic acid in ethyl esters of lard fatty acids has been measured in the presence and absence of quinone. The synergism of quinone with ascorbic acid in the stabilization of these esters has been shown to be due to the catalytic action of quinone. Quinone acts as a catalyst by being reduced to a semiquinone, which latter regenerates quinone by being oxidized by the activated peroxide radicals; this reduction of the peroxide radical prevents the accumulation of peroxides and thus protects the substrate. Quinone serves as an intermediary agent in the ascorbic acid–ester system by lowering the free energy of formation of the activated complex to such an extent that it doubles the number of particles of ascorbic acid possessing sufficient energy of reaction. The results follow closely the views of Michaelis on compulsory univalent oxidation, and on the basis of these data a mechanism for the synergistic action of quinone with ascorbic acid is proposed.

The Preparation of 2-Ketopolyhydroxy Acids

BY PETER P. REGNA[1] AND B. P. CALDWELL

It was observed by one of the authors[2] that when an aqueous solution of a methyl ester of a 2-ketohydroxy acid is heated in the presence of certain metallic elements, the esters are transformed into their corresponding ascorbic acid analogs. A marked difference was noted in the speeds with which the isomeric esters methyl 2-keto-D-gluconate and methyl 2-keto-L-gulonate, enolize and lactonize during this treatment.

In view of this, the present authors decided to study the rates of rearrangements of the four theoretically possible 2-ketohydroxy acids of the six-carbon series, namely, 2-keto-gluconic, -gulonic, -galactonic and -altronic acids. The latter two acids had not previously been prepared; 2-keto-D-gluconic acid was first obtained by Ohle,[3] from diacetone fructose, and 2-keto-L-gulonic acid was later prepared by Reichstein,[4] who used it as an intermediate in the synthesis of L-ascorbic acid. While the preparation of 2-keto-D-galactonic acid is described in the present paper, that of 2-keto-D-altronic acid is the subject of an ensuing communication.

In addition, it was thought advisable and of interest to explore the rearrangement mechanisms of seven-carbon 2-ketohydroxy acids. For purposes of structure the hitherto unknown 2-keto-D-glucoheptonic and 2-keto-D-galactoheptonic acids were prepared. These acids were expressly chosen because each has the hydroxy groups of carbon atoms 3 and 4 in *trans* position. If the rates of transformations into their ascorbic analogs are functions only of those groups which enter into the rearrangement, then their rates should be practically the same. If, however, the rate is influenced by the remaining part of the

COOH	COOH
CO	CO
HCOH	HCOH
HOCH	HOCH
HCOH	HOCH
HCOH	HCOH
CH_2OH	CH_2OH
(I)	(II)

molecule, then these acids should show a marked difference in rate of rearrangement, since the hydroxy groups on carbon atoms 4 and 5 of 2-keto-D-glucoheptonic acid (I) are in the *trans* position while on 5 and 6 they are in the *cis* position. But the structure of 2-keto-D-galactoheptonic acid (II) is the opposite of this; the hydroxy groups on carbon atoms 4 and 5 are in the *cis* position while on carbon atoms 5 and 6 they are in the *trans* position.

The present paper, which describes only the preparation of these acids (with the one exception above noted) will be followed by another containing the results of the rate studies.

Experimental

Calcium 2-Keto-D-gluconate.[5]—To 178 g. of D-glucono-γ-lactone dissolved by refluxing in one liter of methanol containing 5 cc. of 85% phosphoric acid, after cooling, 37 g. of sodium chlorate and 6 g. of vanadium pentoxide were added. The mixture was shaken for four days (20°) until dehydrogenation was complete as shown by the change from the yellow of the pentoxide to the green of the vanadium trioxide. The solid catalyst was then removed, and the solution was concentrated *in vacuo* to a sirup. After standing for two days at 3° the methyl 2-keto-D-gluconate (yield 60%) contaminated with sodium chloride, was collected, washed with methanol–acetone and recrystallized from dioxane: m. p. 175–176°; $[\alpha]^{20}D$ −76.8° (*c*, 2 in water) at equilibrium.[6]

The ester was hydrolyzed by dissolving 100 g. in one liter of 2 *N* sulfuric acid and storing at 30° for four days. The SO_4^{--} precipitated with barium carbonate, was filtered, the filtrate neutralized with calcium carbonate and evaporated to 250 cc. *in vacuo* at 40°. On standing overnight (20°) the calcium 2-keto-D-gluconate·$3H_2O$ crystallized. Two recrystallizations from water gave $[\alpha]^{20}D$ −70.8° (*c*, 2 in water).

Anal. Calcd. for $Ca(C_6H_9O_7)_2 \cdot 3H_2O$: Ca, 8.34; H_2O, 11.25. Found: Ca, 8.30; H_2O, 11.2.

The physical properties and composition of the salt have apparently not been previously reported. The degree of hydration was determined by heating the salt to constant weight at 90° for sixteen hours under 0.01 mm. pressure.

2-Keto-D-galactonic Acid.—To a solution containing 43.8 g. of potassium D-galactonate in 200 cc. of water, 8.2 g. of potassium chlorate, 0.5 g. of vanadium pentoxide and 3 cc. of phosphoric acid were added. After four days the solution was filtered, treated with calcium ferrocyanide and the vanadium ferrocyanide discarded. The filtrate was neutralized with calcium hydroxide to precipitate the PO_4^{---}, filtered, treated with 15 g. of calcium acetate, evaporated *in vacuo* to 60 cc., and the unreacted calcium D-galactonate allowed to crystallize (0°) during two days. Two further crops were recovered (a total of 40% of starting material), the excess Ca^{++} precipitated with oxalic acid, and the filtrate evaporated to dryness *in vacuo*. The residue was dissolved in 25 cc. of water, methanol slowly added, and after standing several days crude crystalline potassium 2-keto-D-galactonate was obtained (yield 30%). Two recrystallizations from water gave $[\alpha]^{20}D$ −6.7° (*c*, 1.2 in water).

Anal. Calcd. for $KC_6H_9O_7$: K, 16.84. Found: K, 16.78.

The free acid was liberated from the potassium salt by treatment with the exact amount of aqueous sulfuric acid and the potassium sulfate precipitated with dioxane. From the filtrate evaporated *in vacuo* to a sirup, and al-

lowed to stand overnight (0°) the crystalline 2-keto-D-galactonic acid was recovered, washed with aqueous dioxane and recrystallized from water: m. p. 170–171°; $[\alpha]^{20}D$ −6.0° (*c*, 2 in water), and on titration with alkali showed 99.9% purity.

Anal. Calcd. for $C_6H_{10}O_7$: C, 37.12; H, 5.19. Found: C, 37.02; H, 5.30.

Methyl 2-Keto-D-galactonate.—The acid (5 g.) was dissolved in 100 cc. of freshly distilled methanol containing 0.15% hydrogen chloride. The mixture was refluxed for two hours, and evaporated by repeated concentration *in vacuo* with methanol. Crystals of methyl 2-keto-D-galactonate were washed and recrystallized from alcohol–chloroform mixtures: m. p. 138–139° and $[\alpha]^{20}D$ −11.3° (*c*, 1.2 in water). D-Ascorbic acid m. p. 192° and $[\alpha]^{20}D$ −23° was made from this ester by the method of Maurer and Schiedt,[7] and this served to establish further the constitution of 2-keto-D-galactonic acid.

Sodium 2-Keto-D-glucoheptonate Monohydrate.—A hot solution of α-D-glucohepto-γ-lactone[8] (416 g.) was neutralized with 106 g. sodium carbonate, cooled, diluted to 4.2 liters and 73 g. of sodium chlorate, 40 cc. of 85% phosphoric acid and 20 g. of vanadium pentoxide were added. After stirring for two days, the reaction was complete; it was filtered, treated with enough calcium ferrocyanide to precipitate the V^{+++}, filtered again, the PO_4^{---} precipitated with calcium hydroxide, and the excess Ca^{++} removed with oxalic acid. The colorless solution containing only sodium salts was concentrated to 2 liters and an equal volume of methanol added dropwise with stirring during thirty-six hours. The crude crystalline sodium 2-keto-D-glucoheptonate (yield 38%) was recrystallized twice from 40% aqueous methanol: $[\alpha]^{20}D$ +45.5° (*c*, 2 in water).

Anal. Calcd. for $Na(C_7H_{11}O_8)\cdot H_2O$: Na, 8.70; C, 31.82; H, 4.96. Found: Na, 8.60; C, 31.87; H, 5.10.

The constitution of the 2-keto acid was established by preparing D-glucoascorbic acid from it. The free acid liberated from the sodium salt (26.4 g.) by sulfuric acid and precipitation with methanol was repeatedly evaporated *in vacuo* with methanol. The final residue was dissolved in 100 cc. of absolute methanol, treated with a measured quantity of diazomethane and concentrated *in vacuo* to 50 cc. The ester solution was stirred with 50 cc. of sodium methylate (containing 2.42 g. of sodium) at 45° under a current of nitrogen. When the suspension thinned out, it was treated with 10 cc. of 51.5% sulfuric acid, filtered, evaporated to dryness *in vacuo*, the residue dissolved in methanol, Norite was added and filtered. The filtrate was concentrated *in vacuo* to 25 cc. and allowed to stand several days at 0°. D-Glucoascorbic acid monohydrate recrystallized twice from methanol–acetone showed m. p. 140°, $[\alpha]^{20}D$ −22.0° (*c*, 1 in water) and iodine titration 99.7% which values agree with those obtained by Haworth, Hirst and Jones[9] who prepared D-glucoascorbic acid through the addition of hydrogen cyanide to glucosone.

Potassium 2-Keto-D-galactoheptonate.—A mixture of α- and β-D-galactoheptonic acids prepared by the addition of hydrogen cyanide to galactose, was neutralized with potassium carbonate. The dehydrogenation procedure described above for the isomeric acid was followed. However, the potassium 2-keto-D-galactoheptonate crystallized very readily on the addition of methanol to the aqueous solution of the potassium salts (yield about 65%). The crude potassium salt was recrystallized from water until a constant rotation was obtained; $[\alpha]^{20}D$ +67.5° (*c*, 2 in water).

Anal. Calcd. for $KC_7H_{11}O_8$: K, 14.91; C, 32.06; H, 4.23. Found: K, 14.90; C, 32.08; H, 4.37.

The constitution of 2-keto-D-galactoheptonic acid was established by preparing *d*-galactoascorbic acid from it by employing the procedure described above for 2-keto-D-glucoheptonic acid. Recrystallization from methanol–acetone yields the monohydrate. There is an evolution of gas at its m. p. 109° and a blackening at 190°, which observations are in agreement with those of Haworth,[10] *et al.*, who prepared D-galactoascorbic acid through the addition of hydrogen cyanide to galactosone.

Summary

1. A general method is described for the catalytic dehydrogenation of α-hydroxy groups of six- and seven-carbon membered polyhydroxy acids.

2. Of the six-membered polyhydroxy acids, the previously unknown 2-keto-D-galactonic acid is described, and the properties of calcium 2-keto-gluconate trihydrate are noted.

3. In the seven-membered polyhydroxy acids, 2-keto-D-glucoheptonic and 2-keto-D-galactoheptonic acids have been prepared and described, and from these keto acids, corresponding ascorbic acid analogs were made.

A Method for the Preparation of Calcium D-Altronate[1]

BY PETER P. REGNA[2] AND B. P. CALDWELL

In the course of work being carried out in this Laboratory in connection with the rates of transformation of 2-ketopolyhydroxy acids[3] into their ascorbic acid analogs, 2-ketoaltronic acid was needed. For this purpose we were interested in catalytically dehydrogenating either allonic or altronic acid in attempts to prepare the last remaining unknown 2-ketoaldonic acid. Accordingly we have produced D-altronic acid in large quantities by the following series of reactions: pectin → sodium calcium D-galacturonate → calcium 5-keto-L-galactonate → calcium D-altronate and calcium L-galactonate. The steps in the procedure, indicated by the acids of the foregoing salts, are represented by the configurational formulas

The simplicity of this method provides a convenient source of D-altronic acid for the preparation of D-ribose.[4] In addition the procedure yields about equal quantities of the isomeric L-galactonic acid as a by-product. The heretofore almost unavailable L-galactonic acid may also be prepared by direct hydrogenation of sodium calcium D-galacturonate.

The existing methods for obtaining altronic acid are of limited applicability. Levene and Jacobs[5] made use of the addition of hydrogen cyanide to the costly sugar D-ribose, while the difficultly obtainable D-talonic acid is required for a method reported by Steiger and Reichstein.[6] The recent procedure of Richtmyer, Hann and Hudson[7] starting from *Sedum spectabile* was ineffectual because of the low yields of altronic acid.

The D-altronic acid prepared by the authors was readily oxidized by the procedure previously described[8] for the catalytic dehydrogenation of α-hydroxy groups of polyhydroxy acids. Although a number of salts of D-altronic acid were oxidized to the 2-ketoaltronates, none was found to be crystalline.

Experimental

Sodium Calcium-D-Galacturonate Hexahydrate.—D-Galacturonic acid was prepared by a modification of the joint methods of Pigman[9] and Mottern and Cole.[10] To six liters of distilled water was added 35 g. of Rohm and Haas Pectinol 46 AP, standardized with diatomaceous earth 100 D. The suspension was mechanically stirred and 600 g. of commercial citrus pectin was added in small portions. The viscous solution was covered with a thin layer of toluene to prevent mold growth, stoppered and allowed to stand for fourteen days at room temperature. At the end of this time a portion of the solution was titrated with standard alkali and showed 433 g. of D-galacturonic acid. An analysis by Fehling solution and calculated on the basis of galacturonic acid, indicated 487 g.

The main solution was treated with norite and filtered. Then two-thirds of the galacturonic acid in solution was neutralized with 77 g. of calcium carbonate, and the remaining one-third with 41 g. of sodium carbonate. There was an immediate precipitation of the double salt of galacturonic acid upon stirring the solution. This crop was filtered off and washed with water. Succeeding crops were obtained as the filtrates were repeatedly evaporated *in vacuo*. The combined crops after drying at about 50° weighed 464 g. A small sample of the double salt recrystallized from water was found upon analysis to have a composition corresponding to the hexahydrate, $[\alpha]^{20}D$ +33.0 (*c*, 1 in water), corresponding to $[\alpha]^{20}D$ +38.6° for the anhydrous salt.

Anal. Calcd. for $NaCa(C_6H_9O_7)_3 \cdot 6H_2O$: Ca, 5.33; Na, 3.07, uronic acid by CO_2 determination, 77.6. Found: Ca, 5.33; Na, 2.98; uronic acid by CO_2 determination, 78.1.

Calcium 5-Keto-L-galactonate.—Ehrlich and Guttmann,[11] found that in saturated limewater D-galacturonic acid undergoes the usual Lobry de Bruyn interconversion reaction by isomerizing the end CH(OH)CHO group into $COCH_2OH$. This produces the basic calcium salt of 5-keto-L-galactonic acid which is sparingly soluble in water, and consequently, the equilibrium shifts continuously in favor of the insoluble salt. The normal calcium 5-keto-L-galactonate was prepared from the basic calcium salt which, in turn, was produced by a modification of the method of Ehrlich and Guttmann.

In a typical run, 8.2 g. of calcium chloride was added to ten liters of filtered limewater containing 16.2 g. of calcium hydroxide. Sodium calcium D-galacturonate hexahydrate (111 g.) was then dissolved in this solution with stirring until it was clear. After about six days the basic calcium salt of 5-keto-L-galactonate, $(C_6H_9O_7)\cdot Ca(OH)\cdot 2H_2O$, precipitated in pale yellow crystals. These were separated from the large volume of water by a suction filter, washed with water and dried (110 g.). The salt was not further purified, but was suspended in water, neutralized with oxalic acid to a *p*H of 6.0 and the precipitated calcium oxalate filtered off. The filtrate was treated with norite, warmed, refiltered, and the filtrate evaporated *in vacuo*.

Erhlich and Guttmann were unable to crystallize sufficient of the normal calcium 5-keto-L-galactonate to obtain its analysis and physical properties. In the present case, however, after long standing a seed was obtained which caused the ready crystallization of the main solution. Normal calcium 5-keto-L-galactonate pentahydrate is a moderately soluble white salt: $[\alpha]^{20}D$ −14.0 (*c*, 1.15 in water), corresponding to $[\alpha]^{20}D$ −17.0 for the anhydrous salt. The specific rotation on the amorphous salt was obtained by Ehrlich and Guttmann as −15.25°, perhaps due to a less hydrated salt.

Anal. Calcd. for $Ca(C_6H_9O_7)_2 \cdot 5H_2O$; Ca, 7.76. Found: Ca, 7.80.

Calcium D-Altronate.—Reichstein and Bossard[12] catalytically hydrogenated diacetone-D-tagaturonic acid (diacetone-5-keto-L-galactonic acid) for the preparation of L-galactonic acid, but they did not report the isolation of D-altronic acid. In German Patent 618,907[13] is described the hydrogenation of free 5-keto-L-galactonic acid in aque-

ous acetic acid using platinum oxide catalyst at 50 atm. and 120–140° to a mixture of L-galactonic and D-altronic acids, which were isolated as the cadmium and calcium salts, respectively.

The authors hydrogenated 100 g. of the normal calcium 5-keto-L-galactonate by suspending it in about one liter of water in a stainless steel, high-pressure autoclave containing about 10 g. of Raney nickel catalyst. The reduction was carried out by slowly heating the mixture to 80° under 2300 lb. pressure. At the end of the hydrogenation period the nickel was removed by filtration. The filtrate showed no reduction of Fehling solution, indicating a fully hydrogenated mixture of the calcium salts of L-galactonic and D-altronic acids. The hot solution after removal of the nickel catalyst was concentrated under diminished pressure to about 200 cc. It was allowed to stand several days after which 45 g. of calcium L-galactonate was obtained. The solution was evaporated further and 2 g. more of calcium L-galactonate was gained.

The mother liquor containing chiefly calcium D-altronate could not be made to crystallize readily. Seeds were finally obtained by keeping a few cc. of the solution on a watch glass in an evacuated desiccator over barium oxide for several days. These were then used to inoculate the original solution and with the aid of stirring, 32 g. of calcium D-altronate·$3^1/_2H_2O$ was finally obtained. One recrystallization from water yielded pure calcium D-altronate·$3^1/_2H_2O$ which was identified by its analysis and its mutarotation in *N* hydrochloric acid. Table I shows the observations on the rotation of the salt made by the authors and the corresponding values obtained by Richtmyer, Hann and Hudson[7] for this compound prepared from sedoheptulose.

By concentrating the mother liquor and cautiously adding methanol, 9.2 g. more of the salt was gained. From 100 g. of the normal calcium 5-keto-L-galactonate·$5H_2O$, a total of 47 g. of calcium L-galactonate·$5H_2O$ and 41.2 g. of calcium D-altronate·$3^1/_2H_2O$ was obtained.

The separation of calcium L-galactonate from calcium D-altronate was relatively simple before seeds of the latter salt were obtained. But as we worked with these calcium salts in the laboratory, we found it increasingly more difficult to effect the fractionation of the calcium salts. Hence, recourse was made to separating their cadmium salts. This was readily done by removing the calcium ions from the mixture following the high pressure hydrogenation. The solution of the free acids was heated and neutralized with a suspension of freshly precipitated cadmium hydroxide. The separation of the cadmium salts was effected as described above for the calcium salts.

TABLE I

MUTAROTATION OF CALCIUM D-ALTRONATE·$3^1/_2H_2O$ IN *N* HCl (*c*, 3) AT 20°

Acknowledgment.—One of the authors (P. P. R.) wishes to express his indebtedness to Dr. Richard Pasternack, with whom he collaborated in a separate investigation during which was developed the convenient method of isolating D-galacturonic acid by means of precipitation as its sodium calcium salt.

Summary

A new preparation for large quantities of D-altronic acid is reported and two intermediate products, sodium calcium D-galacturonate hexahydrate and calcium 5-keto-L-galactonate pentahydrate, are described.

Kinetics of Transformation of 2-Ketopolyhydroxy Acids

BY PETER P. REGNA[1] AND B. P. CALDWELL

Ohle[2] and Maurer and Schiedt[3] were first to show that weak alkaline agents and alkoxides convert methyl 2-keto-D-gluconate into D-araboascorbic acid. Reichstein[4] recognized that this procedure was general for the rearrangements of 2-keto-3,4-dihydroxy acids and utilized the reaction for the enolization and lactonization of its isomer methyl 2-keto-L-gulonate into L-ascorbic acid (vitamin C). In addition he showed that hydrochloric acid can also bring about this transformation, but that the continued action of the hydrochloric acid results in decomposition of the L-ascorbic acid.

In the course of previous work, one of the authors had noted marked differences in the effect of hydrochloric acid on the rates of rearrangement of the isomers of 2-ketogluconic and 2-ketogulonic acids although similar intramolecular processes are involved. This observation led the present investigators to study the rates of the transformation of a series of 2-ketohydroxy acids into their ascorbic acid analogs and the rates at which the corresponding ascorbic acid analogs decompose.

Preliminary experiments showed the action of hydrochloric acid on L-ascorbic acid to be essentially a constant pseudo-unimolecular or first-order reaction. An analytical examination of the end product corroborated the observations of Hirst[5] and his collaborators, who showed that when ascorbic acid is heated with 12% hydro-

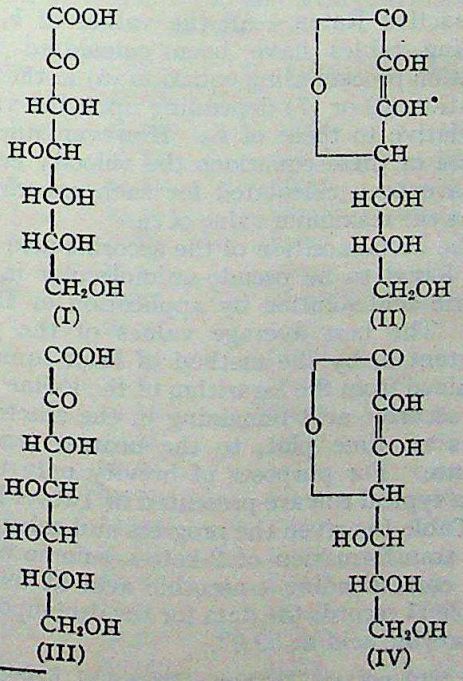
chloric acid furfural, confirmed as the phloroglucide, is readily obtained. In addition, long heating with hydrochloric acid tends to polymerize the furfural. Hence, the consecutive reactions involved in the complete process can be formulated thus

$$K \xrightarrow[(1)]{k_1} A \xrightarrow[(2)]{k_2} F \xrightarrow[(3)]{k_3} P \qquad (1)$$

where K is a 2-ketohydroxy acid, A is the corresponding ascorbic acid analog, F is the furfural formed by the decomposition of the ascorbic acid and P is the polymerized furfural. However, we are here concerned only with the first two steps. Inasmuch as a precise method is unavailable for determining the concentration of the 2-keto acid during the rearrangement, it was necessary to measure the velocities of reactions (1) and (2) independently. Such a procedure is justified by the fact that both reactions are carried out in the presence of a high concentration of hydrochloric acid.

These measurements were made by titrating portions of each reaction mixture with a standard iodine solution of approximately 0.025 *N*. This gives a quantitative indication of the ascorbic acid present in each flask at that moment, since iodine oxidizes ascorbic acid to its first oxidation product, dehydroascorbic acid.[6]

After preliminary experiments, the temperatures 59.9 and 69.9° were chosen, since the rearrangements are nearly complete within a reasonable time. Reaction rates were measured on the following pairs of acids: 2-keto-D-gluconic and D-araboascorbic acids, 2-keto-L-gulonic and L-ascorbic acids, 2-keto-D-galactonic and D-ascorbic acids, 2-keto-D-glucoheptonic (I) and D-glucoascorbic acids (II) and 2-keto-D-galactoheptonic (III) and D-galactoascorbic acids (IV).



The two particular 2-ketoheptonic acids (I) and (III) were expressly chosen in this study for their relative differences of structure. The hydroxy groups on carbon atoms 3 and 4 of both molecules are in *trans* position while the hydroxy groups on carbon atoms 5 and 6 are in *cis* position in (I) and in *trans* position in (III). Thus as a result of the identity of arrangement of substituents on the first four carbon atoms, the ascorbic acid analogs have their ring closures on the same side of the molecule.

Experimental

Apparatus and Method.—Exactly 5 *M* hydrochloric acid solutions were prepared by weighing the required amount of a previously determined stock solution in calibrated 500-ml. flasks. Stock solutions were stored in all-glass apparatus and were prepared as needed by diluting C. P. analyzed hydrochloric acid to approximately 6 *M*. Just before each kinetic run a portion of the stock solution was weighed and titrated with standard sodium hydroxide. The theoretical amount of 2-keto acid to make a 0.0500 *M* solution was weighed out and dissolved in distilled water at 20°. This solution was then quickly transferred to the flask containing the hydrochloric acid at 20°, and rapidly shaken to ensure thorough mixing. The flask was then filled exactly to the mark with distilled water, attached to its air-tight connections and the temperature rapidly raised in a steam-bath to within 0.5° of that of the thermostat. It was necessary to use thick-walled flasks to withstand the internal pressure developed during the rise in temperature. The flask was continuously shaken during its immersion in the steam-bath which usually required less than three minutes, and was then quickly submerged in the constant temperature bath. In this way thermal equilibrium between solution and thermostat was quickly reached, and it was possible to withdraw the first sample soon after the addition of the 2-keto acid. The same technique was employed in handling the ascorbic acid analogs and several portions were withdrawn from the reaction mixture as soon as equilibrium was attained, thus establishing the zero reading with considerable certainty.

Each calibrated 500-ml. flask carried a two-hole stopper, through one opening of which a fine capillary (1.5 mm.) glass tube reached 5 mm. from the bottom of the flask and led to an automatic pipet. The capillary tubes and the pipets were covered with cloth, asbestos and rubber tape to insulate the solutions against temperature drop when withdrawing samples. Through the second hole in the stopper passed a short glass tube to a source of purified nitrogen. The nitrogen was maintained at a slight positive pressure over the solution and served to force the hydrochloric acid into the capillary tube and into the two-way pipet.

Two automatic pipets were used for withdrawing samples from the reaction mixtures. These pipets were calibrated at the two temperatures of the experiments, 59.9 and 69.9° by making eight determinations of the amount of standardized 5 *M* hydrochloric acid delivered by each pipet.

The thermostat was equipped with a good mechanical stirrer mounted independent of the bath. A "mercoid-mercury" thermo-regulator, when once set, maintained the temperature inside the reaction flasks within ±0.02° during the whole series of runs at the particular temperature. The general procedure for measuring the rate was as follows: the reactions were observed by iodine titrations of the ascorbic acid present in each flask. During a run, the iodine solution was frequently standardized against a purified sample of the ascorbic acid analog. Then 1 cc. of a 0.5% solution of starch was used as an indicator and was added just before the stoichiometric point was reached. At frequent intervals the automatic pipets were flushed

(6) Hirst, *Chemistry & Industry*, 52, 221 (1933).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

with a part of the solution which then was used to locate the approximate end-point before being discarded. However, before this titration was made the pipets were filled a second time and drained, and this portion reserved for the precise titration. Samples of the reactions were arrested by draining the solutions into 75 ml. of water containing crushed ice. The time was taken as that of half drainage of the pipet.

Materials.—The crystalline, free 2-keto acids were used whenever possible. When, however, the crystalline acids were not available, the free acids were liberated from their purified salts. The absence of cations was established by ashing a portion of the acid solution, whereupon weighed portions were titrated with standard sodium hydroxide before being used for the kinetic studies. All the ascorbic acid analogs were crystalline substances and were used only after several recrystallizations. The preparations of 2-keto-D-gluconic, 2-keto-D-galactonic, 2-keto-D-glucoheptonic, 2-keto-D-galactoheptonic, D-ascorbic, D-glucoascorbic and D-galactoascorbic acids have been the subject of a preceding communication.[7]

D-Araboascorbic Acid.—This ascorbic acid was prepared, from methyl 2-keto-D-gluconate by the method of Maurer and Schiedt.[3] It showed $[\alpha]^{20}D$ −17.7° (*c*, 10 in water), m. p. 168°, and titration with standard iodine 99.7%.

2-Keto-L-gulonic Acid.—Prepared by the method of Reichstein and Grüssner[4]; m. p. 170–171°; $[\alpha]^{20}D$ −48.8° (*c*, 1.0 in water).

L-Ascorbic Acid.—This was obtained by the rearrangement of methyl 2-keto-L-gulonate as proposed by Pasternack and Regna.[8] The methyl ester[3] (41.6 g.) was dissolved in 200 ml. of water and to this solution was added 2.13 g. of magnesium powder. To the cooled solution 12 g. of oxalic acid dihydrate was added and the magnesium oxalate filtered off. The filtrate was evaporated to dryness *in vacuo* and the crystalline residue was taken up with hot methanol, treated with norite and filtered. On concentrating the filtrate *in vacuo* the L-ascorbic acid crystallized readily. After two recrystallizations from methanol, it showed $[\alpha]^{20}D$ +23°, m. p. 191–192°, and titration with iodine, 99.5%.

Rate Calculations

Inasmuch as the rates by iodine titers show the reactions to be of the first order, preliminary experiments which varied the concentration of the solvent showed the rates to be proportional to the concentration of the hydrochloric acid. However, the solvent is in such large excess (100:1) over the solute that the first-order rates are to be expected. Since the reaction of 2-ketohydroxy acid (K) to furfural (F) is a consecutive process of the first order, it can be generalized into the equation

$$\mathrm{K} \xrightarrow[(1)]{k_1} \mathrm{A} \xrightarrow[(2)]{k_2} \mathrm{F} \qquad (2)$$

where (A) is the intermediate ascorbic acid. Since the concentration of ascorbic acid c_A decreases during the course of the reaction by an amount equivalent to c_F, we will have then $c_A - c_F = c_B$ as the amount of ascorbic acid present at time t. Hence

$$c_0 = c_K + c_B + c_F \qquad (3)$$

where c_0 is the initial molecular concentration of the 2-ketohydroxy acid.

The velocity constants k_2 which evaluate the rates of decomposition of the ascorbic acid analogs were determined independently for each acid and calculated simply by the first order equation

$$k_2 = \frac{1}{t} \ln \frac{c_A}{c_A - c_F} \qquad (4)$$

where c_A is the initial concentration of the ascorbic acid, and c_F is the decrease after a lapse of time, t.

The rates of transformations, k_1, of the 2-keto-hydroxy acids into their ascorbic acid analogs were calculated from the equation[9]

$$c_A - c_F = c_B = c_0 \left(\frac{k_1}{k_2 - k_1} e^{-k_1 t} - \frac{k_1}{k_2 - k_1} e^{-k_2 t} \right) \qquad (5)$$

where c_B is equal to the amount of ascorbic acid present at any time t, and is the only constituent which was measured at progressive times, t. Equation 5, however, was rewritten and solved in the following form

$$\frac{\log \left(e^{-k_2 t} - \frac{c_B(k_1 - k_2)}{c_0 k_1} \right)}{t \log e} = -k_1 \qquad (6)$$

The value of k_1 was obtained by an iteration process. For example, on substituting an approximate value of k_1 in the left side of equation 6 when the values of c_B and t are taken from some one observation, we gained a value of k_1 usually better than the one which was assumed. This new value was again substituted in the left side of equation 6 and a second value for k_1 was obtained. This process was repeated until convergence was reached, *i. e.*, until the value satisfied the equation. Equation (6), however, converges only if $k_1 > k_2$; for the alternative case, namely, when $k_1 < k_2$, the equation was solved by writing it in the form

$$\frac{c_B k_2}{c_B + c_0(e^{-k_1 t} - e^{-k_2 t})} = k_1 \qquad (7)$$

Reaction Rates.—All the values of k_1 in the ensuing tables have been calculated by the iteration process using equation (5) in the form of equation (6) or (7) depending upon the values of k_1 relative to those of k_2. However, due to the nature of these equations the velocity constants k_1 have been calculated for each experiment as far as the maximum value of c_B.

The decomposition of the ascorbic acid analogs was found to be pseudo-unimolecular in hydrochloric acid solution by application of Equation (4). The best average values of the velocity constant k_2 by the method of least squares was obtained from the logarithm of the iodine titers of the ascorbic acid remaining in the reaction mixtures *vs.* time plot, to the nearest tenth of a minute. For purposes of brevity only the data for a typical run are presented in Tables I and II. In Table I is given the progress and calculation of the transformation of 2-keto-L-gulonic acid into the corresponding L-ascorbic acid at 59.9°, and Table II records the data for the decomposition of L-ascorbic acid at 59.9°.

Column 2 in Table I gives the actual values of c_B in terms of the number of ml. of standard iodine solution at the times indicated in column 1. V_∞ is the theoretical volume of iodine which the original amount of 2-ketohydroxy acid would have required if it were quantitatively transformed into its ascorbic acid analog.

In Table II, V_0 is the ml. of iodine at $t = 0$ for the ascorbic acid. This is the reading obtained immediately after the flask was submerged into the thermostat and connected to the automatic pipet. V_t is the ml. of iodine which the remaining ascorbic acid required at time t. Tables III and IV give a summary of the average values of k_1 and k_2 for the other 2-keto acids at the temperatures of the experiments.

TABLE III

THE RATES OF THE TRANSFORMATIONS OF 0.05 *M* 2-KETOHYDROXY ACIDS INTO THEIR CORRESPONDING ASCORBIC ACID ANALOGS AT 59.9 AND 69.9°, IN 5 *M* HYDROCHLORIC ACID

2-Keto acids	k_1 min.$^{-1}$ at 59.9°	k_1 min.$^{-1}$ at 69.9°	E, kcal./mole
L-Gulonic	0.00253	0.00820	26.7
D-Gluconic	.000566	.00186	27.0
D-Galactonic	.000654	.00208	26.3
D-Glucoheptonic	.000478	.00164	28.0
D-Galactoheptonic	.000207	.000704	27.7

TABLE IV

THE RATES OF THE DECOMPOSITIONS OF 0.05 *M* ASCORBIC ACID ANALOGS IN 5 *M* HYDROCHLORIC ACID

Acids	k_2 min.$^{-1}$ at 59.9°	k_2 min.$^{-1}$ at 69.9°	E, kcal./mole
L-Ascorbic	0.000491	0.00141	23.9
D-Araboascorbic	.00162	.00388	19.9
D-Glucoascorbic	.000920	.00279	25.2
D-Galactoascorbic	.00329	.00943	23.9

In some cases there was evidence of slowly drifting k_1 values for the 2-keto acid rearrangements and this may be due to a portion of the keto acids decomposing without first going through the ascorbic acid rearrangement. This is quite small, however, because there was usually no darkening of the solutions due to furfural formation during the first six hours of the kinetic studies until an appreciable amount of ascorbic acid had already formed. The iodine titrations during the rearrangement of the 2-ketohexonic acids behaved more or less normally. Yet, in a number of cases the 2-ketoheptonic acids acted erratically and the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

experiments had to be discarded because there was no increased iodine consumption, but rather periods of stationary iodine readings followed by sharp increases of iodine consumption.

The k_2 values for the decomposition of the ascorbic acids exclude any effects due to the presence of the parent substances, namely, the 2-keto acids. However, the maximum amounts of all the ascorbic acids calculated by the equation

$$c_{B\,(max.)} = c_0 \left(\frac{k_2}{k_1}\right)^{\frac{k_2}{k_1 - k_2}} \qquad (8)$$

agree with the maxima obtained from the graphs when the volumes of the iodine titers were plotted against the times of the transformations of the 2-ketohydroxy acids. These results are given in Table V.

TABLE V

OBSERVED AND CALCULATED VALUES OF THE MAXIMUM YIELDS OF ASCORBIC ACIDS FROM 2-KETOHYDROXY ACIDS

Acid	Temp., °C.	Calcd., %	Observed, %
2-Keto-L-gulonic	59.9	67.5	67.6
	69.9	69.4	69.9
2-Keto-D-gluconic	59.9	20.5	20.8
	69.9	24.3	24.4
2-Keto-D-galactonic	59.9	42.1	41.7
	69.9	44.3	42.5
2-Keto-D-glucoheptonic	59.9	25.4	27.7
	69.9	27.6	28.2
2-Keto-D-galactoheptonic	59.9	6.3	6.1
	69.9	5.2	7.3

Activation Energy.—From the values of k_1 and k_2 obtained at the two temperatures, the energies of activation were determined in the usual way using the Arrhenius equation, and are shown in Columns 4 of Tables III and IV. The energies of activation of the 2-keto acids in the six and seven carbon series show a variance of not more than 1.7 kcal./mole, although their reaction velocities vary widely. This would indicate that essentially the same intramolecular mechanism is involved for all of the acids. However, this cannot be wholly the case since the two seven carbon 2-keto acids which we have studied possess the same arrangement of atoms with respect to the first four groups of the molecules. Were the same intramolecular mechanism involved we should expect their rates of transformations into their corresponding ascorbic acids to be very nearly the same, inasmuch as only the first four groups enter into the rearrangement. Yet, the specific rate constants have a 2.3/1 ratio. The only structural explanation for this wide difference lies in the *cis–trans* arrangement of the groups in the parts of the molecule which do not enter into the rearrangement.

A similar condition exists in the six carbon 2-ketoaldonic series. Although 2-ketogulonic and -gluconic acids have identical structures on all but the last two carbon atoms, this alteration accounts for more than a fourfold difference in their rates of transformation.

In the case of 2-ketogalactonic acid with *cis* arrangement of the hydroxy groups on carbon atoms 3 and 4 and 2-ketogluconic with the same hydroxy groups in *trans* position there result almost equal rates of rearrangement. These observations strongly suggest that the groups in the molecules which do not enter into the enolization and lactonization materially affect the rate of transformation.

Summary

1. The kinetics of the consecutive reactions of five 2-ketopolyhydroxy acids and the decomposition of their ascorbic acid analogs have been studied at 59.9° and 69.9° in 5 *M* hydrochloric acid.

2. The rates of rearrangement of 2-ketopolyhydroxy acids into their ascorbic acid analogs are affected by the groups on the carbon atoms outside the lactone ring.

3. The rate constants of the decomposition of the ascorbic acids are greater for molecules which exhibit *cis* arrangement of the hydrogen atoms on carbon atoms 4 and 5 than for those which have *trans* arrangement of the hydrogen atoms.

4. A method is given for calculating rate constants in a reaction A → B → C where only B can be experimentally determined.

Hydrogenation–Dehydrogenation Reactions Involving Some Compounds of Ammono-aldehyde, Ammono-acetal and Aquo-ammono-aldehyde Types

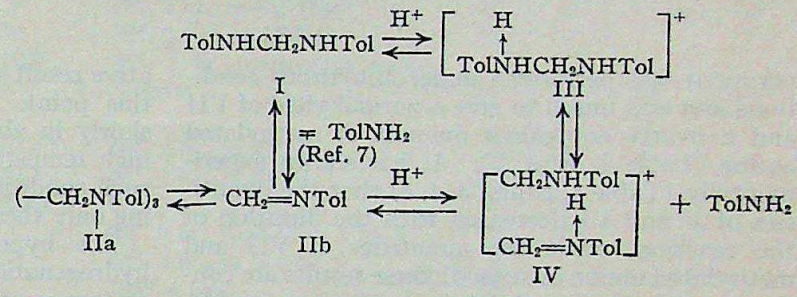
BY PAUL J. MCLAUGHLIN[1,2] AND E. C. WAGNER

In an earlier paper from this Laboratory Simons[3] showed that the incidental formation of methyl-*p*-toluidine which accompanies conversion of methylene-bis-*p*-toluidine (I) to 3-*p*-tolyl-6-methyl-3,4-dihydroquinazoline (VII) by warming with amine salt results by a complementary hydrogenation–dehydrogenation reaction, essentially

$$-NHCH_2N- + RNHCH_2NHR \longrightarrow -N{=}CHN- + RNH_2 + CH_3NHR.$$

Methylation has been observed also during interaction of *p*-substituted amines with formaldehyde in aqueous acid solution[4,5] to form dihydroquinazolines and other products, but the propriety of extending Simons' explanation to such cases is doubtful, as are explanations suggested by Maffei[4] and by Eisner and Wagner.[5] The formal resemblance of Simons' reaction to a crossed Cannizzaro reaction is obvious, and recalls some other hydrogenation–dehydrogenation reactions involving compounds of ammonoaldehyde type.[6]

This paper presents the results of a further study of the oxidation of 3-*p*-tolyl-6-methyl-1,2,3,4-tetrahydroquinazoline (VI) to the corresponding dihydroquinazoline (VII) by substances of aldehyde or acetal type in presence of acid, and an interpretation and rationalization of the findings. Though the reaction (at lower temperatures) requires presence of acid the environment is prevailingly basic, and the function of the acid is believed to be the cleavage of the methylene-bis-amines (compounds which can be regarded as ammono-aldehyde "hydrates" or ammono-acetals) to aldehydic structures, *i. e.*, to induce a reaction which is preliminary to the pseudo-Cannizzaro reaction which follows. It has been found that trimeric methylene-*p*-toluidine can function as hydrogen acceptor; in this case the acid may operate in a similar manner to open the triazine ring. These preliminary steps are shown in the scheme.



In acid-induced reactions the hydrogen acceptor is believed to be the Schiff base IIb or its cation IV, obtainable from the trimer or from the methylene-bis-amine *via* the Schiff base monomer, or from the methylene-bis-amine via its cation III, as shown in the scheme. In thermally induced reactions the hydrogen acceptor may be IIb. The several subsequent reactions which may be initiated in presence of acid were established in their proper relationships by Simons[3]: (1) formation of the *o*-aminobenzylarylamine base V,[8] presumably from IV and *p*-toluidine by ortho-coupling, (2) conversion of V to the diphenylmethane base VIII by action of acid in absence of I or II,[9] a reaction not encountered under the conditions of the present study, (3) conversion of V to the tetrahydroquinazoline VI, a reaction whose reversibility[3] in presence of acid was confirmed in the present study, though the reaction is not sensibly reversible in absence of acid,[10] and (4) the hydrogenation–dehydrogenation reaction which is the principal subject of study. These interrelated reactions are shown in the accompanying scheme. The extent of reaction 4 was estimated from the quantity of VII formed, and the nature of the reaction was inferred from the presence of methylated amine. The possibility cannot be excluded that the amine products of reaction 4 could enter the reaction system, with eventual formation of dimethylated amine of which, however, little or none has been encountered. The presence and amount of unmethylated amine, some of which may be liberated by incidental hydrolysis, are regarded as not diagnostic. To test the possibility that a small quantity of water, operating cyclically, might generate formaldehyde by hydrolysis of I or II and so modify the reaction series, an ex-

periment was performed under anhydrous conditions and was found to give a normal yield of VII and a nearly equivalent amount of methylated amine (Table I, expt. 6). It has shown experimentally (Table I, expts. 3, 4, 5) that the quantities of V and VI decreased with the duration of the reaction, while the quantities of VII and methylated amine increased; these results are consistent with the view that reaction 4 is irreversible.

Reaction 4 was realized with compound VI using as the second aldehydic reactant methylene-bis-*p*-toluidine, trimeric methylene-*p*-toluidine, methylene-bis-piperidine, and benzalaniline, and as the sources of acid *p*-toluidine hydrochloride, piperidine hydrochloride, trimethylamine hydrochloride, the hydrochloride of VII, and ammonium chloride. The salts named appeared to vary with respect to the effectiveness of each in promoting reaction 3 (ring opening–ring closure) and reaction 4 (hydrogenation–dehydrogenation). In experiments with salts of tertiary amines (trimethylamine and VII), which are not eligible to participate in ring opening with formation of V and I, both V and VII were formed (Table I, expts. 2, 5); the ring opening in each of these cases must be attributed to operation of the amines formed in reaction 4. The amine salts used all proved to be more effective than ammonium chloride with respect to reactions 3 and 4 (Table I, expts. 1–10), the order of decreasing effectiveness being *p*-toluidine hydrochloride, trimethylamine hydrochloride, the hydrochloride of VII, piperidine hydrochloride, and ammonium chloride. The comparative activities of these salts as proton donors should be related in an inverse sense to the dissociation constants of the bases represented. Results with *p*-toluidine hydrochloride, trimethylamine hydrochloride and piperidine hydrochloride are consistent with this view; the basicity of VII is not known. The low activity of ammonium chloride thus appears to be anomalous, but may be attributable to the low solubility of this salt in alcohol or in molten amine mixtures. Actually the identity of the salt used is not preserved, for the acid so introduced may be assumed to become distributed among all bases present in a manner determined jointly by the relative strengths and concentrations of the bases and by the relative solubilities of their salts in the reaction mixture.

The possibility that oxidation of VI to VII might be caused by ready loss of hydrogen[11] was tested (expt. 23) by heating VI in contact with air; no VII precipitable as picrate was present. The possibility that picric acid, used to precipitate VII in the experiments, might serve to some extent as oxidant was excluded by the negative result of an experiment (expt. 24) to test this point. Reaction 4 was found to proceed slowly in absence of added acid at a relatively high temperature (expt. 12), indicating that for such conditions an alternate mechanism, involving only thermal effects, must be admitted.

The hypothesis that the hydrogenation–dehydrogenation reaction is analogous to the Cannizzaro reaction was further tested by experiments in which the abilities of compounds of ammono-aldehyde or aldehyde types to serve as hydrogen acceptors were contrasted with those of similar nonaldehydic ammono-carbonyl or carbonyl compounds. The pairs of compounds tested were diphenylformamidine and diphenylacetamidine, formyl-*p*-toluidine and acetanilide, and formamide and acetamide. The first named of each pair possesses an aldehydic structure, and in each case only this compound was found to oxidize VI to VII (expts. 14–22). The behavior of diphenylformamidine, a derivative of ammono-formic acid and also an aldehyde in the sense that formic acid is an aldehyde, is of interest. Dains[12] reported diphenylformamidine to condense with reactive methylene compounds after the manner of aldehydes, and the conversion of VI to VII by formic acid has been recorded.[13] In the oxidation of VI to VII by diphenylformamidine the results showed the reaction to proceed in two stages, essentially

$$\mathrm{PhNHCH{=}NPh} \xrightarrow{\mathrm{VI}} \begin{cases} \mathrm{VII} \\ \mathrm{PhNHCH_2NHPh} \end{cases} \xrightarrow{\mathrm{VI}} \begin{cases} \mathrm{VII} \\ \mathrm{PhNH_2 + CH_3NHPh.} \end{cases}$$

In the experiments reported in Table I (expts. 14, 15, 16) the reactants were used in this over-all proportion. The reaction was favorably affected by presence of acid (expt. 14), but diphenylformamidine, form-*p*-toluidide and formamide all reacted in absence of added acid but at somewhat elevated temperatures (105–210°; expts. 15, 16, 18, 21). These conversions may be wholly thermal, or they may be induced in part by the acid characters of the compounds named; similar

[a] In most cases 0.005 mole each of VI and acceptor. [b] In experiments involving use of acid (amine salt or NH_4Cl) the amount was two molar equivalents with respect to the other reactants, unless specified otherwise. [c] When alcohol was used as solvent, the amount was 50 ml. [d] 0.009 mol. [e] All reagents were dried over sulfuric acid in a desiccator for a week. The glass apparatus was kept in an oven at 135° for four days. The return condenser was protected by a calcium chloride tube. No solvent was used. [f] Benzaldehyde gave a small precipitate, but the m. p. (162°) and the m. p. of a mixture with the benzal derivative of V (106°) indicates probable formation of some diphenylmethane base in the reaction.[3] [g] Presence of methyl piperidine was suggested by the nature of the picrate obtained following removal of piperidine as benzenesulfonyl derivative. Results of attempts to identify and determine methylpiperidine as hydrochloride were not satisfactory. The steam volatile bases were apparently only piperidine and methylpiperidine, for the refractive index of the mixture, redistilled over sodium, was $n^{20}D$ 1.4453, the values for pure specimens of piperidine and methylpiperidine being 1.4532 and 1.4376, respectively. [h] Only VII was determined, as the isolation of benzylaniline presented difficulties not wholly overcome. [i] The amount of diphenylformamidine was 0.5 equivalent with respect to the amount of VI. [j] Experiment to test possible thermal dehydrogenation of VI to form VII. The mass, after heating, was dissolved in ethanol, and picric acid solution was added. No precipitate appeared. [k] Experiment to test possible formation of some VII by oxidation of residual VI by picric acid added to precipitate VII. A solution of 0.6 g. of VI in 25 ml. of ethanol was treated with 15 ml. of a saturated solution of picric acid in ethanol, and the liquid was chilled in the refrigerator. After six hours only a scanty precipitate of picric acid had separated.

effects have been observed in certain reactions studied recently.[14]

The experimental results available show that the following structure types, all of which are aldehydic, can function as hydrogen acceptors in the reaction studied: (1) $-\overset{|}{N}CH_2\overset{|}{N}-$ (methylene-bis-amines), (2) $-N{=}CH-$ (methylene-amine, Schiff base), (3) $-NHCHO$ (formylamine), (4) $-NHCH{=}N-$ (substituted formamidine), and (5) formic acid. The following structures, respectively, homologous with 3 and 4 but lacking aldehydic structural characteristics, were found to be incapable of serving as hydrogen acceptors: CH_3CONH- and $-NHC(CH_3){=}N-$. It is concluded that, within the scope of this study, possession of a structure of aldehydic type is necessary in order that a compound may function as a dehydrogenating agent in the oxidation of VI to VII, and that the action is promoted at moderate temperatures by presence of acid or, in its absence and less effectively, by considerably higher temperatures.

Experimental

Starting Materials.—Methylene-bis-*p*-toluidine was prepared by the method of Eberhardt and Welter,[15] and methylene-bis-piperidine as described by Ehrenberg.[16]

The tetrahydroquinazoline VI was made from *o*-amino-*m*-xylyl-*p*-toluidine (V),[8] prepared by the method of Miller and Wagner,[8] and the dihydroquinazoline VII was made from *p*-toluidine, formalin and formic acid.[13] Trimeric methylene-*p*-toluidine was prepared as described by Miller and Wagner,[17] and diphenylformamidine and diphenylacetamidine were made by the methods of Walther[18] and Sen and Ray,[19] respectively.

General Procedures.—For reactions at lower temperatures the reactants (0.005 mole each of tetrahydroquinazoline VI and hydrogen acceptor and 0.011 mole of amine salt in most experiments) were dissolved in ethanol (50 ml.) in a round-bottomed flask (200 ml.) fitted with a short return condenser, and the mixture was heated on a steam-bath. For reactions at higher temperatures the reactants, in a test-tube (25 × 200 mm.) provided with a short return condenser, were heated in a sand-bath. In each procedure temperatures were observed by means of a thermometer with its bulb in the reaction mixture. At the end of the heating period any acid present was neutralized with sodium hydroxide solution and the mixture was submitted to steam distillation to remove volatile amines.

Analysis of Reaction Mixtures.—The amines in the steam distillate were extracted in ether. The amines were fixed by conversion to hydrochlorides and the ether was removed by evaporation. The residue was analyzed by the Hinsberg–Kessler procedure[20] modified in one particular. Following the precipitation of the benzenesulfonamides these were dissolved in ether, and the solution was shaken with 10% sodium hydroxide solution to remove the monosulfonamide of any primary amine present. This improved the separation of primary and secondary amines; after the sodium and alcohol treatment the amount of primary amine derivative recovered was small, but the melting point of the secondary amine derivative was better than that observed when the unmodified procedure was used. The sulfonamides of the several amines were identified by mixed melting point tests.

For the analysis of the solid residue in the steam distillation flask a procedure similar to that of Simons[3] was used. The solid was separated by filtration and was dissolved in 25 ml. of ethanol. The solution was heated to boiling, 3 ml. of benzaldehyde was added, and the mixture was kept for ten hours in a refrigerator (about 10°), after which any precipitated benzal derivative of compound V was removed by filtration, dried, weighed and identified by mixed melting point test. The filtrate from the benzal derivative was heated to boiling and was treated with 15 ml. of a saturated solution of picric acid in ethanol. The mixture was chilled, and the picrate of VII was collected, dried, weighed, and identified by mixed melting point test and by its rather unique sensitivity to light, which changes its color from bright yellow to deep orange-red.

The accuracy of this separation procedure, tested by analysis of mixtures of known amounts of the substances named, is indicated by the following recoveries: dihydroquinazoline VII, 87%; *o*-amino-*m*-xylyl-*p*-toluidine (V), 89%; *p*-toluidine, 96%; N-methyl-*p*-toluidine, 82%. Appropriate corrections were thereafter applied to analytical data for reactions involving VI and I or trimeric II.

In the hope of avoiding the rather troublesome isolation and purification of the benzenesulfonyl derivative of methyl-*p*-toluidine a zinc chloride separation based on that of Frankland[21] was submitted to trial. The precipitate of *p*-toluidine zincichloride was found to be chalky and to occlude methyl-*p*-toluidine, recovery of which (as nitrosamine) was variable and did not exceed 79%. Trials of the 3-nitrophthalic anhydride procedure of Alexander and McElvain,[22] designed for use in qualitative analysis, showed the yields of the derivatives of both amines to be far from quantitative.

The separation of piperidine and methylpiperidine by the Hinsberg–Kessler procedure was satisfactory, but the determination of the latter as picrate proved to be inaccurate. Haase[23] reported methylpiperidine picrate to melt at 148°. Several yields of picrate obtained in the separations failed to melt at this temperature, the melting points being indefinite and diverse. The normal (1:1) picrate resulted only when methylpiperidine and picric acid were brought together in exactly equivalent amounts in alcohol. The product was a compound which melted sharply at 228° cor. as first precipitated, and at the same temperature after recrystallization from 95% ethanol; the yield was 87%. The use of methylpiperidine and picric acid in other proportions gave products which melted badly, and which are believed to be loose compounds of the 1:1 picrate and picric acid. Thus methylpiperidine and 2.5 equivalents of picric acid gave a product which melted in the range 146–180° as obtained, and in the range 147–179° after recrystallization; the yield was 118% of the amount calculated for the 1:1 picrate.

Significant data for the hydrogenation–dehydrogenation experiments are presented in Table I.

Summary

Study of the dehydrogenation of 3-*p*-tolyl-6-methyl-1,2,3,4-tetrahydroquinazoline to the corresponding dihydroquinazoline by action of methylene-bis-amine in presence of acid and at temperatures ordinarily not above 100°, the methylene-bis-amine being cleaved by hydrogenation to yield amine and methylated amine, was extended by use of methylene-bis-*p*-toluidine, trimeric methylene-*p*-toluidine and methylene-bis-piperidine with the acids *p*-toluidine hydrochloride, piperidine hydrochloride, trimethylamine hydrochloride and ammonium chloride. The results confirm the opinion that the over-all reaction is an acid catalyzed hydrogenation–dehydrogenation involving two compounds of ammono-aldehydic type, with formation of compounds of ammono-acidic and ammono-alcoholic types, the essential change having at least a formal resemblance to a crossed Cannizzaro reaction. This interpretation was supported by the demonstration that only compounds which possess an aldehydic structure are able to participate in the oxidation–reduction reaction. The structurally aldehydic compounds diphenylformamidine, form-*p*-toluidide, formamide and benzalaniline all reacted; the analogous non-aldehydic compounds diphenylacetamidine, acetanilide and acetamide failed to react.

The function of the acid appears to be the formation, either by cleavage of a methylene-bis-amine (considered as an ammono-acetal) or from a Schiff base (taken as such or derived from the methylene-bis-amine), of a reactive cation capable of serving as a hydrogen acceptor. Higher temperatures (*circa* 200°) force the reaction in absence of added acid. A general reaction scheme for the acid-induced reaction is presented which appears to be consistent with the observed facts.

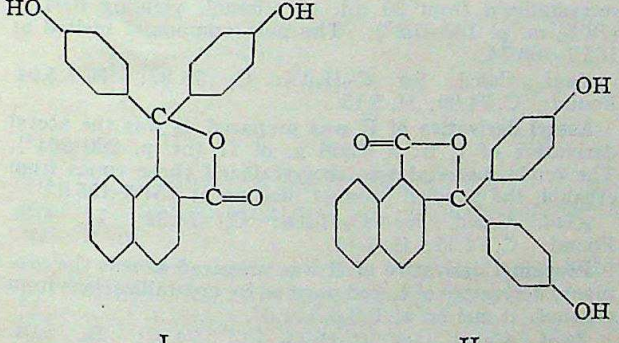
The Phthaleins from Phenol and 1,2-Naphthalenedicarboxylic Acid

BY MAX H. HUBACHER

A study is being made in this Laboratory of the relationship, if any, between the molecular structure of aromatic compounds, especially of phthaleins, and their laxative potency.[1] Of the four theoretically possible phenolnaphthaleins, only one is known, the phenol-1,8-naphthalein.[2] Therefore, the synthesis of the phthaleins from phenol and 1,2-naphthalenedicarboxylic acid anhydride was undertaken. The two theoretically possible phthaleins were obtained. The main product (I) melted at 292° and yielded, on fusion with potassium hydroxide, 2-naphthoic acid and 4,4′-dihydroxybenzophenone. It is, therefore, the γ-lactone of the 1-(α,4,4′-trihydroxybenzohydryl)-2-naphthoic acid or the phenol-2,1-naphthalein. The by-product (II) melted at 268° and yielded, on treatment with potassium hydroxide, the 1-naphthoic acid and 4,4′-dihydroxybenzophenone. Therefore, it must be the γ-lactone of the 2-(α,4,4′-trihydroxybenzohydryl)-1-naphthoic acid or the phenol-1,2-naphthalein.



I II

According to Dr. W. W. Hartman, the *p*H range for both phthaleins is approximately identical, 8.6 to 10.5, the color change from colorless to red magenta. Based on the color density curves, compound I is about four times more intense in color than II. The tests indicate that phenol-2,1-naphthalein (I) is the better indicator of the two, with the advantage over phenolphthalein that it does not fade.

In contrast to that of phenolphthalein and many other phthaleins,[3] the color of solutions of either of the two phthaleins in dilute alkali does not fade. Likewise, phenol-2,1-naphthalein resists oxidation by hydrogen peroxide, while phenolphthalein is easily oxidized under the same conditions.

Acknowledgment.—The author is indebted to Dr. L. T. Capell of *Chemical Abstracts* for the nomenclature and to Dr. W. W. Hartman of the Eastman Kodak Company for the preparation of the transmission curves.

Experimental[4]

Condensation of 1,2-Naphthalenedicarboxylic Anhydride with Phenol.—To 19.8 g. (0.1 mole) of 1,2-naphthalenedicarboxylic anhydride (m. p. 164–169°)[5] and 18.8 g. (0.2 mole) of phenol was added 8 ml. of stannic chloride and the mixture stirred for four hours at 113–116°. The reaction mass was treated with hot 0.1 *N* hydrochloric acid, filtered, and the residue dissolved in 300 ml. of 1 *N* sodium hydroxide. The red filtrate was saturated with carbon dioxide. The precipitated crude phthaleins weighed 16.4 g. (m. p. 240–270°). Separation into two compounds was effected by crystallization from acetic acid. The first crop consisted of the main product (I), crystallizing in fine needles arranged in star-like clusters. The by-product (II) was separated from subsequent fractions in the form of coarse, granular crystals. On heating a solution containing crystals of both compounds, the fine crystals of I dissolve first. This observation can be helpful in the separation; yield of I, 8.03 g. (22%) of m. p. 288–291°; of II, 1.82 g. (5%) of m. p. 261–267°.

Phenol-2,1-naphthalein.—Phthalein I was recrystallized for analysis from acetic acid (1 g. in 20 ml.) or from ethanol (1 g. in 4.5 ml.). It melts at 291.1–292.4°. One gram dissolves in 6.7 ml. of methanol (100%) and 16.5 ml. of ethanol (92.3%) at 20°. A 0.001 molar solution of I in 0.1 *N* sodium hydroxide is red magenta in color[6] or similar to that of a phenolphthalein solution of the same concentration. The solution has a maximum absorption at 562 λ. The color of such an alkaline solution, as well as that of phenol-1,8-naphthalein[2] in the same concentration, does not fade.[3] A 0.1 molar solution of I in 5 *N* sodium hydroxide is dark red and remains unchanged for months; a phenolphthalein solution of the same concentration turns to light red within a few minutes.

The color of I in concd. sulfuric acid is red.

Phenol-2,1-naphthalein turns from colorless to red at a *p*H of 8.6 to 10.5 or at a slightly higher *p*H than phenolphthalein. It is about one-third as strong in color as phenolphthalein and four times as strong as phenol-1,2-naphthalein (see Fig. 1).

By methylation of I with methyl iodide or dimethyl sulfate, an alkali-insoluble, non-crystallizable product was obtained.

Phenol-2,1-naphthalein could not be made to react with hydrogen peroxide, whereas phenolphthalein, under similar conditions, is oxidized readily.[3] Nor did I react with hydroxylamine.

Anal. Calcd. for $C_{24}H_{16}O_4$: C, 78.24; H, 4.37; mol. wt., 368. Found: C, 77.97; H, 4.34; mol. wt., 388, 366, 377, 322 (Signer method[7]).

Phenol-1,2-naphthalein.—The by-product was purified further by recrystallizations from acetic acid (1 g. in 16 ml.)

(4) All melting points are corrected and determined in a Hershberg precision melting point apparatus. Before analysis, the compounds were dried to constant weight at 110° and 10 microns pressure, with the exception of the dipropionate of II, which was dried at 80° and high vacuum. Analyses by William Saschek.

Phenol-2,1-naphthalein (I), 1:21,000, 1-cm. layer at λ 562. Phenol-1,2-naphthalein (II), 1:7,666, 1-cm. layer at λ 558. Phenolphthalein, 1:70,000, 1-cm. layer at λ 555.

Fig. 1.—Density–*p*H range characteristics.

and finally from ethanol. It melts at 267.5-269.5°. The color of a 0.001 molar solution in 0.1 *N* sodium hydroxide is red magenta[6] and orange in concd. sulfuric acid. The maximum of absorption is at 558 λ.

Anal. Calcd. for $C_{24}H_{16}O_4$: C, 78.24; H, 4.37; mol. wt., 368. Found: C, 78.06; H, 4.08; mol. wt., 352 (Rast in camphor).

Some 1,2-naphthalenedicarboxylic anhydride (8.1 g., m. p. 168–169°) was recovered from the mother liquor of the crude phthalein by acidification and sublimation of the precipitate at 160° in high vacuum.[8]

Fusion of I with Potassium Hydroxide.—Twenty grams of potassium hydroxide was heated in a nickel crucible to 240–245° (oil-bath temperature) and then 3.0 g. of I stirred in. After ten minutes, the melt was dissolved in water and treated for the separation of phenolic and acidic compounds by the usual method. The phenolic fraction was purified by sublimation at 180° and 20 microns pressure,[8] yielding 0.697 g. (40%) of 4,4′-dihydroxybenzophenone melting at 208–214° (no depression when mixed with a pure specimen of m. p. 216.8–217.2°).[9] The acidic fraction, likewise purified by sublimation at 150° and 10 microns, weighed 1.006 g. (72%) and melted at 181.5–184.4° (no depression when mixed with 2-naphthoic acid (Eastman Kodak Co.) of m. p. 183.2–184.8°).

Fusion of II with Potassium Hydroxide.—Seven grams of potassium hydroxide was stirred with 0.726 g. of II (m. p. 260–265°) for ten minutes at 240–245° (oil-bath temperature). The reaction product consisted of 0.270 g. (64%) of 4,4′-dihydroxybenzophenone (m. p. 208–215°) and 0.279 g. (82%) of 1-naphthoic acid (m. p. 161.7–162.8°) (no depression when mixed with 1-naphthoic acid (Eastman Kodak Co.) of m. p. 159.8–161.1°).

(8) In tube A of the apparatus described in *Ind. Eng. Chem., Anal. Ed.*, **15**, 448 (1943).

(9) Prepared according to A. Baeyer and J. B. Burkhardt, *Ann.*, **202**, 126 (1880).

Acetyl Derivative of I.—A solution of 1.84 g. (0.005 mole) of I, 1.50 g. (0.015 mole) of acetic anhydride, 5 ml. of acetic acid and one drop of concd. sulfuric acid was refluxed for one hour. The product weighed 2.22 g. (98%, m. p. 218–223°) and after two crystallizations from ethanol (1 g. in 100 ml.) melted at 223.8–225.9°.

Anal. Calcd. for $C_{28}H_{20}O_6$: C, 74.32; H, 4.46; mol. wt., 452. Found: C, 74.01; H, 4.52; mol. wt., 435, 409, 460 (Signer method[7]).

Propionyl derivative of I was prepared by refluxing for one hour 0.92 g. of I, 3.0 ml. of propionic anhydride and a trace of concd. sulfuric acid. The crude product was recrystallized from 20 ml. of ethanol, yielding 0.94 g. (78%, m. p. 159–162°). The pure compound melted at 162.7–163.7°.

Anal. Calcd. for $C_{30}H_{24}O_6$: C, 74.97; H, 5.04. Found: C, 74.99; H, 5.13.

Acetyl derivative of II was prepared as was the acetyl derivative of I, from 0.368 g. of II (m. p. 260–264°). The crude material was recrystallized three times from ethanol, the purified product melting at 154.5–155.6°.

Anal. Calcd. for $C_{28}H_{20}O_6$: C, 74.32; H, 4.46. Found: C, 74.11; H, 4.41.

Propionyl derivative of II was prepared as was the propionyl derivative of I, and purified by crystallizations from ethanol; it melted at 109.6–111.0°.

Anal. Calcd. for $C_{30}H_{24}O_6$: C, 74.97; H, 5.04. Found: C, 74.59; H, 4.83.

Summary

The two theoretically possible phthaleins from phenol and 1,2-naphthalenedicarboxylic acid anhydride were prepared and their structure proved. The corresponding acetyl and propionyl derivatives were made also.

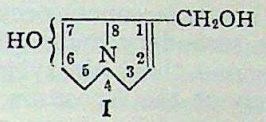
Structure of Monocrotaline. XI. Proof of the Structure of Retronecine[1]

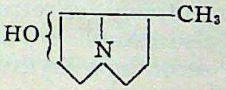
BY ROGER ADAMS AND N. J. LEONARD

Retronecine, the base obtained along with carbon dioxide and monocrotic acid upon alkaline hydrolysis of monocrotaline, has been postulated[2,3] as having structure I. The presence of the

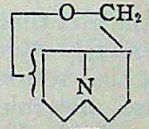


I

—CH_2OH group in the 1-position of the pyrrolizidine nucleus[3] and the location of the double bond in the 1,2-position[4] have been proved conclusively. The location of the secondary hydroxyl group in retronecine (I) or in retronecanol (II)[3] has been in doubt. The experimental evidence favors either the 6- or the 7-position. The degradation of retronecanol by bromocyanogen indicates that the 7-position is the more likely.[2] Corroborative evidence for the 7-position is obtained by construction of models representing anhydroplatynecine (III). When the secondary



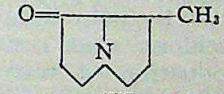
II



III

hydroxyl group is in the 7-position, the structural model of anhydroplatynecine involves somewhat less strain.

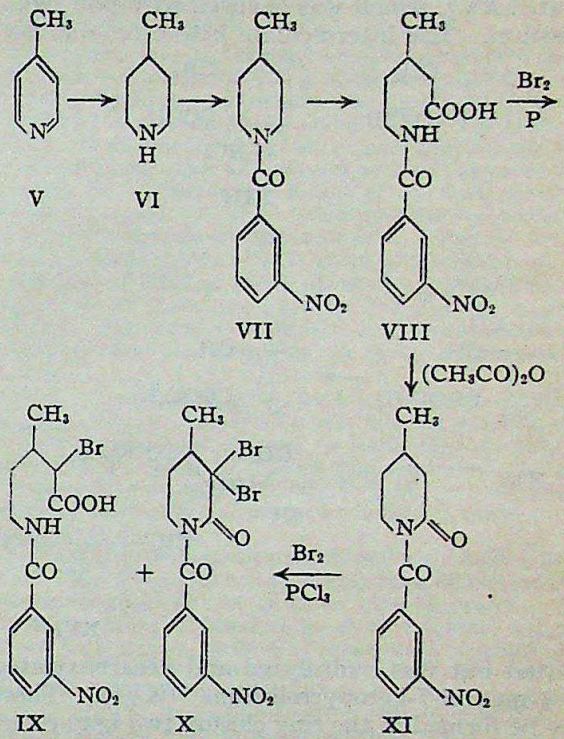
An optically active form of 1-methyl-7-ketopyrrolizidine has now been synthesized by an unequivocal method and found to be identical with the retronecanone (IV)[3] obtained by oxidation of



IV

retronecanol with aluminum *t*-butoxide. It has thus been proved that retronecine and its derivatives have the secondary hydroxyl group in the 7-position.

4-Methylpyridine (V) was reduced catalytically to 4-methylpiperidine (VI), which was converted into 1-*m*-nitrobenzoyl-4-methyl-piperidine (VII) by a Schotten–Baumann reaction with *m*-nitrobenzoyl chloride. Oxidation of compound VII with potassium permanganate according to the method of Schotten[5,6] and Fischer and Zemplén[7]



gave β-methyl-δ-*m*-nitrobenzoylaminovaleric acid (VIII), which would be formed by cleavage of either ring carbon–nitrogen bond. Bromination of this acid (VIII) in the presence of red phosphorus resulted in the formation of two products IX and X. Compound X was identified as N-*m*-nitrobenzoyl-γ-methyl-β,β-dibromo-α-piperidone by bromination of N-*m*-nitrobenzoyl-γ-methyl-α-piperidone (XI).[8] The structure of compound IX was accepted on the basis of the results of the researches of Fischer and Zemplén,[7] who prepared the analogous compound through a similar series of reactions from pyridine.

α-Bromo-β-methyl-δ-*m*-nitrobenzoylaminovaleric acid (IX) was not obtained in a pure state but the crude product was converted to ethyl 3-methylpyrrolidine-2-carboxylate (XIV) through the intermediates XII and XIII. The formation of 1-*m*-nitrobenzoyl-3-methylpyrrolidine-2-carboxylic acid (XII) resulted from the reaction of alkali upon IX, and 3-methylpyrrolidine-2-carboxylic acid hydrochloride (XIII) was obtained by the hydrolysis of XII with hydrochloric acid. Owing to the difficulty in purifying either XII or XIII, compound XIII was esterified directly to XIV, which was obtained readily in pure form by distillation. The physical properties and analyses of XIV and its picrate indicated conclusively that the compound was ethyl 3-methylpyrrolidine-2-

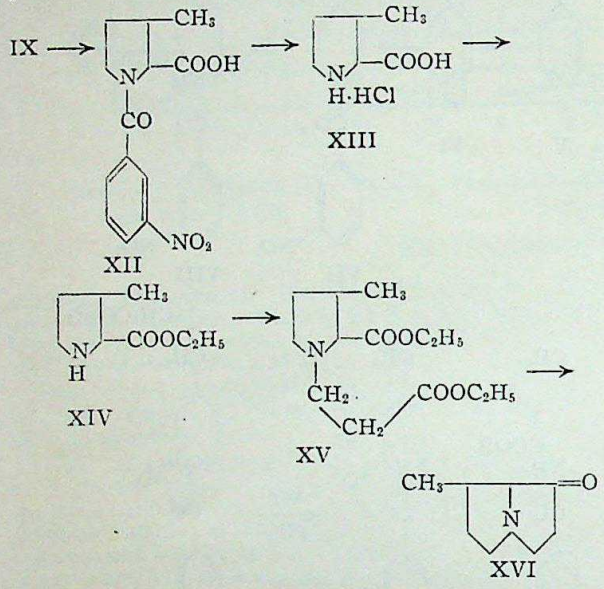
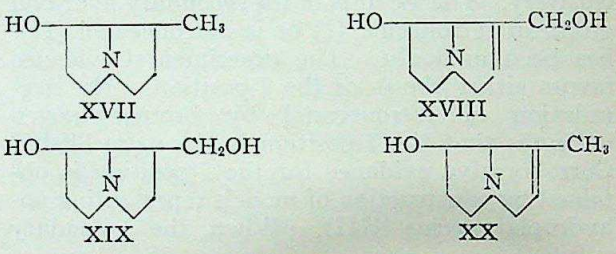
carboxylate. Proline has been made previously by a similar series of reactions.[7] Ethyl 3-methylpyrrolidine-2-carboxylate underwent practically quantitative addition to ethyl acrylate to give ethyl β-N-(3-methyl-2-carbethoxypyrrolidyl)-propionate (XV), which was cyclized with powdered potassium. The intermediate keto-ester was not



isolated but was hydrolyzed and decarboxylated to 1-methyl-7-ketopyrrolizidine (XVI). There may be formed in the ring closure two keto-esters depending upon which ethoxy group is eliminated as ethanol. Both of these, however, on hydrolysis and decarboxylation would yield the same ketone.

The picrate, methiodide and oxime of compound XVI were prepared. Although theoretically two racemic modifications might be present in the liquid XVI as synthesized only single derivatives were isolated in each case. An attempt was made to isolate an optically active 1-methyl-7-ketopyrrolizidine from the possible mixture of four forms by the use of *l*-menthydrazide. A pure *l*-menthydrazone was obtained but it proved to have a different melting point and specific rotation from the *l*-menthydrazone of retronecanone. Moreover, hydrolysis of the 1-methyl-7-ketopyrrolizidine *l*-menthydrazone and conversion of the ketone to the oxime gave an optically inactive product.

In order to decrease the stereochemical possibilities in the final product as a result of working with racemic modifications, a similar series of reactions was carried out using *l*-β-methyl-δ-*m*-nitrobenzoylaminovaleric acid. This optically active acid was obtained by resolution through the quinidine salt of the racemic acid (VIII). There was thus obtained optically active 1-methyl-7-ketopyrrolizidine (XVI) which could not consist of a mixture of more than two forms. Like the product from the racemic acid this was an oil. When treated with hydroxylamine, however, a single, pure, optically active oxime was isolated. This proved to be identical in melting point, crystalline form as observed under the microscope, and specific rotation with retronecanone oxime, and the melting points of mixtures of the two compounds showed no depression. The picrates of the aminoketoximes obtained from natural and synthetic sources were also found to be identical and showed no depression of melting-decomposition point when mixed. Likewise, the picrolonates of the oximes were identical. Since the keto group in retronecanone occupies the same position as the secondary hydroxyl group in its parent, retronecanol, this hydroxyl group has been located definitely at the 7-position, and the precise structure of retronecanol may now be represented by XVII. Retronecine, therefore, has structure XVIII; platynecine,[9] structure XIX; and desoxyretronecine,[10] structure XX. Owing



to the fact that heliotridine and oxyheliotridane[11] are merely stereoisomers, respectively, of retronecine and retronecanol, it is also established that these molecules have the secondary hydroxyl group in the 7-position.

Monocrotaline, the acetyl and benzoyl esters of retronecine, and retronecine itself have been reduced to retronecanol.[10,12,13] These reductions have been carried out in solutions of widely different *p*H over palladium or platinum oxide catalysts, and retronecanol is the only 1-methyl-7-hydroxypyrrolizidine isomer which has been obtained, always in essentially quantitative yield. Likewise, the catalytic reduction of desoxyretronecine in hydrochloric acid resulted in almost quantitative production of retronecanol,[10] and isoheliotridene was reduced in ethanol over platinum oxide to heliotridane,[4] which is related to retronecanol through chlororetronecane,[14]

Reduction of all of these $\Delta^{1,2}$-unsaturated pyrrolizidines makes carbon atom-1 asymmetrical. There is the possibility of reduction proceeding to give a mixture of isomers in which the C_1-CH_3 would be both *cis* and *trans* with respect to the C_8-H; the other possibility would be asymmetric reduction proceeding to give *either* the *cis*- or the *trans*-C_1-CH_3 configuration. Asymmetric reduction is indicated because of the fact that synthetic (and, therefore, naturally-obtained) retronecanone possesses the C_1-CH_3 fixed in one stereo-

chemical configuration. This may be deduced from the fact that the starting material for its preparation was *l*-β-methyl-δ-*m*-nitrobenzoylaminovaleric acid, in which the C_{β}-CH_3 had a fixed configuration.

Reduction of retronecanone could yield a mixture of a maximum of four stereoisomeric 1-methyl-7-hydroxypyrrolizidines if C-8 were racemized in the aluminum *t*-butoxide oxidation of retronecanol to retronecanone. A maximum of two isomers, of which one would be retronecanol, could result on reduction of retronecanone if the latter possessed only one stereochemical configuration about C-8. Neither retronecanol nor its derivatives could be obtained by reduction of retronecanone over platinum oxide in ethanol or in ethanolic hydrochloric acid solution. The reaction products from reductions carried out both in neutral and acid solution were mixtures. In each of the two experiments it was possible to isolate a pure compound as a picrate, but these were not identical with each other or with retronecanol picrate. Upon acetylation of each reduction product mixture and then treatment with methyl iodide, the same pure acetyl methiodide was isolated in small yield. This methiodide was not identical but stereoisomeric with acetylretronecanol methiodide. As a consequence of these results no attempt was made to synthesize natural retronecanol from synthetic optically active 1-methyl-7-ketopyrrolizidine.

Experimental

4-Methylpiperidine (VI).—Hydrogenation of 482 g. (5.18 moles) of redistilled 4-methylpyridine (V) (b. p. 142–144°) was concluded after twenty-four hours at 210° and 150–300 atm. with 50 g. of Raney nickel catalyst. The product was fractionally distilled and the fraction boiling at 126–129° was collected[15]; $n^{20}D$ 1.4487; yield 283 g. (55%, or 90% on the basis of unrecovered 4-methylpyridine).

1-*m*-Nitrobenzoyl-4-methylpiperidine (VII).—To a well-stirred mixture of 265 g. (2.67 moles) of 4-methylpiperidine and 120 g. (3.00 moles) of sodium hydroxide in 630 cc. of water was added slowly, during the course of two hours, 500 g. (2.69 moles) of molten *m*-nitrobenzoyl chloride.[6] The temperature was maintained at 35–40°. When addition was complete the mixture was stirred for an additional hour and then cooled in ice. The yellow crystals were filtered, washed with water and dried; yield of crude product, 582 g. (88%). After recrystallization from aqueous ethanol, 550 g. of large colorless prisms was obtained, m. p. 72–73°. The compound may be recrystallized also from benzene–ligroin (b. p. 90–110°).

Anal. Calcd. for $C_{13}H_{16}N_2O_3$: C, 62.89; H, 6.49. Found: C, 63.00; H, 6.50.

***dl*-β-Methyl-δ-*m*-nitrobenzoylaminovaleric Acid (VIII).**—A total of 520 g. (2.1 moles) of 1-*m*-nitrobenzoyl-4-methylpiperidine was oxidized in thirteen batches of 40 g. each. The amide (40 g.) was dissolved in 2.5 liters of boiling water and a solution of 60 g. of potassium permanganate in 500 cc. of hot water was added during one hour, while stirring vigorously and refluxing. The reaction mixture was filtered hot and the alkaline filtrate was cooled and extracted with ether. The combined ether extracts of thirteen runs furnished 88 g. of crude starting material which again was subjected to permanganate oxidation. The aqueous solution (above) was acidified with dilute sulfuric acid and cooled in ice. The colorless crystalline product which separated was collected on a filter; extraction of the acidic filtrate with ether furnished additional product. The total combined yield was 340 g. (57%) which was purified by recrystallization from dilute acetic acid or aqueous ethanol; colorless elongated prisms, m. p. 103–105°.

Anal. Calcd. for $C_{13}H_{16}N_2O_5$: C, 55.71; H, 5.75; N, 9.99. Found: C, 55.78; H, 5.93; N, 9.84.

Resolution of *dl*-β-Methyl-δ-*m*-nitrobenzoylaminovaleric Acid.—A mixture of 100 g. of the *dl*-acid and 116 g. of anhydrous quinidine was dissolved in hot absolute ethanol, boiled with Darco and Norite and filtered. The ethanolic filtrate, which amounted to 450 cc., was diluted with 1300 cc. of anhydrous ether and allowed to stand at room temperature for several days. Rosets of colorless elongated prisms separated and these were isolated by filtration, washed with anhydrous ether and dried (Fraction 1); m. p., 125.0–126.5° (cor.); yield 77 g. (36% of total).

Rotation. 0.2286 g. made up to 5 cc. with absolute ethanol at 28° gave αD +5.10°; *l*, 1; $[\alpha]^{28}D$ +111.5° (±0.5°). Further recrystallization from absolute ethanol–anhydrous ether altered neither the melting point nor the rotation.

After removal of 77 g. of the most insoluble quinidine salt (Fraction 1), the filtrate was diluted further with anhydrous ether and allowed to stand in the cold. A further 48 g. (22%) of yellow, semicrystalline material separated, leaving approximately 42% of the total salt in solution (Fraction 2). The more soluble salt could not be obtained crystalline.

***l*-β-Methyl-δ-*m*-nitrobenzoylaminovaleric Acid.**—Fraction 1 (75 g.) was shaken thoroughly with 500 cc. of 2 *N* sulfuric acid and 200 cc. of ether, then separated. The mixture of dilute acid and undissolved quinidine salt was shaken with 200-cc. portions of ether until no more solid material remained. The ethereal extracts were combined, dried over anhydrous magnesium sulfate, and evaporated to give 30 g. of crystalline *l*-acid. This was purified by recrystallization from aqueous ethanol: colorless rods, m. p. 113–114°.

Anal. Calcd. for $C_{13}H_{16}N_2O_5$: C, 55.71; H, 5.75; N, 9.99. Found: C, 55.96; H, 6.02; N, 9.92.

Rotation. 0.2040 g. made up to 5 cc. with absolute ethanol at 30° gave αD −0.205°; *l*, 1; $[\alpha]^{30}D$ −5.0° (±0.2°).

***d*-β-Methyl-δ-*m*-nitrobenzoylaminovaleric Acid.**—The ethereal solution containing Fraction 2 was shaken with 2 *N* sulfuric acid, and 34 g. of the *d*-acid was obtained by the same procedure as that outlined above. Purification was accomplished by recrystallization from chloroform–ligroin (b. p. 90–110°): colorless elongated prisms, m. p., 113–114°.

Anal. Calcd. for $C_{13}H_{16}N_2O_5$: C, 55.71; H, 5.75; N, 9.99. Found: C, 55.94; H, 5.84; N, 10.09.

Rotation. 0.2164 g. made up to 5 cc. with absolute ethanol at 25° gave αD +0.23°; *l*, 1; $[\alpha]^{25}D$ +5.3° (±0.2°).

Bromination of *dl*-β-Methyl-δ-*m*-nitrobenzoylaminovaleric Acid.—An intimate mixture of 50 g. (0.18 mole) of *dl*-β-methyl-δ-*m*-nitrobenzoylaminovaleric acid and 8 g. of red phosphorus was protected from moisture, cooled in ice, and stirred manually during the thirty-minute addition of 51.5 cc. (*ca.* 0.94 mole) of dry bromine. When addition was complete the mixture was stirred at room temperature for thirty minutes, warmed to 90° during ten minutes, and kept at 90° for a further ten minutes. The reaction mixture was cooled in ice and ice-water was added gradually. Excess bromine was reduced by passing a slow stream of sulfur dioxide into the cold solution. After addition of excess sodium carbonate solution the mixture was stirred vigorously and filtered. The sodium carbonate-insoluble material weighed 15 g. It was purified by recrystallization from ethanol, from which it separated in leaf-like aggregates of colorless elongated prisms, m. p. 152–153° (cor.). It proved to be N-*m*-nitrobenzoyl-γ-methyl-β,β-dibromo-α-piperidone (X).

Anal. Calcd. for $C_{13}H_{12}Br_2N_2O_4$: C, 37.17; H, 2.88; N, 6.67. Found: C, 37.36; H, 3.08; N, 6.62.

After removal of the alkali-insoluble material the filtrate was cooled, acidified with 1 *N* sulfuric acid and extracted thoroughly with ether. The ethereal solution was dried over anhydrous magnesium sulfate, and the ether was removed to leave a residue of 42 g. of straw-colored oil which could not be crystallized. The crude α-bromo-β-methyl-δ-*m*-nitrobenzoylaminovaleric acid (IX) was not purified but was used directly in the next step (ring-closure).

N-*m*-Nitrobenzoyl-γ-methyl-α-piperidone (XI).—A solution of 2 g. of *dl*-β-methyl-δ-*m*-nitrobenzoylaminovaleric acid (VIII)[6] in 25 cc. of acetic anhydride was refluxed for two and one-half hours in all-glass apparatus. The acetic anhydride was removed *in vacuo* and the residue was recrystallized from aqueous ethanol: colorless elongated prisms, m. p. 102–103°. The melting point of a mixture of this product and the starting material (m. p. 103–104°) was depressed to 85–95°.

Anal. Calcd. for $C_{13}H_{14}N_2O_4$: C, 59.53; H, 5.38; N, 10.68. Found: C, 59.71; H, 5.44; N, 10.82.

N-*m*-Nitrobenzoyl-γ-methyl-β,β-dibromo-α-piperidone (X).—To 0.25 g. of N-*m*-nitrobenzoyl-γ-methyl-α-piperidone in 5 cc. of dry chloroform were added three drops of phosphorus trichloride and 0.6 g. of bromine.[8] The solution was illuminated by a bright electric light for forty-eight hours, then the reaction mixture was treated with water and sufficient sodium bisulfite to decompose the excess bromine. The chloroform layer was separated and evaporated to dryness, leaving 0.10 g. of product which was recrystallized from ethanol: colorless elongated prisms, m. p., 152–153° (cor.). When this product was mixed with the alkali-insoluble material obtained in brominating *dl*-β-methyl-δ-*m*-nitrobenzoylaminovaleric acid, there was no depression of melting point.

Bromination of *l*-β-Methyl-δ-*m*-nitrobenzoylaminovaleric Acid.—The bromination was carried out in a manner identical with that used for the *dl*-acid. The quantities employed were 25 g. (0.09 mole) of *l*-acid, 3.5 g. of red phosphorus, and 20 cc. of bromine (*ca.* 0.36 mole), and two products were obtained. The alkali-insoluble bromination product was recrystallized from ethanol: colorless prisms, m. p., 167–168° (cor.). This was *l*-N-*m*-nitrobenzoyl-γ-methyl-β,β-dibromo-α-piperidone.

Anal. Calcd. for $C_{13}H_{12}Br_2N_2O_4$: C, 37.17; H, 2.88; N, 6.67. Found: C, 37.33; H, 3.05; N, 6.54.

Rotation. 0.1211 g. made up to 5 cc. with pyridine at 30° gave α_D −0.49°; *l*, 1; $[\alpha]^{30}_D$ −20.2° (±0.2°).

The alkali-soluble product of bromination weighed 19 g. but was not obtained crystalline. It was crude optically active α-bromo-β-methyl-δ-*m*-nitrobenzoylaminovaleric acid and was used directly in the next step.

1-*m*-Nitrobenzoyl-3-methylpyrrolidine-2-carboxylic Acid (XII).—A solution of 42 g. of crude α-bromo-β-methyl-δ-*m*-nitrobenzoylaminovaleric acid (IX) in 350 cc. of 1 *N* sodium hydroxide was kept at 37° for forty-eight hours. The red solution was nearly neutralized with 1 *N* sulfuric acid and concentrated *in vacuo* to 100 cc. The solution was cooled, acidified strongly with sulfuric acid and extracted with five 100-cc. portions of ether. The combined ether extracts were washed with a small quantity of water, dried over anhydrous magnesium sulfate, and the ether was removed. The residue amounted to 29 g. of thick yellow oil which could not be induced to crystallize.

The crude 1-*m*-nitrobenzoyl-3-methylpyrrolidine-2-carboxylic acid was esterified directly.

Optically Active 1-*m*-Nitrobenzoyl-3-methylpyrrolidine-2-carboxylic Acid.—This compound was prepared in the same manner as the above acid, starting with a solution of 19 g. of crude optically active α-bromo-β-methyl-δ-*m*-nitrobenzoylaminovaleric acid in 160 cc. of 1 *N* sodium hydroxide. The product was obtained as 14 g. of yellow oil which was used directly in the next step in the synthesis.

Ethyl 3-Methylpyrrolidine-2-carboxylate (XIV).—A solution of 27.5 g. of crude 1-*m*-nitrobenzoyl-3-methylpyrrolidine-2-carboxylic acid in 1 l. of 3 *N* hydrochloric acid was refluxed for four hours. The solution was cooled, and the *m*-nitrobenzoic acid was removed by filtration. The filtrate was concentrated to small volume *in vacuo*, cooled and filtered free of additional precipitated *m*-nitrobenzoic acid. This filtrate was extracted with three portions of ether and evaporated to dryness *in vacuo* to yield 9 g. of crude 3-methylpyrrolidine-2-carboxylic acid hydrochloride (XIII) as a viscous oil. This amino acid hydrochloride was esterified by a method analogous to that used for preparing the ethyl ester of *l*-proline.[16] The crude material was suspended in 150 cc. of freshly distilled absolute ethanol. The suspension was saturated with dry hydrogen chloride which brought about complete solution. The solution was refluxed gently for ten minutes, allowed to stand for several hours protected from moisture, and then evaporated *in vacuo*. The residue was redissolved in 100 cc. of absolute ethanol and again saturated with dry hydrogen chloride, with natural refluxing. After standing overnight the solution was evaporated to dryness *in vacuo*. The brown viscous residue was dissolved in 25 cc. of warm absolute ethanol and 175 cc. of anhydrous ether was added. The solution was cooled in an ice–salt-bath and dry ammonia was passed through, slowly at first, then in a rapid stream until the solution was saturated. It was allowed to stand overnight and, after filtration and removal of the ether, the residue was distilled under diminished pressure; b. p. 90–91.5° (17.5 mm.), 96–97° (21 mm.); $n^{20}D$ 1.4470; d^{20}_4 0.993. The yield was 4 g., or an over-all yield of 14% of the theoretical amount, based upon 50 g. (0.18 mole) of *dl*-β-methyl-δ-*m*-nitrobenzoylaminovaleric acid (VIII).

Anal. Calcd. for $C_8H_{15}NO_2$: C, 61.13; H, 9.61; N, 8.91; MR_D, 42.36. Found: C, 61.18; H, 9.60; N, 8.92; MR_D, 42.31.

Picrate.—Prepared in and recrystallized from dry benzene, the picrate formed long yellow prisms, m. p. 112.5–114°.

Anal. Calcd. for $C_{14}H_{18}N_4O_9$: C, 43.53; H, 4.69. Found: C, 43.67; H, 4.81.

Optically Active Ethyl 3-Methylpyrrolidine-2-carboxylate.—The same procedure was followed as for the optically inactive compound. The hydrolysis was carried out by refluxing a solution of 14 g. of crude optically active 1-*m*-nitrobenzoyl-3-methylpyrrolidine-2-carboxylic acid in 400 cc. of 3 *N* hydrochloric acid for five hours. The crude optically active 3-methylpyrrolidine-2-carboxylic acid hydrochloride weighed 4.7 g. and was esterified with absolute ethanol saturated with dry hydrogen chloride as described above. The ethyl ester boiled at 97–98° (23 mm.); $n^{20}D$ 1.4458; yield, 1.2 g.

Anal. Calcd. for $C_8H_{15}NO_2$: N, 8.91. Found: N, 8.76.

Rotation. 0.0686 g. made up to 5 cc. with absolute ethanol at 28° showed no measurable rotation.

Ethyl β-N-(3-Methyl-2-carbethoxypyrrolidyl)-propionate (XV).[17]—A solution of 3.8 g. (24 millimoles) of ethyl 3-methylpyrrolidine-2-carboxylate and 8 cc. (*ca.* 70 millimoles) of ethyl acrylate containing a trace of hydroquinone was heated under reflux for twenty-four hours on the steam-bath, protected from moisture. The clear yellow solution was fractionally distilled *in vacuo*. The boiling point of the colorless product was 163.5–165.5° (18 mm.), 126–127° (4 mm.); $n^{20}D$ 1.4523; d^{20}_4 1.032; yield, 6.0 g. (97%).

Anal. Calcd. for $C_{13}H_{23}NO_4$: C, 60.69; H, 8.98; N, 5.44; MR_D, 67.46. Found: C, 60.73; H, 8.96; N, 5.36; MR_D, 67.27.

Picrate.—Prepared in anhydrous ether and recrystallized from dry benzene, the picrate formed glistening yellow platelets, m. p., 98–99°.

Anal. Calcd. for $C_{19}H_{26}N_4O_{11}$: C, 46.92; H, 5.39. Found: C, 47.07; H, 5.50.

Optically Active Ethyl β-N-(3-Methyl-2-carbethoxypyrrolidyl)-propionate.—A solution of 1.2 g. of the ethyl 3-methylpyrrolidine-2-carboxylate prepared from optically active starting material and 4 cc. of ethyl acrylate was refluxed on a steam-bath for twenty hours, protected from moisture. The product boiled at 170–171° (25 mm.); $n^{20}D$ 1.4512; yield, 1.5 g.

Anal. Calcd. for $C_{13}H_{23}NO_4$: C, 60.69; H, 8.98; N, 5.44. Found: C, 60.88; H, 9.16; N, 5.69.

Rotation. 0.1038 g. in 2.5 cc. of absolute ethanol at 30° gave αD −1.45°; *l*, 1; $[\alpha]^{30}D$ −34.9° (±0.5°).

1-Methyl-7-ketopyrrolizidine (XVI).—Metallic potassium (2.5 g.) was finely powdered under 20 cc. of dry xylene. The mixture was cooled and 10 cc. of dry benzene was added. With vigorous stirring, a solution of 6 g. (23 millimoles) of optically inactive ethyl β-N-(3-methyl-2-carbethoxypyrrolidyl)-propionate and 10 cc. of dry benzene was added dropwise over a period of thirty-five minutes. The residual diester solution was washed in with an additional 10 cc. of dry benzene and the reaction mixture was heated under reflux on the steam-bath for four and one-half hours, protected from moisture. The mixture was cooled and the excess potassium was decomposed by the addition of 8 cc. of ethanol, followed by 20 cc. of distilled water. The mixture was separated and the benzene–xylene solution was extracted with four 5-cc. portions of water. To the combined aqueous extracts was added 30 cc. of concentrated hydrochloric acid, and the solution was heated under reflux for two and one-half hours on the steam-bath. After the hydrochloric acid had been removed by distillation *in vacuo*, the dark reddish residue was taken up in 20 cc. of water, basified with saturated sodium hydroxide solution, and extracted five times with ether. The ethereal solution was dried, the ether removed, and the residue distilled under reduced pressure. The optically inactive 1-methyl-7-ketopyrrolizidine was obtained as a colorless mobile liquid which rapidly darkened; b. p. 96.5–98° (18 mm.), 79–80° (8 mm.); $n^{20}D$ 1.4770; yield, 1.9 g. (59%).

Anal. Calcd. for $C_8H_{13}NO$: C, 69.03; H, 9.41. Found: C, 68.91; H, 9.33.

Picrate.—Prepared in anhydrous ether and recrystallized from absolute ethanol, the picrate formed yellow, feathery elongated prisms which melted, with decomposition, at 189–190° (cor.).

Anal. Calcd. for $C_{14}H_{16}N_4O_8$: C, 45.65; H, 4.37. Found: C, 45.73; H, 4.49.

Methiodide.—Prepared in and recrystallized from dry benzene the methiodide formed colorless prisms, m. p. 149.5–150.5° (cor.).

Anal. Calcd. for $C_9H_{16}INO$: C, 38.46; H, 5.73. Found: C, 38.33; H, 5.94.

***l*-Menthydrazone.**—A solution of 1.9 g. of optically inactive 1-methyl-7-ketopyrrolizidine and 2.25 g. of *l*-menthydrazide[18] in the minimum amount of absolute ethanol (containing 2 g. of fused sodium acetate and 1 g. of glacial acetic acid per 100 cc. of absolute ethanol) was heated under reflux on the steam-bath for twenty-five hours, protected from moisture. After standing at room temperature, crystals separated. These were collected on a filter, washed with a little absolute ethanol, and recrystallized from ligroin (b. p. 90–110°). After the first recrystallization, 160 mg. of colorless elongated prisms was obtained; these melted at 169.5–171° (cor.) and the melting point was unchanged after three more recrystallizations from ligroin.

Anal. Calcd. for $C_{19}H_{33}N_3O_2$: C, 68.02; H, 9.92; N, 12.53. Found: C, 68.09; H, 9.79; N, 12.64.

Rotation. 0.0658 g. made up to 5 cc. with absolute ethanol at 27° gave αD −0.52°; *l*, 1; $[\alpha]^{27}D$ −39.5° (±0.5°).

After the above crystals had been removed by filtration, the ethanolic filtrate was heated and diluted with water. When the solution was allowed to cool slowly, 2.7 g. of crystals was obtained and submitted to a systematic six-stage fractionation from ligroin. The melting points of all of the fractions remained nearly identical and the specific rotations of widely separated fractions also were identical within the precision of measurement. Chromatographic adsorption of a dilute ligroin solution of the *l*-menthydrazone on activated alumina brought about no recognizable separation of the diastereoisomers. In order to check the assumption that no resolution was being accomplished through this derivative, the most insoluble fraction of *l*-menthydrazone obtained at the sixth fractional recrystallization stage was converted to the oxime.

Oxime.—Approximately 0.6 g. of the most insoluble portion of *l*-menthydrazone was refluxed for one hour in 20 cc. of 2 *N* sulfuric acid. The solution was cooled, extracted with ether and the ether extract discarded. The aqueous solution was made strongly basic with sodium hydroxide and extracted again with ether. The combined ether extracts of the alkaline solution were dried over anhydrous magnesium sulfate and evaporated to small volume. Addition of excess picric acid in dry ether resulted in the precipitation of yellow crystals. This picrate, after one recrystallization from absolute ethanol, melted at 189–190° (cor.) and gave no depression of melting point when mixed with the picrate of optically inactive 1-methyl-7-ketopyrrolizidine. The picrate was decomposed in hydrochloric acid solution, and the picric acid was removed by extraction with ether. The aqueous solution was evaporated to dryness *in vacuo*. The residue was redissolved in 3 cc. of water and treated with 3 cc. of 5 *N* sodium hydroxide and 0.25 g. of hydroxylamine hydrochloride. The oxime was formed and isolated in the same manner as described for the oxime of retronecanone.[3] Recrystallization from chloroform–petroleum ether (b. p. 40–60°) gave colorless prisms, m. p. 128–130° (cor.). The compound showed no optical activity.

Anal. Calcd. for $C_8H_{14}N_2O$: C, 62.31; H, 9.15; N, 18.17. Found: C, 62.54; H, 9.16; N, 18.26.

Optically Active 1-Methyl-7-ketopyrrolizidine.—Cyclization of levorotatory ethyl β-N-(3-methyl-2-carbethoxypyrrolidyl)-propionate was carried out under the same conditions employed in the formation of the optically inactive 1-methyl-7-ketopyrrolizidine (XVI). A suspension of 0.6 g. of finely powdered potassium in 6 cc. of dry xylene and 3 cc. of dry benzene was treated with a solution of 1.3 g. of the levorotatory diester and 6 cc. of benzene added dropwise during one-half hour. The aminoketone was obtained as 0.4 g. of light amber-colored oil which was not distilled but was converted directly to the oxime in the usual manner, by treating with 0.6 g. of hydroxylamine hydrochloride in 6 cc. of 2.5 *N* sodium hydroxide. The **oxime** was purified by recrystallization from chloroform–petroleum ether (b. p. 40–60°), from which it separated as colorless elongated prisms, m. p. 166–167° (cor.).

Anal. Calcd. for $C_8H_{14}N_2O$: C, 62.31; H, 9.15; N, 18.17. Found: C, 62.44; H, 9.06; N, 18.08.

Rotation. 0.0659 g. made up to 5 cc. with absolute ethanol at 32° gave αD −1.02°; *l*, 1; $[\alpha]^{32}D$ −77.3° (±1.5°).

The melting point was not depressed when the oxime was mixed with varying proportions of authentic retronecanone oxime (reported m. p. 167–168° (cor.)). The crystalline form of the synthetic oxime was identical with that of retronecanone oxime as observed under the microscope. Furthermore, the specific rotation of this synthetic oxime was identical, within the precision of measurement, with that recorded for retronecanone oxime ($[\alpha]^{24}D$ −76.0° ±2.5°).

Picrate of Optically Active 1-Methyl-7-ketopyrolizidine Oxime.—Prepared in anhydrous ether, from the oxime of optically active 1-methyl-7-ketopyrrolizidine and dry picric acid, and recrystallized from absolute ethanol, the picrate formed yellow elongated prisms which melted, with decomposition, at 188–190° (cor.).

Anal. Calcd. for $C_{14}H_{17}N_5O_8$: C, 43.86; H, 4.47; N, 18.27. Found: C, 43.97; H, 4.66; N, 18.23.

(18) Woodward, Kohman and Harris, THIS JOURNAL, 63, 120 (1941).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The melting–decomposition point was not depressed when the synthetic picrate was mixed with the picrate of retronecanone oxime.

Picrolonate of Optically Active 1-Methyl-7-ketopyrrolizidine Oxime.—Prepared in absolute ethanol and recrystallized from ethanol–benzene solution, the picrolonate formed clusters of yellow elongated prisms which melted, with decomposition, at 209–211° (cor.).

Anal. Calcd. for $C_{18}H_{22}N_6O_6$: C, 51.67; H, 5.30; N, 20.09. Found: C, 51.83; H, 5.48; N, 20.02.

The melting–decomposition point was not depressed when the picrolonate was mixed with the picrolonate of retronecanone oxime.

Retronecanone Picrolonate.—Prepared in and recrystallized from absolute ethanol, the picrolonate formed yellow elongated prisms which melted, with decomposition and foaming, at 195–196° (cor.).

Retronecanone Methiodide.—Formed by warming retronecanone with excess methyl iodide in benzene solution and recrystallized from absolute ethanol, the methiodide formed colorless elongated prisms, m. p. 160–161° (cor.).

Retronecanone *l*-Menthydrazone.—An absolute ethanol solution of 0.8 g. of retronecanone and 0.95 g. of *l*-menthydrazide was heated on the steam-bath for twenty-four hours under reflux. When the reaction mixture was cooled and diluted with water, 0.8 g. of fine elongated prisms separated in a closely adhering mass. After seven recrystallizations from ligroin (b. p. 90–110°) the product melted at 175.5–176.5° (cor.).

Anal. Calcd. for $C_{19}H_{33}N_3O_2$: C, 68.02; H, 9.92; N, 12.53. Found: C, 68.20; H, 9.95; N, 12.65.

Rotation. 0.0655 g. made up to 5 cc. with absolute ethanol at 28° gave α_D −1.09°; *l*, 1; $[\alpha]^{28}D$ −83.2° (±0.5°); $[M]^{28}D$ −279°.

Hydrolysis of Retronecanone *l*-Menthydrazone.—A representative sample was boiled with 20 cc. of 1 *N* sulfuric acid for one hour. The solution was cooled and extracted with ether, which removed most of the coloration. After the aqueous solution had been made strongly basic, it was thoroughly extracted with ether, the combined ether extracts dried, and the ether solution concentrated to 10 cc. Picric acid in anhydrous ether was added until there was no further yellow precipitation. The solid picrate was collected on a filter and recrystallized from ethanol, from which it separated as fine elongated prisms, m. p. 195° (cor.), with decomposition. There was no depression of melting point when the sample was mixed with retronecanone picrate.

Picrate of Retronecanone Oxime.—Formed in anhydrous ether from picric acid and retronecanone oxime[3] and recrystallized from absolute ethanol, the picrate formed yellow elongated prisms which melted, with decomposition, at 188–190° (cor.).

Picrolonate of Retronecanone Oxime.—Prepared in absolute ethanol and recrystallized from ethanol–benzene, the picrolonate formed clusters of yellow elongated prisms which melted, with decomposition, at 209–211° (cor.).

Acetylretronecanol Methiodide.—This derivative of retronecanol was prepared according to the method of Barger, Seshadri, Watt and Yabuta,[12] but the stout colorless prisms from acetone were found to melt at 215–216° (cor.) instead of 207–208° as reported.

Rotation. 0.0709 g. made up to 5 cc. with absolute methanol at 28° gave α_D −1.24°; *l*, 1; $[\alpha]^{28}D$ −87.4° (±1.0°).

Reduction of Retronecanone

(a) Neutral Solution.—A solution of 366 mg. of retronecanone in 20 cc. of absolute ethanol was hydrogenated at normal pressure over 50 mg. of platinum oxide catalyst. The theoretical volume of hydrogen was absorbed in one hour. The reduction product was not obtained crystalline but the impure oil obtained exhibited a specific rotation in absolute ethanol of $[\alpha]^{33}D$ −9.5° (c = 1.266). This differs widely from that reported for retronecanol (−91.1°).[13]

The methiodide, obtained crystalline at first from acetone solution, was extremely hygroscopic (unlike retronecanol methiodide) and could not be recrystallized.

The picrate, formed in ether solution and recrystallized from absolute ethanol, separated as yellow elongated prisms which melted, with decomposition, at 218–219° (cor.). Retronecanol picrate melts, with decomposition, at 210° (cor.).[13]

Anal. Calcd. for $C_{14}H_{18}N_4O_8$: C, 45.41; H, 4.89. Found: C, 45.51; H, 4.96.

The reduction product of retronecanone was acetylated by heating under reflux on the steam-bath for four hours with excess acetyl chloride. The acetyl chloride was removed *in vacuo*, leaving a brown semicrystalline residue which was dissolved in 5 cc. of water. The aqueous solution was made alkaline with potassium carbonate and the acetylated base was extracted with ether. The ethereal solution was dried, decolorized and the ether removed. The residue did not crystallize, but the **methiodide** was obtained crystalline from benzene. After repeated fractional crystallization from acetone, the least-soluble fraction, obtained as colorless elongated prisms, possessed a maximum constant melting point of 210–212° (cor.). No other methiodide was obtained pure in the fractional crystallization process.

Anal. Calcd. for $C_{11}H_{20}INO_2$: C, 40.62; H, 6.20. Found: C, 40.79; H, 6.37.

Rotation. 0.0234 g. made up to 2.5 cc. with absolute methanol at 28° gave α_D +0.07°; *l*, 1; $[\alpha]^{28}D$ +7.5° (±1.5°).

The rotation differs widely from that of acetylretronecanol methiodide (−87.4°), and a melting point of a mixture of the two methiodides is depressed to 135–190°.

(b) Acid Solution.—Reduction of retronecanone over platinum oxide catalyst was carried out in 20 cc. of absolute ethanol containing 1 cc. of concentrated hydrochloric acid. The reduction was complete after nine hours. The reduced free base was liberated but was not obtained crystalline.

The methiodide, obtained crystalline at first from acetone solution, was hygroscopic and could not be recrystallized.

The picrate, formed in and recrystallized from absolute ethanol, separated as yellow platelets which melted, with decomposition, at 230–232° (cor.). The picrate differed from the picrate of the reduction product of retronecanone in neutral solution, and also from retronecanol picrate and oxyheliotridane picrate.[11]

Anal. Calcd. for $C_{14}H_{18}N_4O_8$: N, 15.13. Found: N, 15.23. Carbon and hydrogen values are not reported since the analytical sample exploded.

Acetylation of the reduced product was carried out as before and **the picrate** of the acetylated reduction product was formed in anhydrous ether and recrystallized from absolute ethanol: yellow elongated prisms, m. p. 178.5–179.5° (cor.).

Anal. Calcd. for $C_{16}H_{20}N_4O_9$: C, 46.60; H, 4.89. Found: C, 46.64; H, 4.91.

The methiodide of the acetylated reduction product was formed in benzene and subjected to repeated fractional crystallization from acetone. The least-soluble methiodide fraction was finally obtained as colorless elongated prisms, m. p. 210.5–211.5° (cor.). This was identical with the methiodide of the acetylated reduction product of retronecanone in neutral solution and gave no melting point depression when mixed with it. Mixing with acetylretronecanol methiodide again produced a sharp depression of melting point. No other methiodide could be obtained pure in the fractional crystallization process.

Reduction of 1-Methyl-7-ketopyrrolizidine: 1-Methyl-7-hydroxypyrrolizidine.—Hydrogenation of 520 mg. of optically inactive 1-methyl-7-ketopyrrolizidine in 20 cc. of absolute ethanol was carried out at atmospheric pressure in the presence of 50 mg. of platinum oxide catalyst. The theoretical volume of hydrogen was taken up in one-half hour, after which the ethanol solution was filtered free of catalyst and used directly for the formation of derivatives.

Neither the picrate nor the methiodide was ob-

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

tained pure because both were very hygroscopic. The picrate and picrolonate were obtained as well-characterized crystalline salts.

Picrate.—Prepared in and recrystallized from absolute ethanol, the picrate formed yellow elongated prisms which softened at 210° and melted, with decomposition, at 218.5–219.5° (cor.).

Anal. Calcd. for $C_{14}H_{18}N_4O_8$: C, 45.41; H, 4.89. Found: C, 45.57; H, 5.06.

Picrolonate.—Prepared in and recrystallized from absolute ethanol, the picrolonate formed yellow elongated prisms, m. p. 182.5–183.5° (cor.). It is interesting that the melting point of the racemic 1-methyl-7-hydroxypyrrolizidine picrolonate is almost the same as that of retronecanol picrolonate, m. p. 184–185°.[19] These picrolonates, of course, are not identical.

Anal. Calcd. for $C_{18}H_{23}N_5O_6$: C, 53.33; H, 5.72; N, 17.28. Found: C, 53.26; H, 5.71; N, 17.32.

Summary

1. 1-Methyl-7-ketopyrrolizidine has been synthesized through ethyl 3-methylpyrrolidine-2-carboxylate (obtained from γ-picoline) by addition to ethyl acrylate followed by a Dieckmann cyclization and hydrolysis. The final product probably was a mixture of two racemates. By condensation with *l*-menthydrazide a single pure 1 - methyl - 7 - ketopyrrolizidine - *l* - menthydrazone was isolated. This was different from the *l*-menthydrazone of retronecanone in melting point and rotation.

2. Optically active ethyl 3-methylpyrrolidine-2-carboxylate was converted to the corresponding optically active 1-methyl-7-ketopyrrolizidine by a similar series of reactions. By treatment of the reaction mixture with hydroxylamine, a pure optically-active 1 - methyl - 7 - ketopyrrolizidine oxime resulted, which was identical with retronecanone oxime in melting point and rotation. The identity was verified further by the preparation of identical picrates and picrolonates.

3. It has been proved that the keto group in retronecanone is in the 7-position. From this it may be deduced that the secondary hydroxyl group in retronecanol, retronecine, platynecine, desoxyretronecine, heliotridine, and oxyheliotridane is in the 7-position.

4. It has been shown that in the reduction of desoxyretronecine, retronecine, and esters of retronecine to give retronecanol, asymmetric reduction has taken plaec with the exclusive formation of one stereochemical configuration of the C_1-CH_3.

5. Reduction of retronecanone in neutral and acid solutions gave a mixture of corresponding hydroxy compounds, from which retronecanol could not be isolated.

The Preparation of N-Mono-substituted and Unsymmetrically Disubstituted Piperazines

BY RICHARD BALTZLY, JOHANNES S. BUCK, EMIL LORZ AND WILLIAM SCHÖN

The direct alkylation of piperazine produces a mixture of substitution products from which the isolation of mono-substituted compounds is difficult or impossible when the substituting group is relatively small. Because of this the belief has arisen that mono-substitution products are not formed, although examination of reported experiments shows only that they were not isolated. A similar situation has prevailed in regard to acylation, although even mono-acetylpiperazine can be obtained easily by logical manipulation.

In Table I are shown the yields of mono- and di-substituted piperazines from a number of reactions, together with the reaction conditions. It seems indicated that in the ideal case where the entire reaction takes place in one homogeneous phase, equimolecular proportions of reactants result in the 1:2:1 proportions of piperazine, mono-substituted piperazine and di-substitution product predicted on general considerations.

Major deviations from these proportions would be expected if a salt of piperazine itself (such as the dihydrochloride which is sparingly soluble in absolute ethanol) were to precipitate during the reaction, or if the acylating or alkylating agent were to form a second liquid phase, thus tending to extract preferentially mono-substituted piperazine already present.

The yields here recorded compare favorably with those claimed for more involved procedures.[1] The argument by which Moore[1a] was led to operate at low *p*H is probably valid. The second benzylation recorded in Table I, run at *p*H about 3.5 gave a proportion of mono-benzyl to dibenzyl piperazine of about 5–1. Similarly a proportion of 2.7–1 was observed in the carbethoxylation, where a low *p*H must have existed toward the end of the reaction. As a preparative method with moderately priced chemicals, however, the buffering procedures seem unprofitable.

From the mono-substituted piperazines that were thus rendered available a number of unsymmetrically disubstituted derivatives have been prepared. These are characterized in Table II.

(1) (a) Moore, Boyle and Thorn, *J. Chem. Soc.*, 39 (1929); (b) Jacobi, *Ber.*, **66**, 113 (1933). The methods described in these papers are two-phase acylations at low *p*H. The conditions are difficult to reproduce exactly and it is doubtful if yields significantly above 50% should be expected from them.

[a] Piperazine hexahydrate used. [b] Anhydrous piperazine used. [c] This run was made at about the *p*H specified by Moore.[1a] [d] 0.5 mole of anisyl alcohol was treated with gaseous HCl and the crude but dry and neutral product used directly. [e] Disubstituted product not isolated. [f] At end of hour soln. was allowed to cool and stand overnight. [g] 15% of original piperazine recovered.

Since, further, the benzyl group can be removed by catalytic hydrogenation,[2] preferably with palladium, a variety of mono-substituted piperazines that would be difficult to separate from a reaction mixture can be obtained pure. The lower alkyl piperazines can also be prepared by alkylating N-piperazine ethyl carboxylate, but this intermediate is unsuitable with more labile systems for which the debenzylation procedure appears preferable.

Experimental

Benzylations.—Data on the preparations are given in Table I. On completion of the reaction, the solution was evaporated *in vacuo*, and the residue partitioned between ether and sodium hydroxide solution. After drying over potassium hydroxide or potassium carbonate the ethereal extract was evaporated and the residual oil distilled *in vacuo*.

In the preparations with *p*-chlorobenzyl and anisyl chlorides and in one run with benzyl chloride considerable solid separated toward the end of the reaction. These solids were filtered off and recrystallized from alcohol; the mother liquors added to the filtrate, and the whole worked up as indicated above. The recrystallized solids were the fairly pure dihydrochlorides of the respective disubstituted piperazines. In these cases very little disubstituted compound was found in the distillation.

In some cases a small amount of piperazine was present in the first fraction of the mono-benzyl derivative. This could be removed by washing in ether solution with water or dilute alkali.

In view of the considerable reaction of benzyl chlorides with water and alcohols, it is likely that the yields could be improved by additon of excess benzyl chloride, possibly with sodium acetate for buffering.

In the reactions of piperazine with lauryl and phenethyl bromides heating was required. The poor yield of phenethylpiperazine was presumably due to loss of hydrogen bromide. The corresponding di-substituted piperazines were very high-boiling and the *bis*-phenethylpiperazine decomposed at the pressure used instead of distilling.

Reaction with Ethylene Oxide.—The only significant differences from the procedure of Kitchen and Pollard[3] were in the proportions of reactants (see Table I) and the reaction temperature.

Carbethoxylation.—One-half mole (43 g.) of anhydrous piperazine was dissolved in 300 cc. of 95% ethanol. To this was added, with mechanical stirring, 54 g. (0.5 mole) of ethyl chlorocarbonate. The solution warmed itself fairly rapidly (thirteen minutes) to 50° whereupon water cooling was used to keep the temperature below 50°. At this point solid began to separate and 50 cc. of water was added to restore it to solution. The addition of the ethyl chlorocarbonate required about thirty minutes. Shortly thereafter solid was again observed and two types of crystal were apparent. The solution was allowed to stand overnight. The solid was filtered off and washed with 10 cc. of absolute ethanol. The undissolved crystals were piperazine dihydrochloride.

The filtrate, which was acid to congo red, was evaporated *in vacuo*. The residue was dissolved in water and extracted twice with ether. The ethereal extract, on evaporation, yielded 24 g. of N,N'-piperazine *bis*-ethylcarboxylate, a gum that crystallized from hexane and then melted at 49°. The aqueous layer was again taken down *in vacuo* and extracted with a minimum of absolute alcohol, a small residue of piperazine dihydrochloride being again separated. The yellow solution on addition of ethyl acetate and ether, and cooling deposited flesh-colored crystals of piperazine N-ethylcarboxylate hydrochloride. Recrystallization from absolute alcohol with charcoaling gave a colorless product melting at 145°.

Acetylation.—One-half mole (43 g.) of anhydrous piperazine was dissolved in 300 cc. of glacial acetic acid. To this was added with stirring 51 g. (0.5 mole) of acetic anhydride. The addition took fifteen minutes during which the temperature rose from 48 to 54°. Stirring was continued for one-half hour and the solution was allowed to stand overnight. Fifty cc. of concentrated hydrochloric acid was then added and the solution was evaporated *in vacuo*. The residue, a thick, red-brown sirup was extracted with 300 cc. of hot benzene to remove the diacetylpiperazine. The benzene-insoluble material was treated with absolute ethanol and the resulting solution filtered off from piperazine dihydrochloride. On addition of ether and standing in the refrigerator the acetylpiperazine hydrochloride crystallized. The crude product weighed 33 g. and melted at 150°. After three recrystallizations from alcohol–ether mixture the melting point was 183°.[1b]

From the intermediates whose preparation is described above a variety of unsymmetrical piperazines has been

prepared. Pertinent data on these substances are given in Table II. Most are characterized as hydrochlorides.

Aralkylpiperazine Amides.—The benzoates of benzyl, *p*-chlorobenzyl, anisyl and phenethyl piperazines (IX–XII) were prepared by the Schotten–Baumann method. The phenylacetyl derivatives (XIII, XIV) of anisyl and *p*-chlorobenzyl piperazines were obtained by the action of phenylacetyl chloride in boiling benzene on the appropriate bases.

Di-alkylpiperazines.—Benzylpiperazine was reacted in alcoholic solution with methyl and ethyl iodides and with lauryl bromide. The latter required heating to complete the reaction. The methylated and ethylated bases (XV and XVI) were obtained by distillation of the liberated and benzoylated bases from the reaction. Benzyl laurylpiperazine was crystallized as the hydrochloride (XVII). Methylbenzylpiperazine is better prepared from benzylpiperazine by the Clarke–Eschweiler method.[4] Unlike dibenzylpiperazine, benzyl laurylpiperazine forms a dimethiodide (XVIII) without much difficulty. Presumably this is because the monomethiodide (on the lauryl end?) is relatively soluble and is not withdrawn from reaction whereas dibenzylpiperazine forms a rather insoluble monomethiodide that precipitates from solution and reacts further only on prolonged treatment.

Benzyl β-hydroxyethylpiperazine (XIX) resulted from the action of ethylene oxide on benzylpiperazine.

The substituted benzylphenacylpiperazines (XXI–XXIV) were produced by the reaction of the appropriate monosubstituted piperazines with chloroacetocatechol and bromo-acetoveratrone in ethyl acetate solution. Reduction of XXII and XXIV with platinum oxide platinum black at room temperature gave the amino-alcohols, XXV and XXVI.

Catalytic reduction of methylbenzylpiperazine and ethylbenzylpiperazine hydrochlorides with palladized charcoal removed the benzyl group forming methyl and ethyl piperazine dihydrochlorides (VII and VIII).

Similarly, hydrogenation of N-benzyl-N′-benzoyloxyethylpiperazine dihydrochloride (XXIX) (made by benzoylation of XIX) gave benzoyloxyethylpiperazine, XXVII.

Ethylation of β-hydroxyethylpiperazine with ethyl iodide followed by benzoylation of the total bases by the Schotten–Baumann method yielded ethylbenzoyloxyethylpiperazine (XXVIII).

Benzylhydroxyethylpiperazine (XIX) reacted with *p*-chloro and *p*-nitrobenzoyl chlorides in ether or benzene solution to give XXX and XXXI. Reduction of the latter gave the corresponding *p*-amino compound, XXXII which was acetylated to form the acetamido derivative, XXXIII.

Urea Derivatives.—Phenyl isocyanate and *p*-chlorobenzylpiperazine formed the urea, XXXVI. The other ureas recorded in Table II were prepared by the reaction of nitrourea on the appropriate mono-substituted piperazines.

Guanidines and Quaternary Salts.—Benzylpiperazine and S-methylisothiourea sulfate in 65% alcohol yielded the guanidine sulfate, XXXIX. The corresponding hydroiodide, m. p. 155–155.5°, was formed from benzylpiperazine and S-methylisothiourea hydroiodide in absolute alcohol and reacted with methyl iodide in methanol to form the guanidine quaternary salt, XL.

The symmetrical guanidine, XLI, resulted when 2 mols of benzylpiperazine and 1 mol of cyanogen bromide were mixed cautiously in absolute ether solution, the ether blown off and the residual mixture heated at 150–160° (oil-bath) for two and one-half hours.

The spiro-quaternary salt, XLII, was prepared by heating benzyl piperazine with β,β′-dichloro-ethyl ether.

The melting points below 250° given in Table II are corrected.

The authors wish to express their gratitude to Mr. W. S. Ide for the many micro-analyses performed in this study.

Summary

1. When piperazine reacts with acylating and alkylating agents satisfactory yields of monosubstitution product can be isolated provided the substituting group is of moderate size.

2. By catalytic debenzylation of suitable derivatives of monobenzylpiperazine a further variety of mono-substituted piperazines can be prepared.

3. A number of mono-substituted and unsymmetrically disubstituted piperazines have been prepared and characterized.

Folic Acid. I. Concentration from Spinach[1a]

BY HERSCHEL K. MITCHELL, ESMOND E. SNELL AND ROGER J. WILLIAMS

In a preliminary note[1] it was announced that we had concentrated a nutrilite from spinach that had a high degree of activity in stimulating the growth of certain strains of bacteria. Because of its unusual abundance in numerous leaves, we suggested the name "folic acid" for the substance and defined it as the material responsible for growth stimulation of *Streptococcus lactis R* on a given medium.[2]

For purposes of convenience in concentration a sample of Wilson liver fraction "B" was established as a standard of "potency = 1." For comparison of folic acid assay values with those of other vitamins, results have been expressed in terms of micrograms of material of "potency 40,000" per gram of tissue.[3] Fraction "B" is required in concentrations 40,000 times as great as such material in order to produce the same amount of growth stimulation. One milligram of such a concentrate has been designated by Williams[4] to contain "one milligram unit," and this unit has been used throughout this paper.

Experimental

The following typical example best demonstrates the application of the concentration procedure.

Preparation of Extract.—One thousand pounds of raw spinach was ground in a hammer mill and transferred to a jacketed pot with sufficient water to bring the volume to about 350 gallons. The suspension was stirred vigorously and the temperature raised to 30–35°. After thirty-six hours standing the mixture was heated at the boiling temperature for fifteen minutes and the pulp strained out by allowing the solution to drain overnight through muslin bags. The resulting solution was adjusted to *p*H 3.0 to 3.2 with sulfuric acid, followed by addition of 4 gallons of super-cel filter aid. The solution was heated and held at the boiling temperature for about five minutes followed by rapid cooling with cold water in the jacket of the pot. The suspension was filtered in a plate and frame press coated with filter aid to obtain a brilliantly clear filtrate. This material contained 2,700 mg. units; potency of solids = 2.5.

Adsorption on Charcoal 1.—Twelve pounds of charcoal (Darco S-51) was added and the suspension stirred for thirty minutes. Following the addition of 2 gallons of super-cel the suspension was filtered and washed and the filtrate discarded.

Elution from Charcoal 1.—The charcoal containing the adsorbed activity was added to a boiling solution of one gallon of 28% ammonia in 10 gallons of distilled water. The suspension was maintained at boiling temperature for fifteen minutes and filtered while hot. The elution was repeated and the combined filtrates cooled rapidly to 25°. The charcoal was discarded; yield, 1,700 mg. units; potency of solids = 60.

Adsorption on Charcoal 2.—Three pounds of pretreated charcoal[4a] was added to the cooled ammonia solution and the suspension stirred twenty minutes. After addition of 1 gallon of super-cel the suspension was filtered and washed, discarding the filtrate.

Elution from Charcoal 2.—The charcoal with the adsorbed activity was added to a boiling mixture of 500 g. of aniline in 6 liters of water and the boiling continued for fifteen minutes. The suspension was filtered hot and the elution repeated. The charcoal was discarded. After cooling the solution was extracted twice with 20% of its volume of ether and then adjusted to *p*H 3.0 to 3.2 with sulfuric acid. A slight precipitate was removed by filtration with filter aid; yield, 1,400 mg. units; potency = 200.

Adsorption of Charcoal 3.—The solution was stirred twenty minutes with 180 g. of pretreated charcoal which was then filtered off and washed.

Elution from Charcoal 3.—The charcoal containing the activity was added to a boiling solution of 75 g. of aniline in 1 liter of water and the boiling continued for fifteen minutes. The elution was repeated and the combined eluates cooled and extracted twice with ether to remove the aniline; yield, 1,270 mg. units; potency = 800.

Lead Precipitation.—A solution of 37 g. of lead acetate trihydrate in 100 ml. of water was added to the aqueous solution from eluate 3 with vigorous stirring. The resulting precipitate was collected and washed by centrifugation. The activity was regenerated by suspension of the precipitate in 3 liters of water containing 150 g. of ammonium sulfate. The solution was boiled twenty minutes, cooled and filtered, and the filtrate retained; yield, 850 mg. units.

Silver Precipitation.—The filtrate from the lead regeneration step was diluted to 6 liters and a solution of 35 g. of silver nitrate in 100 ml. of water was added. The *p*H was adjusted to 6.5 with ammonium hydroxide with vigorous stirring of the suspension. The precipitate was collected and washed by centrifugation. The folic acid was regenerated from the silver precipitate by five minutes boiling with a solution of 25 g. of ammonium chloride in 150 ml. of water. After cooling the suspension was acidified to *p*H 6 with hydrochloric acid followed by filtration and washing. The precipitate was discarded; yield, 600 mg. units.

Adsorption on Lloyd Reagent.—The solution from the silver regeneration which contained a high concentration of salts was cooled below 10° and acidified to *p*H 1.0 with hydrochloric acid. The cold solution was shaken a few minutes with 15 g. of Lloyd reagent. The suspension was filtered and washed and the filtrate discarded.

Elution from Lloyd Reagent.—The Lloyd reagent was shaken with 50-ml. portions of 5% ammonium hydroxide three times. The volume of this combined eluate (150 ml.) was conveniently reduced to a few ml. by addition of 5 volumes of ether and sufficient ethanol to cause the separation of an aqueous layer of 5 to 10 ml. This product was then evaporated rapidly in a vacuum desiccator over sulfuric acid. The dry ammonium salt obtained in this fashion is stable and was stored as such; yield, 380 mg. units; potency = 5,200.

Products obtained from different batches treated as indicated varied in potency from 2,000 to 10,000 depending largely on the amount of activity in the original spinach.

Fractionation on Alumina.—Further purification was effected by fractional elution from alumina and by precipi-

tation of the acid from a concentrated solution of the ammonium salt. This is best illustrated by the following examples.

A sample (1.86 g.) of potency 3,500 (162 mg. units) was dissolved in 8 ml. of water and 6 ml. of methanol and adsorbed on a column of alumina (Merck according to Brockman) which had been washed with 40% methanol in water. The column was 2 cm. in diameter and 15 cm. long, packed dry. Following adsorption of the sample, the column was washed with 40% methanol. Fourteen 10-ml. fractions were collected followed by a fraction obtained by washing with 50 ml. of 2% ammonia in 40% methanol. Fractions 4–12 were combined giving 330 mg. of potency = 13,000 (143 mg. units). Fractions 1–4 and 13–15 were combined, evaporated and fractionated in an alumina column as before, giving 64.5 mg. of potency 11,000 (17.7 mg. units) and a considerable quantity of low potency material.

The two products, potency 13,000 and potency 11,000, were combined and again subjected to a fractionation on alumina. The sample was dissolved in 40% methanol (5 ml.) and adsorbed on an alumina column 1.5 cm. in diameter by 10 cm. long. Nine fractions of 5 to 10 ml. each were collected followed by one of 30 ml. containing 2% ammonia. Fractions 3–6 were combined giving 148 mg. of potency 25,000. The fractions 1–2 and 7–10 were combined and refractionated giving 36 mg. of potency 25,000 (total activity: 115 mg. units).

Acid Precipitation.—The combined sample of 184 mg. (potency = 25,000) of ammonium folate was triturated with 0.6 ml. of water, centrifuged and the precipitate washed 4 times with 0.1 ml. of water each time. The solution was acidified with 0.06 ml. of concentrated hydrochloric acid and mixed thoroughly. The solution was cooled to 0°, centrifuged and the precipitate washed 3 times with 0.1-ml. portions of ice water. The precipitate was dissolved in dilute ammonia and the solution evaporated in vacuum. The product weighed 88.3 mg., contained 110 mg. units, and had a potency of 46,000.

Fractionation on Alumina.—The sample with potency 46,000 was dissolved in 1 ml. of 40% methanol and adsorbed on a 1.5 × 10 cm. column of alumina as before. The column was washed with 40% methanol containing 1 drop of concentrated ammonium hydroxide per 100 ml. Nine fractions of from 4 to 6 ml. were collected followed by one obtained by using 40 ml. of 2% ammonia in 40% methanol. Fraction number 6 contained 5.8 mg. of solids and had a potency of 105,000. The remaining fractions were recombined and fractionated again under the same conditions. One fraction of 10.9 mg. had a potency of 75,000 (20.5 mg. units) and the remaining high potency fractions contained 28 mg. of potency 48,000 (33.5 mg. units). The total product at this point represented a 42.5% yield of the activity contained in the starting material of 3,500 potency.

Acid Precipitation from Cold Water.—A sample of 9.1 mg. of potency 71,000 (16.1 mg. units) prepared in the same fashion as that described, was dissolved in 0.2 ml. of ice water and 0.1 ml. of concentrated hydrochloric acid added. After a thorough mixing the precipitate was centrifuged and washed twice with 0.05 ml. of ice water. The supernatant liquid and washings contained 6.25 mg. units. The precipitate was triturated with 1 ml. of water at 50°, centrifuged and decanted. The precipitate weighed 1.4 mg. and had a potency of 85,000 (3.0 mg. units). The decanted solution was allowed to cool slowly in the dark to 25° and the resulting amorphous precipitate centrifuged off. It weighed 1.2 mg. and had a potency of 137,000 (4.1 mg. units). The supernatant liquid was cooled to 0° and centrifuged at that temperature. The product contained 0.6 mg. of potency 100,000 (1.5 mg. units). The remaining solution contained 1.5 mg. of material with 45,000 potency (1.67 mg. units).

Discussion

The illustrations cited represent the best single method of concentration that we have developed in this Laboratory though a great many variations have been tried. The problem was complicated by instability of the active principle to oxidation, reduction, acid, alkali, light and heat, as well as a high degree of reactivity with many organic reagents. One of the most complex processes, that of adsorption and elution from charcoal, involved extended study, and this phase of the work will be reported in a separate paper.

In addition to charcoal, alumina and Lloyd reagent we have utilized many kinds of fuller's earths, amberlites, barium carbonate, bentonites, florisil, floridin and permutite with successful adsorptions and elutions. We have also successfully utilized many precipitants other than lead and silver. Among these were salts of copper, mercury, iron, uranium oxide, phosphotungstic acid, alum, zinc, rhodanilic acid and barium. Recoveries of activity from the precipitates were poor in most cases.

A number of attempts to obtain crystalline products resulted unsatisfactorily. All samples prepared having a potency of 110,000 or greater precipitated in an amorphous state from acid solution and recrystallization attempts from warm water also gave amorphous products. Quinine, brucine, or even ammonium salts gave semicrystalline material on evaporation of the solvent on samples of potency 20,000 and up, but satisfactory recrystallization was not accomplished. Adsorption and fractionation from alumina has been a highly effective means of concentration only after the preliminary steps. This method has been most useful in the potency range of 2,000 to 80,000. Higher potency samples are readily adsorbed by the alumina but are not easily eluted. A preliminary treatment of the alumina with aniline allowed easy elution but no concentration was effected. Other eluants than ammonia such as triethanolamine, triisopropylamine, brucine, aniline, pyridine and quinine were tried with mediocre success.

Summary

A concentration procedure is described whereby folic acid has been concentrated from spinach to such an extent that the product is about 137,000 times as active as a standard material (liver extract).

Folic Acid. II. Studies on Adsorption

BY EDWARD H. FRIEDEN,[1a] HERSCHEL K. MITCHELL AND ROGER J. WILLIAMS

The procedure for the concentration of folic acid described in a previous paper[1] is based to a considerable extent upon successive adsorptions upon and elutions from activated charcoal. During the early stages of the work on this problem it was observed that while the active principle from crude extracts adsorbed upon either norite or Darco could readily be eluted by treatment with hot ammonia, the principle from purified preparations, similarly adsorbed, was eluted to a negligible extent with this reagent. This rather peculiar behavior has been subjected to a more extended investigation in order to understand better the phenomenon and make use of it in concentration processes.

Experimental

Elution Experiments.—For preliminary quantitative experiments two extracts of spinach were prepared, one by hot water (110°) extraction of fresh spinach macerate for one-half hour and one by autolysis under toluene at 37° for two days. After the preliminary treatment, the samples were autoclaved for fifteen minutes at 15 lb. pressure. Both samples were then adjusted to *p*H 3.0 and filtered to remove precipitated protein material. Finally, each sample was adjusted to *p*H 6.5–7.0, sterilized, and stored. A concentrate of potency 280 was used as indicated.

The following experimental procedure was used. Aliquots of solution containing known amounts of folic acid were adjusted to *p*H 3.0 and shaken with weighed amounts of Darco S-51 (1 mg. Darco per mg. unit). The shaking was repeated several times during the course of one hour. The suspensions were then centrifuged, and the supernatant liquid removed. The residue was eluted with 5% ammonia (equal in volume to the supernatant liquid) at 90° for ten minutes, filtered while hot, and both filtrate and the supernatant solution assayed for folic acid. Folic acid assays were performed essentially according to the method of Mitchell and Snell,[2] and in all cases adsorption, as measured by the folic acid content of the supernatant solution, was found to be nearly complete (92–100%).

The results of the elution experiments are indicated in Table I.

TABLE I

ELUTION OF FOLIC ACID FROM DARCO S-51 BY 5% AMMONIA

Source of sample	Folic acid concentration, mg. units/ml. ($\times 10^{-4}$)	Eluted, %
Spinach autolysate	8.7	54
Spinach autolysate	3.35	69
Spinach autolysate	0.87	92
Spinach autolysate	.32	91
Spinach water extract	6.7	74
Spinach water extract	3.35	70
Spinach water extract	0.67	89
Spinach water extract	.67	92
Concentrate potency = 280	6.9	4.0
Concentrate potency = 280	3.4	5.4
Concentrate potency = 280	1.7	6.8
Concentrate potency = 280	0.69	25.6

Table I shows that at comparable concentrations the elution of folic acid from crude preparations is considerably more complete than when purified samples are used. It appeared, therefore, that the extent of elution with ammonia was dependent upon the concentration of substances present that interfered in the adsorption. This conclusion was verified by an experiment. A sample of the water extract referred to in Table I was exposed to ultraviolet light at *p*H 1 in order to destroy the folic acid present. This folic acid-free solution was then used as the solvent in the preparation of a solution of concentrate, and the adsorption-elution procedure repeated as described. The results are indicated in Table II.

TABLE II

EFFECT OF THE ADDITION OF FOLIC ACID FREE EXTRACT UPON THE EXTENT OF ELUTION BY AMMONIA

Source of sample	Folic acid concentration, mgu./ml. ($\times 10^{-4}$)	Eluted, %
Concentrate potency = 280	9.6	41
Concentrate potency = 280	4.4	65
Concentrate potency = 280	2.4	100
Concentrate potency = 280	0.96	100

Comparison of the data of Table II with those of Table I indicates the considerably increased elution yields due to the presence of added material. Results like those of Table II were also obtained when the irradiated material, instead of being added to folic acid solutions, was used to pretreat samples of charcoal. When this charcoal was used for adsorption and subsequent elution of purified folic acid, increased yields again resulted. A ten-fold dilution of irradiated extract was as effective in facilitating elution as was the undiluted material.

It seemed reasonable to suppose that the action of irradiated extract in facilitating elution of folic acid could be duplicated by known compounds. This hypothesis was tested by experiment. Samples of norite were shaken with 10 parts of 10% solutions of aniline, hippuric acid, allantoin, and triethanolamine at boiling temperature. The suspensions were filtered, washed with a small volume of water, and air dried overnight. The treated charcoals so

TABLE III

EFFECT OF PRETREATMENT OF NORITE UPON THE ELUTION OF FOLIC ACID

Description	Folic acid concentration, mgu./ml. ($\times 10^{-4}$)	Eluted, %
Norite, untreated	1.15	13
Norite, untreated (added irradiated extract)	1.15	88
Aniline-treated norite	1.15	100
Hippuric acid-treated norite	1.15	71
Allantoin-treated norite	1.15	55
Triethanolamine-treated norite	1.15	44

obtained were tested for adsorption and subsequent elution of concentrate as before. The results are indicated in Table III.

This increase in elution yields by pretreatment of adsorbent with aniline has been found useful in large-scale concentration processes.

Adsorption Isotherms.—From the quantitative adsorption and elution experiments it appeared probable that two different mechanisms of adsorption of folic acid were involved. Since this difference should be evident from adsorption isotherms, the problem was considered from that standpoint. Only two studies of adsorption isotherms at extremely low concentrations were found in the literature. In 1914, Trumpler[3] studied the adsorption of fluorescein upon activated charcoal at equilibrium concentrations ranging upward from 10^{-7} g. per liter. He found that adsorption was essentially complete in one and a half hours, but that slow adsorption continued over a period of thirty hours. For a "reaction time" of one and a half hours, the isotherm was found to be linear from log x/m = -1.6 to log x/m = 0.5, where the symbols have their usual significance.[4] More recently, Cheldelin and Williams[4] reported adsorption studies for a large number of ampholytes upon Darco G-60. Of the substances studied only calcium pantothenate, biotin, pyridoxin hydrochloride and thiamin hydrochloride were investigated at very low concentrations. In all cases, linear log x/m − log C relations were found. No dependence of adsorption on time was noted.

Experiments were carried out on a folic acid concentrate of potency 10,000 using norite charcoal as the adsorbent. The concentration of folic acid was varied from 0 to 0.05 mgu. per ml. and the charcoal concentration was 0.2 mg. per ml. The adsorptions were carried out at *p*H 3. The suspensions were centrifuged, and the supernatant solution assayed for folic acid. The data are given in Fig. 1, plotted according to the Freundlich equation. Quantities of folic acid are expressed in milligram units.

Despite the scattering noted, the curve obtained does appear to exhibit the dual character predicted.

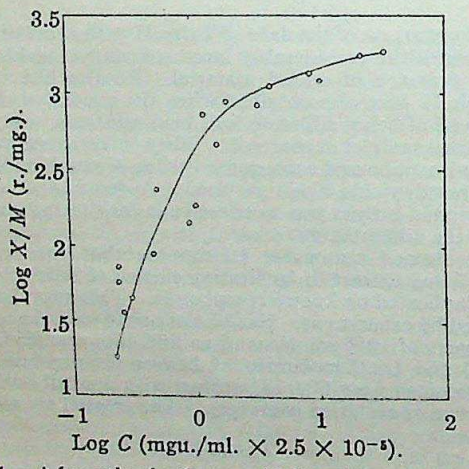

Fig. 1.—Adsorption isotherms of folic acid on norite at 25°.

Since a considerable part of the uncertainty probably lies in the use of a partially purified substance as well as the inherent limitations of microbiological assay methods, the studies were continued using riboflavin and thiochrome, analyses being made fluorometrically. Merck riboflavin was used, and the same Company very generously supplied sufficient pure thiochrome. Fluorescence was determined with a Pfaltz and Bauer fluorophotometer, equipped with a very sensitive triple mirror galvanometer. Equipped with suitable filters, the instrument is sensitive to 3×10^{-4} γ/ml. of riboflavin, and to 2×10^{-4} γ/ml. of thiochrome per galvanometer division.

(3) Trumpler, *Kolloid-Z.*, **15**, 10 (1914).

(4) Cheldelin and Williams, THIS JOURNAL, **64**, 1513 (1942).

Preliminary experiments followed the procedure used for folic acid. Erratic results were obtained, and were traced to a definite dependence of adsorption on time. Accordingly, the following procedure was adopted. Mixtures of norite and the compound being studied were prepared, and placed in an automatic shaking machine. At stated intervals, aliquots were withdrawn, centrifuged, and the supernatant fluid analyzed. The data obtained are shown in graphical form in Figs. 2 and 3.

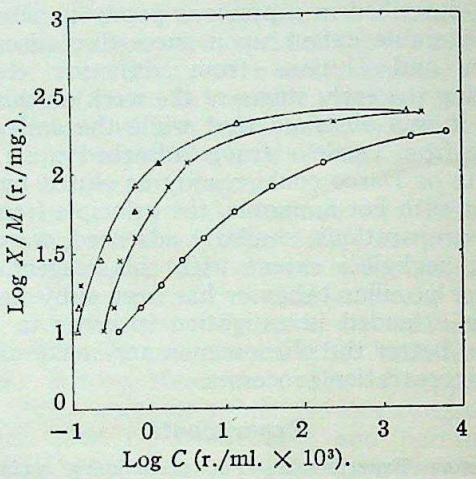

Fig. 2.—Adsorption isotherms for riboflavin at 25°: ⊙—⊙—⊙, after 1.1 hours; ×—×—×, after 17 hours; Δ—Δ—Δ, after 42 hours.

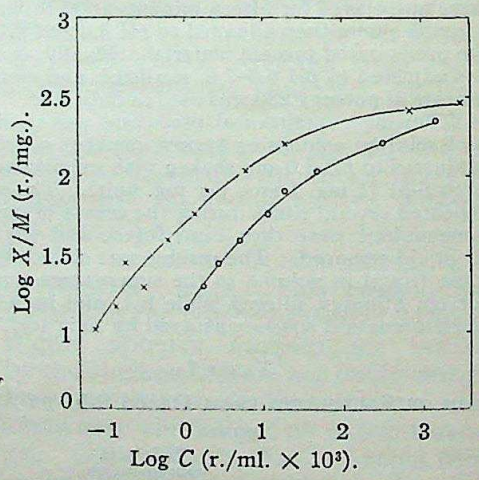

Fig. 3.—Adsorption isotherms for thiochrome on norite at 25°: O—O—O, after 1.5 hours; ×—×—×, after 22 hours.

Discussion

Quantitative elution and adsorption experiments suggest that adsorption of folic acid and presumably some other ampholytes occurs in two steps. From relatively pure solutions of folic acid the active principle is adsorbed in such a way that the resulting union is a very firm one and not readily reversible. If part or all of the charcoal surface is blocked by pretreatment, or by preferential adsorption of another compound, another type of binding manifests itself. In contrast to the initial "primary" adsorption, this "secondary" adsorption appears less tenacious, and its reversibility is more readily effected.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Further evidence of the dual nature of the adsorption was obtained from adsorption isotherms (Figs. 1, 2 and 3). The fact that the change in slope of these curves occurs at very low concentrations may indicate that this behavior is related to the change in energy of adsorption which occurs when the adsorbing surface is covered with a single layer of molecules, and further adsorption involves the formation of secondary layers. Further studies relating the amount of material adsorbed to the surface area of adsorbent exposed might shed light upon the exact mechanism involved.

The slow rate of equilibrium of adsorption is rather surprising, requiring at least forty-two hours in the case of riboflavin. From the shapes of the adsorption curves after different lengths of time (Figs. 2 and 3) it appears that the primary irreversible adsorption is the slow step since this step becomes more sharply defined with increasing time. Data not shown indicated that the equilibrium was nearly reached in forty-two hours with riboflavin and in twenty-two hours with thiochrome.

From a practical standpoint the value of these observations is evident. In dealing with concentration of substances which adsorb and do not readily elute from the adsorbent it appears highly advantageous to pretreat the adsorbent, for a considerable period of time, with a solution of one or more compounds that will block the irreversible adsorption. A dilute solution of a crude tissue extract often may be effective.

Summary

Quantitative studies of charcoal adsorption of folic acid from crude preparations and from concentrates with subsequent elutions have been described. Elution of folic acid after adsorption from crude preparations is much easier than from relatively pure solutions. It has been found that this behavior is apparently due to the presence of interfering substances which affect the manner of adsorption. A working hypothesis of the mechanism of adsorption is proposed.

A study of the adsorption isotherms of folic acid, riboflavin, and thiochrome upon charcoal at low concentrations is reported. There is evidence that the adsorption process is of a dual nature, since the slopes of the isotherms change markedly in the range covered.

The application of these observations to concentration procedures using charcoal is pointed out.

Folic Acid. III. Chemical and Physiological Properties

BY HERSCHEL K. MITCHELL AND ROGER J. WILLIAMS

In order to better evaluate methods of concentration, various studies on stability, reactions and physical properties of folic acid were carried out. For most of this work the alteration of physiological activity of concentrates by various treatments was used as a criterion of reaction. Obviously a lack of destruction of activity by a given reagent does not prove the absence of a reaction since the product might be physiologically active. However, the destruction of activity does indicate a reaction.

Experimental

Esterification.—Two 1-mg. samples of ammonium folate, potency = 11,000, were each suspended in 1 ml. of methanol containing 0.01 ml. of fuming sulfuric acid. After ten minutes at 30° one sample was diluted with ice water and neutralized. After thirty minutes the other sample was treated in a similar fashion and both assayed for folic acid content using *S. lactis R.* The destruction of activity was 90 and 96%. In spite of considerable experimentation on means of hydrolysis of the ester, no consistently satisfactory method has been devised. Treatment with 1 *N* alcoholic potassium hydroxide at 30° for ten minutes usually gave a 60 to 80% recovery of activity.

Fractional adsorption and solubility experiments indicated the properties of the compound were not changed to any great extent by formation of the methyl ester. That the methyl ester was still acidic in nature was demonstrated by the fact that it could be more readily extracted from acid solution with butanol than from neutral or basic solution.

Acylation.—Acetylations using acetic anhydride and sodium acetate or acetic anhydride and pyridine at 100° for twenty minutes resulted in complete destruction of activity. Acetyl chloride as well as ketene (thirty minutes treatment at room temperature) also caused complete destruction of physiological activity. No method was found for regeneration of activity from any of these reaction products. Benzoyl chloride and β-naphthyl-sulfonyl chloride caused similar irreversible destruction of activity.

Solubility characteristics of acylation products were not markedly different than those of the original starting material.

Methylation.—Attempts to esterify folic acid using methyl iodide plus silver folate resulted in a product with no physiological activity. No activity could be recovered by methods used for hydrolysis of esters produced by acid–alcohol esterification. Similar results were obtained using benzyl chloride instead of methyl iodide, but the products in both cases did not show any great difference in solubility as compared to the starting material.

Solubility.—The solubility of free folic acid is very limited. In water it was found to be in the order of 2 mg. per ml. at 30° and about 1 mg. per ml. at 0°. The acid is slightly soluble in glacial acetic acid and liquid ammonia but essentially insoluble in dry methanol, ethanol, butanol, acetone, ether, dioxane, benzene, petroleum ether and chloroform. The ammonium salt is quite soluble in aqueous alcohols and is very soluble in water.

Stability to Various Treatments.—Frequent losses of activity during concentration processes necessitated studies of the stability of the concentrates at various

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

stages of purification. It was observed repeatedly that the activity of higher potency fractions disappeared under milder conditions than that from crude extracts. Numerous tests for stability were performed. Treatments which involved about 50% destruction of activity included: material of potency 75,000, treated with 1 *N* sulfuric acid one-half hour at 100°, or with 1 *N* sodium hydroxide for one and one-half hours at 100°, or with 1 *N* sodium hydroxide for twenty-four hours at 28°. More or less vigorous treatment yielded results about as would be expected on the basis of the above results.

The material in the form of the ammonium salt (potency 17,000) was relatively stable in the neutral condition (even when exposed to ultraviolet light) but was destroyed slightly (17% in twenty minutes) at the boiling temperature in the presence of oxygen gas. Material of even higher potency (45,000) was stable at room temperature when kept at a *p*H of 3, but was destroyed to a considerable extent when exposed at this *p*H to ultraviolet light either in the presence of nitrogen or oxygen. At *p*H of 1, folic acid (potency 2,000–3,000) was readily destroyed by contact with an atmosphere containing ozone. By standing at room temperature for an hour in the presence of 1% hydrogen peroxide, it was about 90% destroyed.

Bubbling hydrogen sulfide through a solution either in 0.1 *N* ammonium hydroxide or at *p*H 4 resulted in 30–40% destruction in a half hour. Nitrous acid under Van Slyke conditions for thirty minutes caused about 90% destruction. Dry heat (98°) caused moderate destruction and heating in the neutral condition in the presence of zinc dust for fifteen minutes caused 50% destruction even in the case of low potency material. In 50% acetic acid at 100° for fifteen minutes, 100% destruction resulted from adding zinc dust, whereas in the presence of the acetic acid alone no destruction took place. Folic acid activity was completely destroyed by bromine, hypobromite and hydroxylamine in the presence of sodium acetate.

Analyses.—Qualitative elementary analyses were carried out at several stages of purification indicating the presence of C, H, O and N, and the absence of halogens, P and S. Following the work on absorption spectra of various fractions some C, H and N determinations were made on highly fractionated material having different physiological activities. It was considered probable that such fractions were made up principally of folic acid and inactivated folic acid and it was therefore expected that analyses of materials of different activities would give similar results.

Potency	C, %	H, %	N, %
80,000	45	3.6	19.2
28,000	46	5.0	..
3,000	45	5.1	..

Micro-Kjeldahl determinations on the potency 80,000 and 28,000 samples gave N values of 10 to 12%. It was found that micro-Kjeldahl determination on xanthopterin under the same digestion conditions accounted for only about three-fifths of the theoretical amount of nitrogen present.

Determination of Glycols.—The apparent high oxygen content of the folic acid concentrates analyzed suggested the possibility of a sugar group being present. Five-micromole samples of erythritol, mannitol, dextrose, riboflavin, xanthopterin, folic acid of potency 80,000 (assuming a molecular weight of 400) and folic acid of potency 28,000 were placed in small test-tubes with 0.5 ml. of solution containing 5 mg. of potassium periodate. One-half ml. of 0.4 *N* sulfuric acid was added and the mixture allowed to stand for twenty-four hours. The formaldehyde produced was distilled into 1 ml. of Schiff reagent. No formaldehyde was obtained from the xanthopterin and the folic acid samples, but strong positive tests were obtained with the rest of the compounds. The absence of a glycol was thus indicated.

Quantitative Acetylation.—As a check on the absence of polyhydroxy groups in folic acid, quantitative acetylations were carried out on 5-micromole samples of folic acid concentrate of potency 28,000 (assuming an average molecular weight of 400 for its ingredients), xanthopterin, mannitol, and riboflavin. The samples were weighed into 0.3 × 5 cm. Pyrex tubes followed by 0.039 ml. of 20% acetic anhydride in pyridine. The reagent was measured with a calibrated capillary pipet and the rinsings from each tube placed in a labeled erlenmeyer flask. The tubes were sealed, heated for one hour at 100°, placed in the proper flasks and the tubes crushed with the end of a glass rod. All samples except the xanthopterin had dissolved in the hot reaction mixture. Five ml. of water was added and the samples titrated with 0.01 *N* sodium hydroxide after standing thirty minutes. The number of moles of acetic acid used per mole of compound is given as follows: mannitol, 5.95; riboflavin, 4.05; folic acid, 1.15; xanthopterin, 0.5.

Since hydroxyl groups were found not to be abundant and since analysis indicated that a concentrate of this potency contained as high a percentage oxygen as a concentrate of potency 80,000, it appears probable that the high oxygen content of folic acid is due to structural features other than polyhydroxy groups.

Molecular Weight.—The determination of molecular weight by diffusion has been previously described and applied.[1,2] An application of this method to low potency fractions of folic acid gave the molecular weight as about 500. Results of more recent studies are described as follows: A sample of ammonium folate, potency = 65,000, was diluted to 20 micrograms per ml. with 0.1 *N* potassium chloride and the solution placed in one compartment of each of three calibrated diffusion cells. The other compartment of the cells contained 0.1 *N* potassium chloride. After twenty hours of diffusion time at 35°, samples were removed from both sides of the cells and the concentration of folic acid determined by biological test. Concentration of material in the solutions was also determined by fluorescence in a Pfaltz and Bauer fluorophotometer. The results are summarized below in terms of diffusion coefficients calculated in sq. cm. per day.

Cell	Physiological test *D* (sq. cm./day)	Fluorometric *D* (sq. cm./day)
E	0.453	0.495
F	.445	.449
J	.396	.462

The molecular weight was determined by comparison of these diffusion coefficients with those obtained from studies of a number of compounds of known molecular weight.[2a] The molecular weight appears to be 400 ± 50.

In order to test further the hypothesis that highly fractionated concentrates are made up of molecules of the same type as folic acid (folic acid plus products of its inactivation) a diffusion experiment was carried out on a sample of potency 10,000. This sample had been subjected to extensive chromatographic and solvent fractionation without appreciable increase in potency of products. Concentrations of the material in the solutions after diffusion were determined in

parallel by (1) physiological test, (2) fluorescence and (3) ultraviolet light absorption at various wave lengths. Results are given as follows

	D (sq. cm./day)
Physiological test	0.48
Fluorescence	.47
Light absorption	.49

It appears from these results that the concentrate either was composed of molecules of very nearly the same molecular weight (about 380) or else the impurities involved showed no fluorescence or light absorption. Since 9 micrograms of this sample (potency 10,000) was found to be equivalent to 7 micrograms of potency 63,000 in ultraviolet light absorption the second possibility is ruled out.

Physiological Properties.—Folic acid was originally defined[3] as the active principle required for the growth of *S. lactis R* under specified conditions.[4] A considerable number of known compounds have been tested for activity under these conditions. One compound, thymine, replaces folic acid if present in sufficient quantity (1 γ per ml. of culture medium). This activity is not sufficient to cause interference with the test for folic acid. A considerable number of other compounds show a slight activity at very high concentrations (10 γ per ml. of culture medium). Among these are hypoxanthine, alloxazine, alloxantine, guanidine, theobromine, xanthopterin, alloxan, allantoin and uric acid. Compounds tested that were completely inactive were: nicotinic acid, pyridoxin, pantothenic acid, ascorbic acid, taurine, asparagin, biotin, riboflavin, *p*-aminobenzoic acid, creatine, inositol, phytin, 4-carboxy - uracil, 4 - carboxy - thymine, 5 - carboxy-uracil, uracil, adenylic acid, indolbutyric acid, cozymase, cystine, theophylline and caffeine.

Until pure folic acid becomes available, specific physiological properties of the compound must necessarily remain uncertain. However, a number of indications as to these physiological activities have been obtained using highly purified concentrates.

In this Laboratory activity of concentrates (potency 400) on four strains of yeast was demonstrated. In the very early stages of concentration "Old Process" yeast was used as a test organism but it was discarded in favor of the more specific and otherwise superior test using *S. lactis R*. Concentrates were found essential for *L. casei*, *L. delbruckii*, and *Clostridiun tetanii*,[5] and stimulated the growth of *L. arabinosus*.[3] The "eluate factor" of Snell and Peterson[6] has been identified with folic acid on the basis of a test using *L. casei* but the exact relationship between the two factors is not yet clear. In view of the recent findings of Pfiffner, *et al.*,[7] and of Stokstad,[8] it appears certain that pure compounds promote the growth of both *S. lactis R* and *L. casei*, but the relative activity of preparations from different sources differs for the two organisms. Keresztesy, *et al.*,[9] have reported isolation of a material of extremely high activity for *S. lactis R* which is almost without activity for *L. casei*. We have found concentrates from spinach acting in a somewhat similar fashion to those from liver described by Keresztesy, *et al.*,[9] *e. g.*, a sample of concentrate of potency 30,000, by *S. lactis R* test had only a potency of 15,000 by *L. casei* test, both being referred to the same standard. These findings support the conclusion drawn here and in a subsequent paper[10] that very minor changes in structure may produce great changes in activity for various organisms.

Antianemia properties of liver concentrates for chicks were reported by Hogan,[11] and this active principle was recently identified with folic acid though some uncertainty still exists.[7]

Early experiments on rats in this Laboratory indicated a higher erythrocyte count with animals receiving a folic acid concentrate than with controls. The difference was about 10% but an insufficient number of animals was used. Consequently, through the very generous coöperation of Dr. Earl R. Norris of the University of Washington, a sample of potency 75,000 folic acid concentrate was tested for antianemia activity on trout. The material was found to be one-fifth as active as xanthopterin for this purpose, since 10 micrograms per g. of fish was required to produce a good response in erythrocyte regeneration.

Concentrates high in folic acid were demonstrated to stimulate growth of chicks[12] and indications were obtained of stimulation of the growth of rats.[3] In both cases the concentrates used were of too low a potency to be certain of the biological specificity of the preparations. That intestinal bacteria can serve as a source of folic acid for the rat was demonstrated in this Laboratory[13] while several investigators have been able to produce a deficiency[14,15,16] by impairment of intestinal production with succinylsulfathiazole. In one case[14] this deficiency was cured by administration of a highly purified concentrate of folic acid obtained from this Laboratory.

a marked instability of the active principle to oxidation, reduction, acid, alkali, light, dry heat, acylation, esterification, methylation, benzylation, nitrous acid, bromine, hypobromite and certain other specific reagents. There is considerable evidence that some of these reactions involve structural changes that are of a minor nature with respect to the whole complex molecule. For example, partial destruction of physiological activity with alkali takes place very rapidly and with dilute reagents but a long and vigorous treatment is necessary for complete destruction. A similar situation appears to exist in the case of light destruction. With acid destruction physiological activity is lost rapidly but absorption spectra data[10] indicate that only minor modifications of the folic acid molecule are involved. It therefore appears evident that folic acid may be converted by various treatments to other very closely related substances which may have quite different physiological properties than the original.

A summation of analyses of our concentrates combined with information on molecular weight indicated that the formula of folic acid may be approximated by $C_{15}H_{15}O_8N_5$. Absorption spectra data[17] indicate the presence of a structural unit similar to xanthopterin. Side chains or other rings of an unknown nature but lacking nitrogen or a sugar residue, are indicated according to our evidence. The explanation of the high oxygen content must await further investigation.

Summary

Reactions and stability of folic acid are considered with reference to concentration problems.

The probability is pointed out that a large proportion of the impurities in purified concentrates are of a very similar nature to folic acid. On the basis of analyses of some of these concentrates an approximate empirical formula of $C_{15}H_{15}O_8N_5$ is given.

The absence of a sugar or poly hydroxy group, and the probable presence of a xanthopterin-like structural unit are indicated.

Folic Acid. IV. Absorption Spectra

BY HERSCHEL K. MITCHELL

It became evident from precipitation reactions, in the early stages of concentration, that folic acid was probably related to the pyrimidines, which show a strong absorption of ultraviolet light. There appeared to be a good possibility that such absorption might serve as a basis for quick quantitative determinations of the substance as well as an aid to chemical identification by showing specific absorption bands. It was also hoped that modification of folic acid by various chemical reactions would alter its absorption spectrum in such fashions as to yield information on the structure of the substance.

For comparative purposes (Figs. 1–4) the absorption data for concentrates are given in terms of extinction for a 1-cm. layer of 1% solution. This is represented according to the notation of Morton[1] by $E^{1\%}_{1\,cm.}$. The data in Figs. 5–11 are plotted in terms of molecular extinction coefficients since most of the substances concerned are pure compounds. In Fig. 11 the molecular weight of the folic acid sample is assumed to be 400.[2]

All of the absorption work was carried out using a Beckman spectrophotometer and a 1-cm. cell.

Experimental

Absorption Curves of Different Concentrates.—The absorption curves for folic acid concentrates covering a wide range of physiological potency are given in Fig. 1. These are illustrative only and represent materials of widely diversified treatment. It is evident that there is little parallelism between absorption and physiological activity. In certain high potency preparations, however, such a parallelism was found. In many low potency preparations, especially among those whose lack of physiological activity was probably due to destruction during fractionation rather than a lack of sufficient fractionation, a high degree of absorption was shown. This is illustrated in Fig. 1 by the two samples of potency 2,400 and 12,000, both of which had undergone more fractionation than the potency 28,000 sample and weight for weight represented much more raw material than either of the high potency samples. It therefore appears probable that concentration processes cause partial inactivation of the folic acid without altering the complex molecule sufficiently to cause a great change in light absorption. This supposition was corroborated by purposely destroying the physiological activity and following the treatment by a determination of the absorption spectra of the products.

Absorption of Inactivated Folic Acid.—Samples of folic acid of potency 33,000 were treated with 1 *N*, 4 *N* and 16 *N* sulfuric acid for one hour at 100°. All of the treatments are sufficient to destroy the folic acid activity. The absorption spectra of these products are compared with the original untreated sample in Fig. 2. It is evident that the molecular structure responsible for the light absorption is not destroyed by these treatments though some changes are produced.

Light absorption curves for products of treatment of folic acid with ultraviolet light in the presence of oxygen

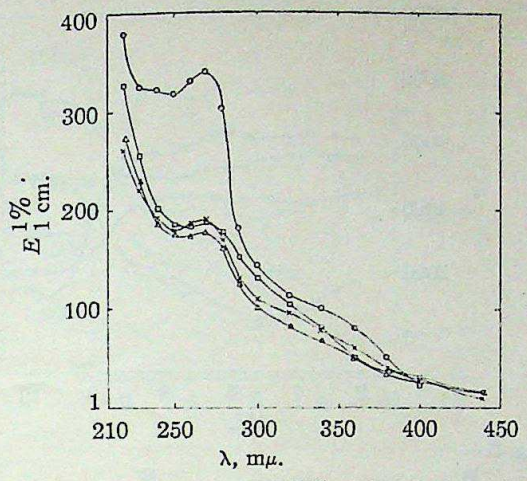

Fig. 1.— ⊙-⊙-⊙, potency 75,000; ×—×—×, potency 30,000; Δ—Δ—Δ, potency 12,000; □—□—□, potency 2,400.

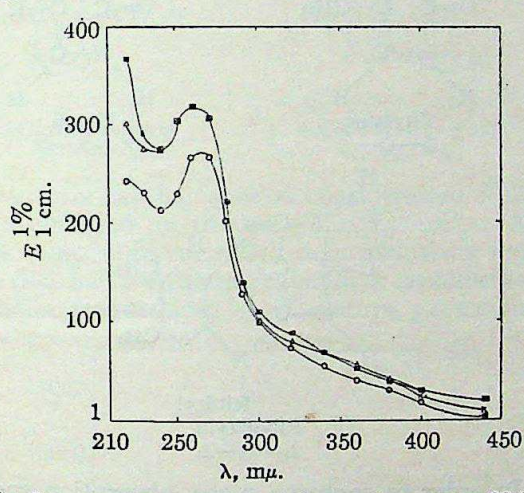

Fig. 2.— ⊙—⊙—⊙, untreated sample, potency 33,000; ×—×—×, 1 *N* H_2SO_4, potency 33,000; □—□—□, 4 *N* H_2SO_4, potency 33,000; Δ—Δ—Δ, 16 *N* H_2SO_4, potency 33,000.

and in the absence of oxygen are given in Fig. 3. The physiological activity was destroyed in both cases. A curve in Fig. 3 represents the absorption curve for a benzylated sample of folic acid. This was prepared by heating 10 mg. of silver folate (potency 12,000) for two hours at 100° with 1 ml. of benzyl chloride. The excess benzyl chloride was removed in vacuum. The product was physiologically inactive.

From these representative curves it appears probable that in spite of easy destruction of the physiological activity of folic acid the nucleus of the molecule is quite stable to varied treatments. The complete destruction by ultraviolet light in the presence of oxygen is attributed to the presence of ozone as well as to the light energy itself. Ozone in the dark produces the same effect though much more slowly. The supposition previously set forth that a large portion of the impurity in many folic acid concentrates consists of inactivated folic acid that still maintains its general structure, seems to be supported by these findings on absorption spectra of concentrates in which the folic acid has been purposely destroyed.

Absorption Spectra of Similar Compounds.—Only one compound has been found that has absorption characteristics with a marked similarity to these folic acid concentrates. A comparison of the absorption spectrum of this compound (xanthopterin) with that of a folic acid concentrate of potency 63,000 is given in Fig. 4. This indicates a probable similarity in structure.

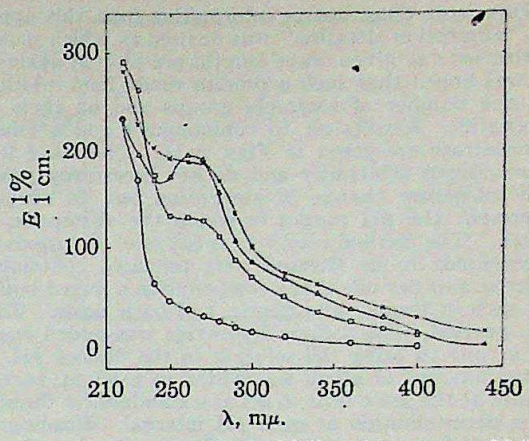

Fig. 3.—Δ—Δ—Δ, untreated folic acid, potency 28,000; ⊙—⊙—⊙, ultraviolet light and oxygen, potency 28,000; ×—×—×, ultraviolet light and nitrogen, potency 28,000; □—□—□, benzylfolic acid, potency 12,000.

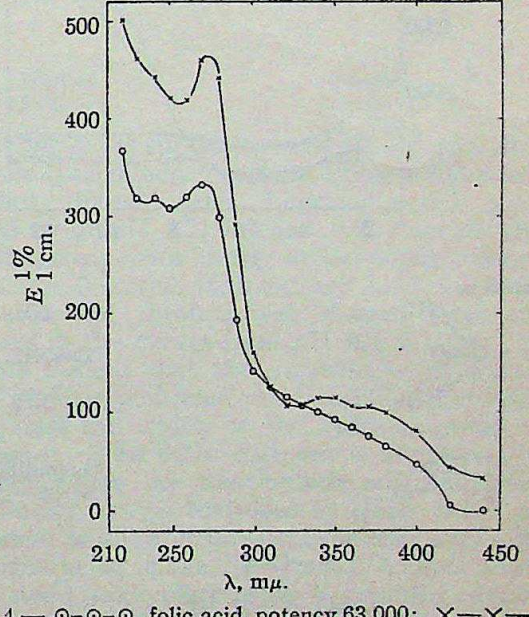

Fig. 4.— ⊙-⊙-⊙, folic acid, potency 63,000; ×—×—×, xanthopterin.

Effect of *p*H on Absorption Spectra.—A number of investigators have studied and adequately reviewed recent work on the effects of acid and alkali on the absorption spectra of solutions of several purines and pyrimidines.[3,4,5] Considerable shifts in absorption bands were observed in compounds containing tautomeric structures which are affected by *p*H. Evidence has been presented by Stuckey[6,7] showing that in certain barbituric acids ionization takes place followed at once by a tautomerism with its accompanying change in absorption.

The absorption spectra of xanthopterin and folic acid (potency 63,000) were determined in 0.1 *N* acid, at neutrality and in 0.1 *N* alkali. Considerable changes were observed as a result of the *p*H differences but both substances changed in a very similar fashion. In order to

obtain more quantitative information from this approach an "absorption titration" was devised in which molecular extinctions at given wave lengths are plotted against pH. It was hoped that such a process would lend information on the number of ionizable groups and on their acidic strengths. Results on 16 compounds[7a] and a folic acid concentrate are given in Figs. 5–11. The wave lengths were chosen arbitrarily and do not necessarily represent the maximum change in absorption but do adequately represent the pH ranges in which the absorption takes place. The method used was as follows. Solutions of the compounds to be titrated were prepared containing 10 micrograms per ml. of the compound in a mixed buffer 0.1 M each in formic, phosphoric, and boric acids. To a 50 ml. portion, 40% sodium hydroxide was added one drop at a time to bring the solution to the desired pH. The same amount of alkali was added to a 50-ml. portion of buffer at the same time to act as a standard for the absorption determination at each pH interval. Readings were taken at five or six arbitrarily chosen wave lengths in the range of absorption of the compound.

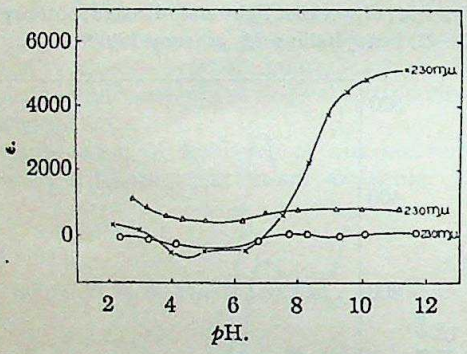

Fig. 5.—

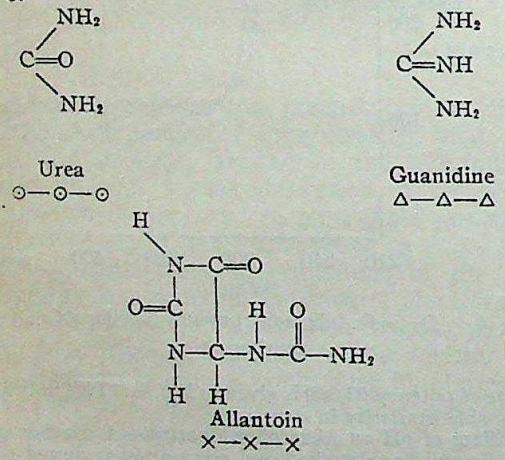

Discussion

Studies of absorption of ultraviolet light by solutions of folic acid concentrates have indicated that the pure substance has an absorption spectrum similar to that of xanthopterin but it appears to have a much higher molecular extinction coefficient. No significant interpretation of that difference can be made at the present time other than the suggestion that the folic acid may contain more carbon to carbon, or carbon to oxygen double bonds.

(7a) The author is indebted to his colleague, E. E. Snell, for samples of thymine, 5-carboxy-uracil, 4-carboxy-thymine, 4-carboxy-uracil ethyl ester, which had been previously prepared by him in this Laboratory.

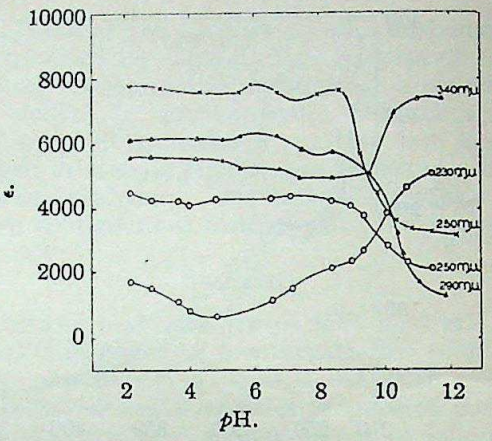

Fig. 6.—

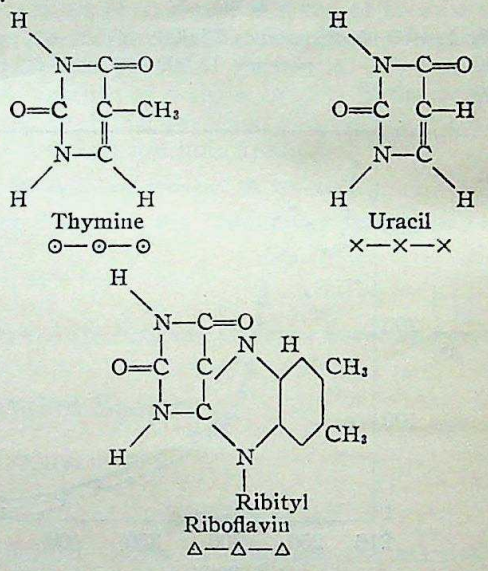

In order to conserve space, absorption spectra on only a few concentrates are given here and all are on samples that have been highly fractionated by processes already described.[8] Low potency fractions that have not been subjected to extensive fractionation do not show a high degree of absorption as do the samples of potency 12,000 and 2,400 in Fig. 1 (Curves 3 and 4). It appears probable that these samples consist of folic acid plus a considerable proportion of folic acid with the structure modified to the extent of destroying the physiological activity of the compound. In view of the ease of destruction of this physiological activity[2] and the stability of the absorbing nucleus, as shown in Figs. 2 and 3, this hypothesis is given considerable support and offers a good explanation for difficulties involved in obtaining fractions of high physiological activity from many low potency concentrates.

The "absorption titrations" given in Figs. 5–11 suggest a strong similarity between the folic acid concentrate and the xanthopterin except for intensity of absorption. Both show two marked inflections in the curves, at about pH 2.5 and at about pH 9.0. Some reasonable interpretations

of these data can be made on consideration of the curves obtained on the known compounds. All of the compounds on which determinations were made that had a structure capable of tautomerism in position 6 as induced by *p*H change, gave major

inflections in the curves between *p*H 7.5 and 10.4. Of these compounds, 4-carboxy-uracil ethyl ester, 4-carboxy-thymine and 5-carboxy-uracil gave inflections at *p*H 7.5, 7.9 and 8.9, respectively. Six other compounds having similar configurations in position 6 (uracil, thymine, uric acid, guanine, riboflavin and theobromine) showed large inflections in the curves from *p*H 9.6 to 10.4. It appears evident that the substitution of a carboxyl group in position 5 and especially in position 4 increases the acidity of the ionizable group in position 6. Two other compounds of interest in this connection are theophylline and allantoin. The former has no hydrogen in either the 1 or 5 position to allow enolization, the only available hydrogen being in the 7 position. A three-atom shift could take place with a resulting major change in absorption characteristics. The ionization could be direct at position 7 but according to Stuckey's work on barbituric acids,[6,7] the ionization alone would not be expected to produce the large absorption changes. Allantoin represents a different series of compounds which appear to have more acidic enolic forms than the pyrimidines. The large inflections in the absorption curves of xanthopterin and folic acid at *p*H 9 appear to represent enolizable groups at position 6 with acidic strength influenced by both an amino group in position 3 and a relatively strong acidic group at some position closer to 6 (position 8 in xanthopterin).

Inflections in the curves in the acid range are not as easily explained as those on the alkaline side since a neutralization of a weak acid is not involved and the changes in absorption necessitate marked changes in electronic structure but do not necessarily involve ionization. Nearly all of the compounds including urea and guanidine

Caffeine
△—△—△

show minor changes in absorption between *p*H 3.0 and 7.0 at short wave lengths. These changes can therefore be attributed to the urea or guanidine portion of the molecules but are insignificant with the more complex compounds. Five compounds, 5-carboxy-uracil, 4-carboxy-thymine, uric acid, xanthopterin and folic acid, show marked inflections in the curves in the acid *p*H range at many wave lengths over the entire wave length scale of absorption. In the cases of the two carboxy compounds it appears evident that the absorption changes are due to electronic shifts involving the carboxyl groups themselves since no such inflection was evident with 4-carboxy-uracil ethyl ester. The uric acid similarly must be involved at the strongly acid group in position 8. The changes in absorption of xanthopterin in the acid range must also be due to electronic changes around position 8 though this change is at a much more acidic *p*H than with uric acid and is in the opposite direction. By inference folic acid also contains an acidic enol in position 8 implying

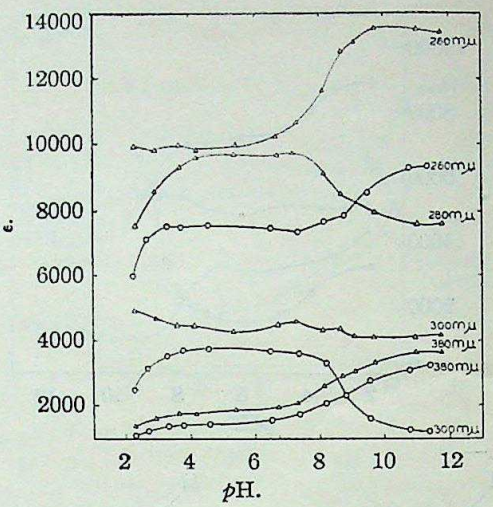

Fig. 11.—

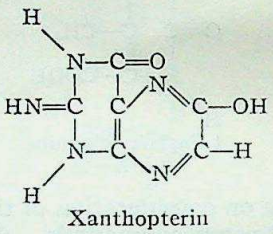

Xanthopterin
⊙—⊙—⊙

Folic acid
△—△—△
Potency = 75000

a further similarity in its structure to that of xanthopterin.[8a] Whether or not these changes in absorption in the acid *p*H range are related to acidic strength of the groups involved cannot be stated at the present time.

Summary

Evidence has been presented to show that the absorption spectrum of folic acid resembles that of xanthopterin. The light absorbing structure in folic acid is much more stable to light and acid treatment than the physiologically active compound. Evidence is cited indicating that the difficulties in purification of many concentrates are due to the impurities consisting of inactivated folic acid with physical properties only slightly changed.

An "absorption titration" plotting molecular extinction coefficients against *p*H is described and its significance discussed briefly.

It is concluded that folic acid contains in its structure a unit very similar to xanthopterin.

AUSTIN, TEXAS RECEIVED SEPTEMBER 14, 1943

(8a) Wright and Welch[9] have recently given further evidence of a structural relationship between xanthopterin and folic acid.

The Heat Capacity, Heat of Transition, Vaporization, Vapor Pressure and Entropy of 1,1,1-Trichloroethane

BY THOR R. RUBIN,[1] BLAINE H. LEVEDAHL AND DON M. YOST

Introduction.—The work of Kemp, Pitzer and other investigators has[2] established the existence of barriers hindering the rotation of methyl groups in ethane and a number of other molecules containing methyl groups. 1,1,1-Trichloroethane, CH_3CCl_3, is another molecule of this class, and it seemed important to determine the height of its barrier since one of the rotating groups is a completely substituted methyl group. The height of the barrier was found to be 2700 ± 350 calories per mole, a value almost equal to that for the ethane molecule. It is of considerable interest that the magnitude of the barrier is but little affected by the substitution of chlorine for hydrogen in ethane.

An additional interesting property of 1,1,1-trichloroethane is that dipole moment studies[3] indicate that its molecules begin to rotate in the solid at a temperature of 224.3°K. The heat capacity data reported here establish the existence of a transition at this temperature.

Material.—Eastman Kodak Co. "methyl chloroform" was purified by fractional distillation and subsequent repeated fractional crystallization. The corrected boiling range of the fraction which was to be recrystallized was 73.8–74.0°. After four recrystallizations the material was dried by passing its vapor over anhydrous calcium sulfate. It is believed that the purity of the final fraction used in the heat capacity measurements is easily 99.7%, high enough for the purposes of the present investigation.

Heat Capacity Measurements.—The heat capacity of solid and liquid 1,1,1-trichloroethane was determined with the adiabatic calorimeter (Gold-plated copper calorimeter I, and a strain-free resistance thermometer CT-2) described elsewhere.[4]

The experimental data are presented in Table I. They are expressed in terms of the defined calorie equal to 4.1833 international joules. The value 273.16°K. was taken for the ice point.

The temperature interval of each heat capacity measurement given in Table I may be estimated from the spacing of the mean temperatures, since there were no gaps between measurements in any series. The data are shown plotted in Fig. 1; the measurements were reproducible at all of the temperatures where the various series of measurements overlap. The deviations of the data from a smooth curve are within 0.2%; the probable accuracy of the measurements is about 1% at a temperature of 15°K. and 0.2% above 25°K. Thermal equilibrium was easily attained even for measurements taken at temperatures in the immediate neighborhood of the peaks shown in Fig. 1.

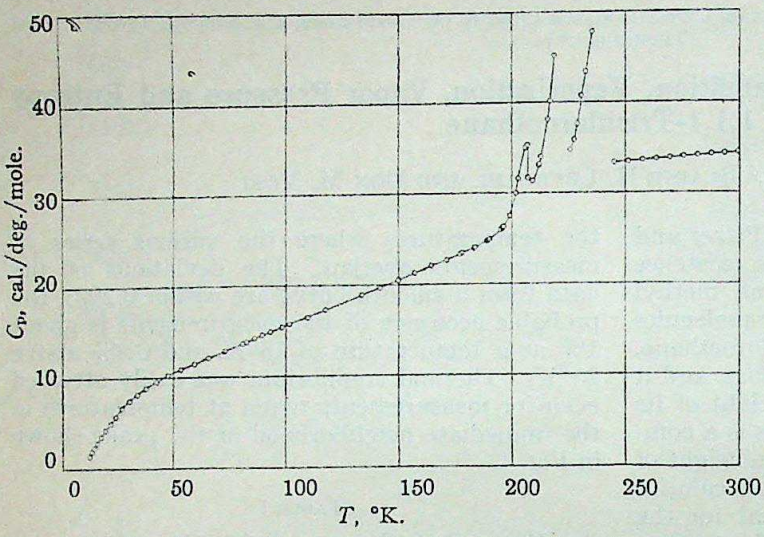

Fig. 1.—The molal heat capacity of 1,1,1-trichloroethane.

Professor E. A. Long showed no such maximum.[5]

Immediately below the melting point, premelting effects obscure the course of the true heat capacity curve. It is obvious that the effect is large for relatively little impurity, since the heat of fusion is small. A correction based on Raoult's law applied in a manner given by Pitzer[6] could not be made, because of the close proximity of the transition temperature to the melting point.

Transition Temperature and Melting Point.—The transition temperature and melting point were carefully measured, and the results are presented in Table II, together with the values obtained by other observers. The melting point value is an extrapolated one, corresponding to a completely melted system in which the mole fraction of dissolved impurities is small.

TABLE II

MELTING AND TRANSITION TEMPERATURES FOR 1,1,1-TRICHLOROETHANE

0°C. = 273.16°K.

Melting point, °K.	Transition temperature, °K.	Observer
240.5	224.3	Turkevich and Smyth[3]
241.0	...	Van de Vloed[7]
242.8		Henne and Hubbard[8]
240.2 ± 0.5	224.20 ± 0.03	This Research

Heats of Transition and Fusion.—The heat of transition of 1,1,1-trichloroethane was observed to be 1785 cal./mole and 1787 cal./mole from measurements over a temperature range of 214.785–225.716°K. and 210.983–227.301°K., respectively; the average value is 1786 ± 2 cal./mole. Each value of the heat of transition contains a correction for the normal heat capacity of the solid obtained by extrapolating the heat capacity curve below 206°K. to the transition temperature. The uncertainty in the heat of transition given includes all calorimetric errors, but errors in the extrapolated heat capacity values at temperatures above 206°K. may increase this uncertainty fivefold. The total entropy and heat content are not affected appreciably by this latter possibility, since errors in the extrapolated heat capacity values are compensated almost completely by the resulting errors in the heat of transition.

An accurate value of the heat of fusion was not determined because of the errors in the heat capacity of the solid just above the transition point. A rough value for the heat of fusion of 1,1,1-trichloroethane of 450 ± 300 calories per mole was calculated from the total heat absorbed over the melting range and from the estimated heat capacity of the solid; it was assumed that the latter were about equal to the heat capacity of the liquid.

Neither this rough value of the heat of fusion nor the melting point given above is used in the calculation of the total entropy, and uncertainties in these quantities do not affect the uncertainty in the total entropy.

Heat of Vaporization.—The heat of vaporization of 1,1,1-trichloroethane was determined in a Giauque type calorimeter fitted with a strain-free platinum resistance thermometer.[4] The usual corrections were made for the heat lost by the calorimeter to its surroundings by radiation and the heat carried off by the vapor. A constant measured pressure was maintained for every determination in a manner described elsewhere.[4] The temperatures of vaporization were calculated from the pressure data using the vapor pressure equation given below.

The observed molal heat of vaporization of 1,1,1-trichloroethane at 284.34°K. and a pressure of 6.899 cm. was 7988 cal./mole and at 286.53°K. and 7.686 cm. was 7969 cal./mole. These values when corrected to 286.53°K. and 7.686 cm. become 7955 and 7969 cal./mole, respectively, with an average value of 7962 ± 12 cal./mole. The correction to 286.53°K. was made using (a) the heat capacity of the gas from spectroscopic data, (b) the heat capacity of the liquid from this research and (c) Berthelot's equation with reasonable estimates for the critical constants of T_c = 533°K. and P_c = 50 atm.

Vapor Pressure.—The vapor pressure of 1,1,1-trichloroethane at various temperatures is given in Table III together with pressures calculated from the derived vapor pressure equation presented below. The temperature of the liquid was measured in the Giauque type calorimeter

used for determining the heat of vaporization. The pressure was measured with a mercury manometer by means of a Gaertner meter bar and a Henson cathetometer. Corrections for the capillary depression were made from the measured height of the menisci and the data of Cawood and Patterson.[9]

TABLE III

THE VAPOR PRESSURE OF 1,1,1-TRICHLOROETHANE

0°C. = 273.16°K., pressures in int. cm.

T, °K.	P, obs., cm.	P,[a] calcd., cm.	P, calcd. − P, obs.
267.796	2.88	2.91	+0.03
272.943	3.87	3.85	− .02
278.269	5.05	5.09	+ .04
284.464	6.93	6.95	+ .02
290.083	9.12	9.12	− .00

[a] $\log_{10} P_{cm.} = -(1729/T) + 6.92013$.

Vapor pressure values were not determined above 17°C. since in this region condensation of vapor in the manometer would result. The uncertainty in any of the pressure values is estimated to be ±0.05 cm. It was not deemed essential, in this case, to measure the vapor pressures with high precision.

The Entropy of 1,1,1-Trichloroethane.—The entropy from the calorimetric data is summarized in Table IV. The entropy of the solid below a temperature of 15°K. was calculated by a Debye extrapolation with three degrees of freedom and $\Theta_D = 78°$; the entropy over the temperature interval from 224.20°K. to 241.00°K., was calculated by graphical evaluation of $\int C_p$ d ln T from 224.20°K. to a known intermediate temperature (about 236°K.). Above this temperature the function $\Sigma \frac{Q}{T_{max.}}$ was used to calculate the rest of the entropy in the interval ending at 241.00°K.; ΣQ is the total energy absorbed over the latter temperature interval, and $T_{max.}$ is the temperature of maximum heat capacity, in this interval (equal to about 240.1 ± 0.2°K.). The imperfect gas correction was made assuming a Berthelot equation of state and the estimated critical data.

TABLE IV

THE MOLAL ENTROPY OF 1,1,1-TRICHLOROETHANE FROM CALORIMETRIC DATA

0°C. = 273.16°K.; molecular weight = 133.415

	Entropy, cal./deg./mole
0–15°K. Debye extrapolation, $\Theta_D = 78.0°$	0.851

[a] S (ideal) − S (real) = $\frac{27RT_c^3P}{32T^3P_c}$, P_c = 50 atm., T_c = 533°K.

The entropy was also calculated from the molecular data given in Table V.

The vibrational frequencies were taken to be harmonic. The fundamental frequencies, of which all are active in the Raman spectrum except the torsional one around the C–C axis, are: 345 (1), 523 (1), 977 (1), 1471 (1), 2939 (1), 241 (2), 340 (2), 713 (2), 1086 (2), 1450 (2) and 3000 (2). The numbers in the parentheses adjoining the frequencies are their degeneracies as assigned by us from rough polarization measurements. The frequency 340 (2) which overlaps 345 (1) is not certain. It corresponds to a bending vibration of the CH_3 and CCl_3 groups about the C–C bond. A more complete discussion of the spectrum will be given elsewhere. The moments of inertia for the rigid molecule were calculated from the following data of Beach and Stevenson[10]: C–Cl distance, 1.76Å.; C–C distance, 1.54Å.;

TABLE V

THE MOLAL ENTROPY OF GASEOUS 1,1,1-TRICHLOROETHANE AT 286.53°K. AND 1 ATM. FROM MOLECULAR DATA

	Entropy in cal./deg./mole
Translational	40.38
Rotational (free rotator)	28.85
Vibrational	8.24
Total for free rotator	77.47 ± 0.10
Calorimetric	76.22 ± 0.16
Difference	1.25 ± 0.16
Diff. calcd. for a potential of 2700 ± 350 cal./mole	1.26 ± 0.16

The Entropy from Molecular Data.—The calculated entropy for 1,1,1-trichloroethane from the molecular data is given in Table V.

An accurate value cannot be given for the mole percentage impurity present, mainly because a precise value of the freezing point and heat of fusion is not known. A rough estimate of an upper limit of 0.3 mole per cent. may be made from the data available. It may be remarked that this estimate is not unreasonable because large premelting effects are to be expected for small amounts of impurities present in substances having a low heat of fusion. The final entropy value is not affected to a significant extent by concentrations of impurity of this order of magnitude.

C–H distance, 1.09Å.; C–C–H angle, 109°28′; and the Cl–C–C angle 110°. The symmetry number for the rigid molecule was taken as three.

The following natural constants, given by Birge,[11] were used in the calculations: 0°C. = 273.16°K., R = 1.9870 cal./deg./mole, r, the Boltzmann constant, = 1.3805×10^{-16} erg/deg., $N = 6.023 \times 10^{23}$ and $h = 6.624 \times 10^{-27}$ erg sec.

The difference between the calorimetric entropy value and the one calculated using molecular constants is 1.25 calories per mole, and this corresponds to a barrier of 2700 calories per mole. This value was calculated using the tables of Pitzer and Gwinn.[12] The reduced moment of inertia of the methyl group of the molecule was taken to be 5.26×10^{-40} c. g. s. units.

We wish to thank Professor Alexander Goetz for supplying us with liquid hydrogen.

Summary

The heat capacity of 1,1,1-trichloroethane has been measured from 14°K. to room temperature. There is a transition point in the solid at 224.20°K. The heat of transition is 1786 ± 2 cal./mole. An approximate value for the melting point is 240.2 ± 0.5°K., and a rough value for the heat of fusion is 450 ± 300 cal./mole. The heat of vaporization is 7962 ± 12 cal./mole at 286.53°K. The entropy of the ideal gas at 286.53°K. and 1 atm. is 76.22 ± 0.16 cal./deg./mole, and 76.97 ± 0.16 cal./deg./mole at 298.16°K. and 1 atm. The entropy of the liquid at 298.16°K. is 54.37 ± 0.11 cal./deg./mole. A comparison of the statistical and calorimetric values of the entropy indicates a barrier of 2700 ± 350 cal./mole.

The Ternary System: Dioxane–Benzene–Water

BY ROBERT J. BERNDT AND CECIL C. LYNCH

Several ternary liquid systems have been examined by Hand[1] for dineric distribution between conjugate phases. Bancroft and Hubbard[2] have recently presented a new method of determining dineric distribution in such systems and have examined two ternary systems in some detail.

The object of this work has been to study the ternary liquid system dioxane–benzene–water, in which the dioxane is the consulate liquid, for dineric distribution between the conjugate phases at 25°. Because of the extensive region of immiscibility in the system, we have employed both the method of Bancroft and an analytical method for determining the composition of conjugate phases.

Preparation of Materials

Dioxane.—Technical 1,4-dioxane from the Eastman Kodak Co. was purified by the method described by Eigenberger.[3] The product was kept over metallic sodium, from which it was distilled when needed; density d^{25}_4 1.0276, $n^{25}D$ 1.4197.

Benzene.—Thiophene-free benzene was dried with calcium oxide, from which it was fractionally distilled. It was kept in bottles protected from moisture with suitable drying tubes.

Freshly boiled redistilled water was used also in all mixtures.

Experimental Method

Mixtures were prepared in glass-stoppered flasks by direct weighing and were allowed to reach equilibrium in a water thermostat (25 ± 0.05°). The conjugate phases were sampled with pipets; for the lower layer, the tips of the pipets used were drawn off and sealed. These tips were broken off under the lower layer for sampling to avoid any contamination with the upper layer. Densities of all solutions were determined with 25-cc. or 10-cc. pycnometers to a precision of ± 0.0001 unit. All refractive indicex measurements were made with an Abbe refractometer to a precision ± 0.0002 unit.

The Binodal Curve.—The binodal curve for the 25° isotherm was determined by titration of binary mixtures of benzene and dioxane with water and of mixtures of dioxane and water with benzene to the first indication of immiscibility. In the overlapping portions from the two sets of titrations, these data were found to agree within ±0.2%. The data for the binodal curve are given in Table I, and the plot in Fig. 1.

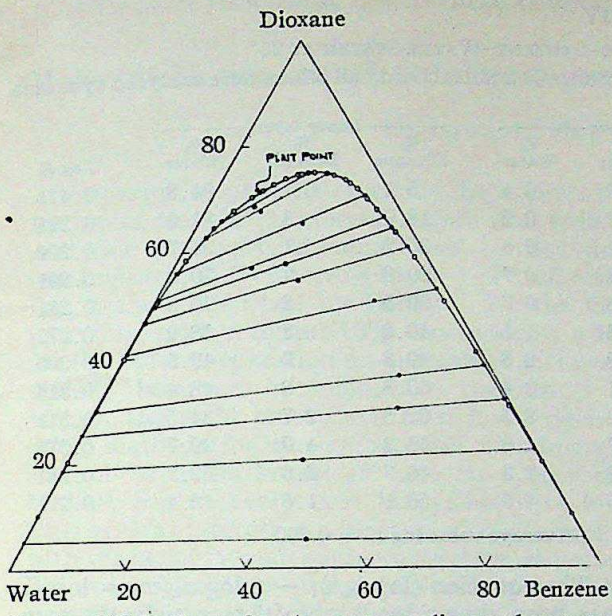

Fig. 1.—25° isotherm for the system: dioxane–benzene–water.

Analysis Data for the System.—Refractive indices and density data have been used for analytical purposes in the system. It was first necessary to consider refractive indices and densities for the binary systems. Hovorka, Shaefer and Dreisbach[4] have determined these data for the dioxane–water system, and Lynch[5] has extended the data on refractive index to lower concentrations for this system. Recently Teague and Felsing[6] have presented refractive index and density data for the dioxane–benzene system for a limited number of points. Accordingly, we have measured the refractive index and density of a number of benzene–dioxane mixtures. These data are included in Table II. All solutions were prepared by direct weighing in glass-stoppered flasks, and all measurements were made at 25°.

TABLE II

DENSITIES AND REFRACTIVE INDICES FOR THE BINARY SYSTEM DIOXANE–BENZENE AT 25°

% Dioxane	Density d^{25}_4	Refractive index, $n^{25}D$

$\log K = \log (a_1/b_1) - 1.32 \log (a_2/w_2)$ Average value $\log K = 0.290$

Dineric Distribution for the System.—For determining the compositions of the conjugate phases, two methods were resorted to: (1) the titration method, which was given in detail by Bancroft and Hubbard[2] and (2) the use of the analysis diagram.

The distribution data for the system are given in Table IV, and the tie lines are plotted in Fig. 1.

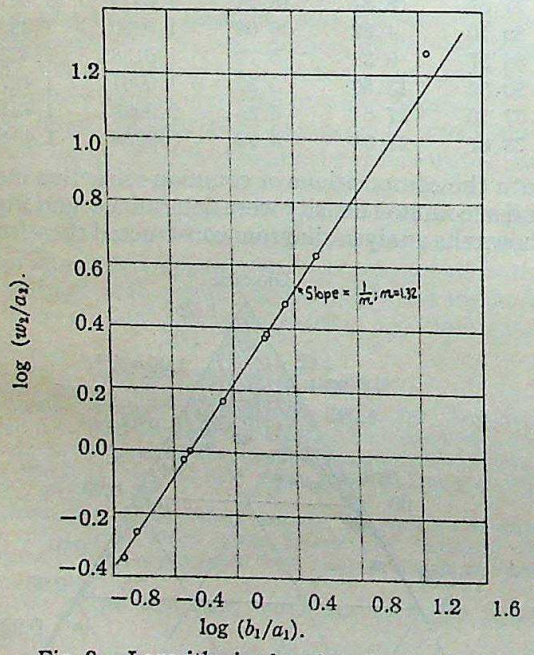

Fig. 3.—Logarithmic plot of the isotherm.

The equation ($\log a_1/b_1 - n \log a_2/w_2 = \log K$) has been shown by Bancroft[2] to satisfy the equilibrium distribution data for such a system. The value of n should be determined simply from the slope of the curve (straight line) in plotting ($\log b_1/a_1$) against ($\log w_2/a_2$), where a_1 and b_1 represent the percentage of dioxane and benzene, respectively, in the benzene-rich layer and a_2 and w_2, the percentage dioxane and water, respectively, in the water-rich layer. Such a plot of the above data is shown in Fig. 3, and the value of n obtained, 1.32. From the above relation employing this value of the slope, the distribution constants in Table IV were obtained. Except for the first value in the $\log K$ column, satisfactory distribution constants resulted. This first value is off, probably due to limitations in attaining equilibrium and in analysis. The plait point estimated from these data corresponds to 71% dioxane, 7.5% benzene, 21.7% water.

Summary

1. The 25° isotherm of the dioxane–benzene–water system has been presented.

2. Refractive index and density data at 25° for the dioxane–benzene and the ternary system dioxane–benzene–water has been given, as well as an analysis diagram for the miscible region of the ternary system.

3. Dineric distribution in the ternary system has been shown to satisfy the relation employed by Bancroft and Hubbard for several ternary liquid systems.

Dehydrochlorination of 3-Chloro-2-propen-1-ol: Preparation of Propargyl Alcohol[1]

BY LEWIS F. HATCH AND ALLEN C. MOORE[2]

Propargyl alcohol has recently been prepared by interaction of paraformaldehyde and sodium acetylide in liquid ammonia[3] and by dehydrochlorination of 2-chloro-2-propen-1-ol[4] following the method described by Henry.[5] By the first procedure a yield of but 10% was reported while for the other preparation no percentage yield was stated; however, in analogy to the results of Henry, the yield must have been low. Several other methods for the preparation of propargyl alcohol[6] or of its homologs[7] also have been described, but in every case the yields were low. This evident interest in propargyl alcohol coupled with the lack of an adequate method for its preparation instigated the present investigation of the dehydrochlorination of *cis* and *trans* 3-chloro-2-propen-1-ol.

Of the possible starting materials, the isomeric *cis* and *trans* 3-chloro-2-propen-1-ols seemed the most promising for they should react in an analogous manner to the 2-bromo-2-propen-1-ol used by Henry to give propargyl alcohol. The isomeric chloroalcohols are easily prepared from the readily available corresponding dichlorides [*cis*- and *trans*-1,3-dichloropropene], by-products of the semi-commercial production of allyl chloride.[8] The 3-chloroalcohols have been reported,[9] but no note was taken of the presence of two isomeric forms, and the physical constants are unreliable.[10] As the geometric configuration of the isomers of both the 3-chloroalchohol and the dichloride has not as yet been definitely established, α- will be used to designate the lower boiling isomer and β- the higher boiling isomer in each case.

The β-isomer is less reactive than the α-, and, under the reaction conditions necessary for removal of hydrogen chloride, yields no propargyl alcohol. This is not surprising, since, under the conditions used (strong alkali at elevated temperatures), acetylenic alcohols are known to be decomposed.[11] The known decomposition products,[12] acetylene and sodium formate, were obtained from the reaction mixture.

When the sodium hydroxide concentration is greater than 10% there is also a certain amount of polymerization, yielding a polymer similar in properties to that obtained from acrolein under similar circumstances.[13] In view of the possible side reactions it would be anticipated that unreactive olefinic chloroalchols would give poor yields of acetylene derivatives. Since the α-3-chloroalcohol used in this work is more reactive than those hitherto employed, the reaction in this case proceeds satisfactorily and good yields are obtained.

TABLE I

DEHYDROCHLORINATION OF 3-CHLORO-2-PROPEN-1-OL

Run no.	Isomer	Moles of 3-chloro-alcohol	Time, hr.	NaOH, %	% Conversion from Cl^-	% Yield of propargyl alcohol

Experimental

1,3-Dichloropropene.—In the semi-commercial distillation of crude allyl chloride, prepared by the chlorination of propylene, there remains an appreciable amount of higher boiling material which contains approximately 60% 1,3-dichloropropene and 30% 1,2-dichloropropane.[8] This crude material[13a] served as the source of 1,3-dichloropropene for this investigation. The unsaturated dichlorides were obtained by distillation through a 26 theoretical plate spiral column.[14] Fractions with a boiling range of 102.5–105.5° and 109.5–112.5° were taken and then refractionated to obtain constant boiling fractions at 104.3° and 112.0°. This careful separation was necessary because the isomeric dichlorides are more easily separated by fractionation than are the chloroalcohols.

α-1,3-Dichloropropene: 104.3°; d^{20}_4 1.224; $n^{20}D$ 1.4682; *MR* (calcd.) 25.32, (obsd.) 25.25.

β-1,3-Dichloropropene: 112.0°; d^{20}_4 1.217; $n^{20}D$ 1.4730; *MR* (calcd.) 25.32, (obsd.) 25.58.

3-Chloro-2-propen-1-ol.—Both α- and β-1,3-dichloropropene were hydrolyzed to the corresponding chloroalcohols by using a 10% excess of 10% sodium carbonate. The reaction mixture was refluxed two hours (reflux temperature: α-1,3-dichloropropene, 82.5–89°; β-1,3-dichloropropene, 86.0–93.5°), then extracted with diethyl ether, dried, and fractionated; yield, α = 81%; β = 76%. The physical data for the two chloroalcohols are given in Table II. Both isomers have a delayed vesicant action and care should be taken in handling them.

Anal. Calcd. for C_3H_5OCl: Cl, 38.32. Found: α-3-chloro-2-propen-1-ol, 38.22; β-3-chloro-2-propen-1-ol, 38.20.

Dehydrochlorination of β-3-Chloro-2-propen-1-ol.—The chloroalcohol was dehydrochlorinated by refluxing for two hours with a 10% excess of the desired concentration of sodium hydroxide. The reflux temperature varied from 102° for 3.8% sodium hydroxide to 117° for 38% sodium hydroxide. During this reflux period a gas was given off which did not condense at *ca.* −75°. The gas formed explosive salts of both copper and silver and was assumed to be acetylene. The extent of dehydrochlorination was determined by Cl^- titration (Volhard) and OH^- titration. In every case the moles of OH^- utilized by the reaction were greater than the moles of Cl^- produced, indicating a side reaction involving OH^-.

The remaining reaction mixture was made slightly acid with hydrochloric acid, filtered and extracted with diethyl ether. Only unreacted chloroalcohol was obtained. When the reaction mixture was acidified, a small amount of a light brown flocculent precipitate separated. This non-crystallizable solid was readily soluble in alkali and in concentrated sulfuric acid, ethyl alcohol and acetic acid but insoluble in benzene and only slightly soluble in water and diethyl ether. After the flocculent precipitate had been removed by filtration, the remaining solution was distilled to recover any unextracted propargyl alcohol as its water azeotrope (b. p. 97°). None was obtained. The presence of a small amount of formic acid, however, was indicated by the precipitation of manganese dioxide from dilute aqueous potassium permanganate and confirmed by crystals of sodium formate (melting at 253° (cor.)) which were obtained by evaporation of the basic solution.

The effect of sodium hydroxide concentration on the extent of dehydrochlorination is shown by runs 1–5 in Table I. Due to the unreactive nature of this isomer, no study was made of the effect of time on the extent of dehydrochlorination.

Dehydrochlorination of α-3-Chloro-2-propen-1-ol.—The method of dehydrochlorinating α-3-chloro-2-propen-1-ol was the same as that used for the β-isomer. Because the reactivity of α-3-chloro-2-propen-1-ol was considerably greater, not only was the effect of sodium hydroxide concentration studied (runs 10–15) but also the effect of time on the extent of dehydrochlorination was determined (runs 6–9). Data for these experiments are given in Table I.

The propargyl alcohol was recovered by distillation from the reaction mixture after acidification with hydrochloric acid. The water–alcohol azeotrope thus obtained contained in addition to propargyl alcohol any unreacted α-3-chloroalcohol. This azeotrope was saturated with potassium carbonate and extracted with diethyl ether; the ether extract was subsequently distilled through an efficient fractionating column to recover both propargyl alcohol and the unreacted α-3-chloro-2-propen-1-ol. The recovery of the propargyl alcohol from a dilute solution presents a difficult problem for there is only a 3° temperature differential between the boiling point of its water azeotrope and that of water. Continuous ether extraction is suggested as a useful alternative to the method used.

The yields of propargyl alcohol reported are calculated from the amount of 3-chloroalcohol converted (reacted) as indicated by chloride ion formation. The unconverted 3-chloroalcohol was in every case recovered nearly quantitatively and used in subsequent experiments for the production of propargyl alcohol.

Dehydrochlorination of a Mixture of α- and β-3-Chloro-2-propen-1-ol.[15]—An equimolar mixture of the two isomers of 3-chloro-2-propen-1-ol was dehydrochlorinated in a manner similar to that previously described. The only modification in technique was in the use of sodium chloride and isopropyl ether in recovering the alcohols from the water–alcohol azeotrope. The data for this experiment (run 18) are given in Table I. Because the unreacted 3-chloroalcohol consisted mainly of the unreactive β-isomer which could not be used in subsequent preparations of propargyl alcohol, the yield is calculated from the total chloroalcohol applied.

Summary

1. The two isomers of 3-chloro-2-propen-1-ol

have been prepared and several physical constants have been determined.

2. The dehydrochlorination of the two isomers has been studied and the lower boiling isomer (α) is appreciably more reactive than the higher boiling isomer (β).

3. Propargyl alcohol has been prepared in good yields from the lower boiling isomer (α) and from a mixture of the two isomers.

4. It is impossible to assign definite geometrical structures to the two isomers from the data available.

The Preparation of Some Unsaturated Fatty Acid Chlorides[1]

BY THOMAS R. WOOD, F. L. JACKSON, A. R. BALDWIN AND H. E. LONGENECKER

A valuable approach to an understanding of the physical nature and physiological properties of natural fats is afforded by the synthesis of mixed triglycerides of known constitution.[2,3] As our attention turned to the important group of unsaturated triglycerides,[4,5,6] it became desirable to develop a satisfactory method for making unsaturated acyl chlorides of oleic, elaidic, linoleic and linolenic acids.

Attempts to prepare the unsaturated chlorides with thionyl chloride were unsatisfactory.[7] The use of oxalyl chloride had been suggested[8] for some saturated fatty acids and was found in this work to be distinctly preferable for the unsaturated acids.

The possibility of double bond rearrangement during the reaction and subsequent purification merits attention. We have considered the possible formation of conjugated systems, known to arise in polyene acids during alkali treatment or following oxidative changes.[9] No consideration has been given here to possible changes in geometric configuration during reaction. Evidence has been presented[10] for the existence of isomers of the *cis-trans* type in debromination linoleic and linolenic acids, such as were employed in the present study.

Conjugated diene, triene and tetraene linkages in preparations of linoleic and linolenic acids and their acid chlorides were estimated by comparison of the ultraviolet absorption of these compounds in appropriate spectral regions with that of pure 18-carbon conjugated polyene acids. We have employed standard absorption values compiled by Bradley and Richardson[11] for 9,11-(or 10,12)-linoleic, eleostearic and parinaric acids, whose molecular extinction coefficients (ϵ) are 33,600 (232 mμ), 46,700 (270 mμ), and 57,700 (320 mμ), respectively.

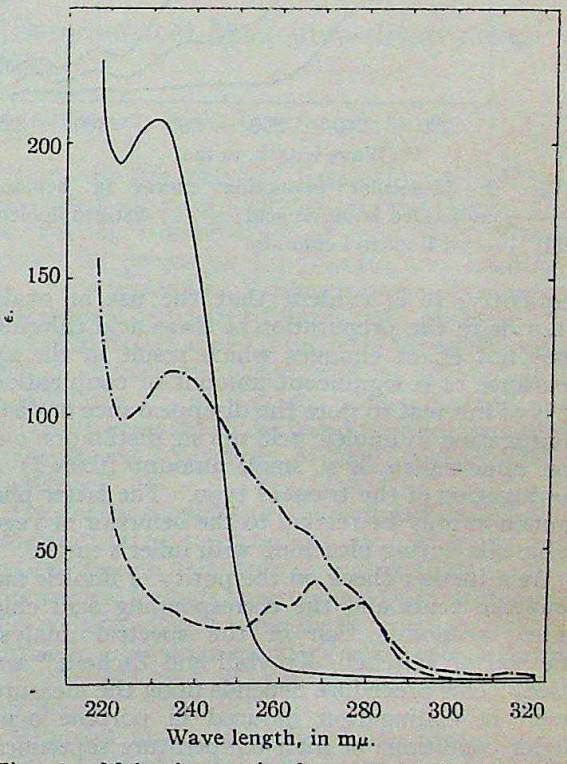

Fig. 1.—Molecular extinction curves in heptane: ———, undistilled linoleic acid; -------, distilled linoleic acid; ------, linoleyl chloride.

The ultraviolet absorption spectra of our linoleic acid and linoleyl chloride are plotted in Fig. 1, while Fig. 2 presents similar data for linolenic acid and linolenyl chloride. It is evident that conversion of the acids to the acid chlorides was in each instance accompanied by an increase in conjugation. In no case, however, was more than 1% of the total acid or acid chloride conjugated (Table II). Moreover, it has been our experience that any manipulation of these highly unsaturated compounds tends to introduce conjugation. Con-

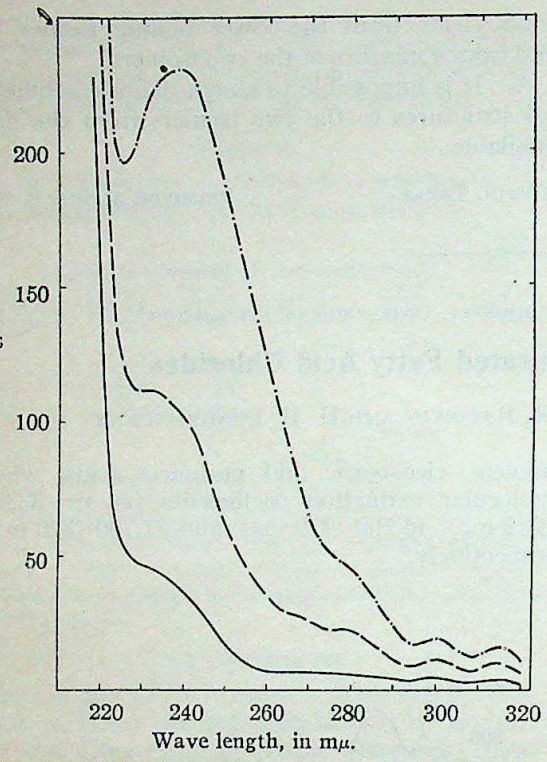

Fig. 2.—Molecular extinction curves in heptane: ———, undistilled linolenic acid; - - - - - -, distilled linolenic acid; ·····, linolenyl chloride.

sequently, it is evident that the use of oxalyl chloride in the preparation of these acid chlorides does not effect changes which result in the appearance of a significant amount of conjugation. It is of interest to note the disappearance of diene conjugation in linoleic acid during distillation and the appearance of a small amount (0.08%) of conjugation of the trienoid type. The latter phenomenon may be related to the behavior of vegetable oils during bleaching with fuller's earth.[9]

As a further check on the purity of linoleic and linolenic acids and the corresponding acid chlorides, a modification of the spectral analysis method of Mitchell, Kraybill and Zscheile[12] was used. This procedure depends upon the measurement of conjugation induced in polyene acids under conditions of high temperature saponification. Kass and Skell[13] postulated that this type of isomerization is effected by the removal of a proton from central active methylene groups in 1,4-diene systems with a final stabilization in conjugated linkages. In any case, it is unlikely that conjugation would be induced in 1,4- and 1,5-diene systems at equal rates. Since the molecular extinction coefficients at 232 and 270 mμ of the soaps derived from either acid and its corresponding acid chloride were identical within experimental error (Table II) it may be assumed that little or no "spreading" of the double bonds within the diene or triene systems takes place during the reaction of the acid with oxalyl chloride.

As previously indicated, migration of double bonds in the opposite direction with resultant conjugated configuration does not occur. Consideration of the remaining possibility of the formation of geometric isomers during acid chloride synthesis must await the preparation of linoleic and linolenic acids by the low-temperature crystallization technique.

(12) Mitchell, Kraybill and Zscheile, *Ind. Eng. Chem., Anal. Ed.*, **15**, 1 (1943).

Experimental

Instrument and Methods.—All of the absorption data were obtained from measurements made with a Beckmann quartz spectrophotometer. Solutions of the acids and the acid chlorides were made in purified heptane. The absorption curves are plotted using the value of the molecular extinction coefficient on the ordinate and the wave length in mμ on the abscissa.

Molecular extinction coefficient (ϵ) = $\log_{10} I_0/I/cl$
I_0 = intensity of radiation transmitted by the solvent
I = intensity of radiation transmitted by the solution
c = concentration of solute in moles per liter
l = length in cm. of solution through which the light passes

Preparation of Highly Purified Fatty Acids.—Oleic acid was prepared by the crystallization technique of Brown and Shinowara,[14] and elaidic acid by the elaidinization of oleic acid according to the method of Lyutenberg.[15] Linoleic and linolenic acids were obtained by the debromination of tetrabromostearic acid (m. p. 115°, cor.) and hexabromostearic acid (m. p. 185°, cor.), respectively.

The debrominations were carried out by the addition of zinc and hydrochloric acid to an ether solution of the bromides.[16] Analytical data for the above acids are presented in Table I.

Preparation of Fatty Acid Chlorides.—The acid chlorides of oleic, elaidic, linoleic and linolenic acids were prepared by the action of oxalyl chloride on the pure acids. As an example of the method, the preparation of linoleyl chloride is given.

Linoleic acid (16.5 g., 0.06 mole) was refluxed at 65 to 70° with 22.4 g. (0.18 mole) of oxalyl chloride (Eastman Kodak Company) for four hours in an all glass still. The excess oxalyl chloride was removed by warming the mixture to 100° *in vacuo*. The acid chloride was distilled under 2 to 3 mm. pressure. The yield was 14.5 g. (82% of the calculated amount) of water-white linoleyl chloride.

Anal. Calcd. for linoleyl chloride, $C_{18}H_{31}OCl$: Cl, 11.87. Found: Cl, 11.68, 11.77.

For the other acid chlorides:

Anal. Calcd. for oleyl chloride, $C_{18}H_{33}OCl$: Cl, 11.78. Found: Cl, 11.68, 11.68.

Anal. Calcd. for elaidyl chloride, $C_{18}H_{33}OCl$: Cl, 11.78. Found: Cl, 11.73, 11.83.

Anal. Calcd. for linolenyl chloride, $C_{18}H_{29}OCl$: Cl, 11.95. Found: Cl, 11.86, 12.08.

(16) Frankel and Brown, THIS JOURNAL, **65**, 415 (1943).

Summary

The preparation of oleyl, elaidyl, linoleyl, and linolenyl chlorides has been successfully accomplished through the use of oxalyl chloride.

Linoleic and linolenic acids and the corresponding chlorides were examined spectrophotometrically, and the results demonstrate that the reaction of the acids with oxalyl chloride was not accompanied by rearrangements of the double bonds to produce conjugated systems.

Unsaturated Synthetic Glycerides. IV. Symmetrical Monoöleo-disaturated Triglycerides[1]

BY F. L. JACKSON, B. F. DAUBERT, C. G. KING AND H. E. LONGENECKER

In other papers[2,3] of this series it was shown that methods available for the synthesis of unsymmetrical mixed triglycerides containing saturated acids were suitable, with little modification, for the preparation of 1-oleyl-2,3-disaturated triglycerides and 1-acyl-2,3-dioleins. This investigation likewise shows that methods suitable for the preparation of symmetrical mixed triglycerides containing saturated fatty acids can be adapted to the synthesis of those containing unsaturated acids. However, the reaction between the symmetrical diglyceride and the unsaturated acyl chloride cannot be completed under less rigorous conditions than refluxing for several hours on a steam-bath.[3] Amberger and Bromig[4] attempted to prepare 2-oleyl-1,3-distearin by treating 1,3-distearin with oleyl chloride in quinoline and pyridine solution at room temperature for several days. Their results were unsatisfactory as they succeeded only in isolating the original diglyceride. It has been our experience that good yields of unsaturated triglycerides may be obtained, in general, only when the acylation of the 1-mono- or 1,3-diglyceride with an unsaturated acyl chloride is carried out at 70 to 85° for three to six hours.

Although the methods of Fischer[5] and Verkade and associates[6,7,8] both were used in this work to prepare the symmetrical diglycerides which later were used as intermediates, it was found that the use of 1-monotrityl glycerol was unsatisfactory for preparing 1,3-dilaurin and 1,3-dicaprin. Poor yields of 1,3-dilaurin were obtained on hydrolysis of 1-trityl-2,3-dilauryl glycerol and successful isolation of 1,3-dicaprin was not accomplished. Hydrolytic cleavage of the low molecular weight fatty acids no doubt occurred simultaneously with removal of the trityl (triphenylmethyl) group during hydrolysis of the 1,2-diacyl-3-tritylglycerol.

The melting points of the symmetrical monoöleo-disaturated triglycerides are, with one exception, two to five degrees higher than the unsymmetrical isomers reported in a previous paper.[2] The melting points were determined on melted samples contained in capillary tubes cooled slowly to −20° and held at −20° for at least twenty-four hours.

Although measurable differences in refractive indices were obtained when compared with the unsymmetrical isomers, no definite conclusions can be drawn concerning this particular physical property.

Experimental

Preparation of Intermediates.—All saturated fatty acids and the corresponding acyl chlorides, oleic acid and oleyl chloride were prepared by the methods given in the first paper of this series.[2]

Two symmetrical diglycerides, 1,3-dipalmitin (m. p. 72.5°) and 1,3-dicaprin (m. p. 45.5°) were prepared using 1-iodohydrin (Alival) as the intermediate by the method described by Fischer.[5] 1-Monotritylglycerol, prepared as described by Verkade and Meerburg,[7] was used for the synthesis of 1,3-distearin (m. p. 79.5°), 1,3-dimyristin (m. p. 64.7°) and 1,3-dilaurin (m .p. 58°). The method is given in detail for 1,3-distearin.

1-Monotrityl glycerol (8.0 g.) was dissolved in a mixture of 25 ml. of chloroform and 13 g. of pyridine. While cooling the solution in an ice-bath, 19 g. of stearyl chloride was added slowly. After standing for four days at room temperature, the mixture was dissolved in ether and the solution was washed successively with water, 0.5 *N* sulfuric acid, 5% potassium carbonate solution and again with water. After drying over anhydrous sodium sulfate and distilling the ether from the filtered liquid, a pale yellow, viscid liquid remained. The liquid solidified slowly on standing at room temperature. The product was dissolved in 400 ml. of petroleum ether and cooled to 0°. Dry hydrogen chloride was passed into the solution for thirty minutes, during which time the diglyceride separated as a white solid. The mixture was allowed to stand at room temperature for one hour. After the addition of sufficient ether to effect solution, it was washed successively with 5% potassium carbonate solution and water. The solution was dried over anhydrous sodium sulfate, filtered, and evaporated to dryness. The 1,3-distearin was crystallized repeatedly from 95% alcohol; yield, 12 g. (80%); m. p. 79.5°.

Preparation of 2-Oleyl-1,3-dilaurin.—Oleyl chloride (3.6 g.) was added slowly to a solution of 1,3-dilaurin (5 g. in 13 g. of chloroform and 5 g. of quinoline) in a glass-stoppered flask. After refluxing for three hours on a steam-bath, the reaction mixture was allowed to stand overnight. It was then dissolved in petroleum ether and washed successively with 0.5 *N* sulfuric acid, 10% potassium carbonate solution and water. After drying over anhydrous sodium sulfate, the solution was filtered and evaporated to dryness under reduced pressure. The yellow liquid remaining was dissolved in ethyl ether and refluxed with activated charcoal for twenty minutes. After filtration the ether was removed from the filtrate and the colorless liquid remaining was redissolved in petroleum ether. Several crops of crystals were obtained as the solution was progressively cooled to −30°. The iodine values of the successive crops of crystals were 34.8, 35.0 and 35.2, respectively (calcd. for 2-oleyl-1,3-dilaurin, 35.2). The iodine value of the residue recovered from the mother liquor was 42.9. The two fractions having iodine values of 35.0 and 35.2 were combined and recrystallized several times from petroleum ether; yield, 6 g. (75%).

Anal. Calcd. for $C_{45}H_{84}O_6$: C, 74.95; H, 11.74. Found: C, 74.81, 74.78; H, 11.69, 11.60.

The physical and chemical constants for 2-oleyl-1,3-distearin, 2-oleyl-1,3-dipalmitin, 2-oleyl-1,3-dimyristin, and 2-oleyl-1,3-dicaprin, prepared in a similar manner, are given in Table I.

Proof of Structure.—Hydrogenation of the symmetrical monoöleo-disaturated triglycerides to the corresponding saturated analogs gave added support to the symmetrical structure (Table I). The hydrogenation procedure was similar to that described previously.[2,3]

Summary

2-Oleyl-1,3-dicaprin, -dilaurin, -dimyristin, -dipalmitin and -distearin have been prepared in high purity, their structure demonstrated by hydrogenation, and their melting points and refractive indices measured. These properties both increase numerically with increasing length of the carbon chain of the saturated fatty acids.

Unsaturated Synthetic Glycerides. V. Unsymmetrical Monoelaidyl-Disaturated and Monosaturated-Dielaidyl Triglycerides[1]

BY B. F. DAUBERT

The evident need of obtaining physical and chemical data on synthetic mixed triglycerides containing unsaturated acids for the purpose of characterizing more adequately those glycerides present as components in natural fats has been discussed recently in previous communications of this series.[2,3]

Elaidic acid, the *trans* isomer of oleic acid, does not occur free or combined in glycerides of natural fats so far as the author is aware. Notwithstanding this fact, however, the physical and chemical properties of this group of glycerides are of considerable interest for the purpose of comparison with the corresponding synthetic oleyl- and stearyl-glycerides.

It is well known that the melting point of a fat may be increased considerably through the process of elaidinization. The melting point data for the synthetic glycerides reported in this paper give ample verification to this observation.

Therefore, physical and chemical data are reported for a series of unsymmetrical monoelaidyl-

[d] 1-Stearyl-2,3-dicaprylin was also prepared from 1-monostearin and caprylyl chloride; m. p. 31.5°; molecular weight, 603 ± 6 (calcd. 610.93); *anal.* calcd. for $C_{37}H_{70}O_6$: C, 72.73; H, 11.55. Found: C, 72.56, 72.62; H, 11.36. 11.42.

disaturated and monosaturated-dielaidyl triglycerides.

Experimental

All saturated fatty acids used in this investigation were prepared as described in the first paper of this series.[2]

Elaidic acid was prepared by the method of Lyutenberg[4] using a highly purified oleic acid. Final crystallization of the acid from ethyl ether yielded a product melting at 44.5°. Saponification equivalent, 282.1 (calcd. 282.2); iodine value (Wijs), 89.8 (calcd. 89.9); refractive index at 50.0°, 1.44682.

Preparation of Elaidyl Chloride.—In a previous communication[5] from this Laboratory it was indicated that oxalyl chloride serves as a satisfactory acylating agent for elaidic acid.

Elaidic acid (38 g.) in a round-bottom flask was treated with oxalyl chloride (38 g.) and the mixture warmed at a bath temperature of 70–80°. After one-half hour the vigorous reaction ceased, but the reaction mixture was refluxed for an additional three hours at 70–80°. Excess oxalyl chloride was removed by distillation at a bath temperature of 100°. The elaidyl chloride was then rapidly distilled at 168–170° under reduced pressure (1 mm.). The distillation yielded 27 g. (91%) of a water-white product.

Anal. Calcd. for $C_{18}H_{33}OCl$: Cl, 11.78. Found: Cl, 11.68, 11.68.

All saturated fatty acid chlorides were prepared with thionyl chloride after the method described by McMasters and Ahmann.[6]

Preparation of 1-Monoelaidin.—Elaidyl chloride (21 g.) was added slowly to a mixture of acetone-glycerol[7] (8 g.), quinoline (15 ml.) and chloroform (20 ml.). The mixture after standing at room temperature twenty-four hours was dissolved in ethyl ether (300 ml.) and the solution washed successively with cold 0.5 *N* sulfuric acid, 5% potassium carbonate solution and distilled water. After drying the ether solution over anhydrous sodium sulfate, it was reduced, *in vacuo*, to a volume of 50 ml. Concentrated hydrochloric acid (100 ml.) was added with constant stirring to the solution, cooled in an ice-bath. After standing one-half hour, ice-water (400 ml.) was added and the flocculent white precipitate which separated was washed repeatedly with ice water until free of mineral acid. The product, after solution in ethyl ether, was dried over anhydrous sodium sulfate. On cooling the filtered liquid to 5° for twenty-four hours crystallization occurred. A constant melting point of 58.5° was obtained after crystallization from a 1:1 mixture of ether and petroleum ether. Molecular weight, 354 ± 2 (calcd. 356.23); iodine value, 71.0 (calcd. 71.2).

The 1-monoglyceride of elaidic acid was also prepared by a slight modification of the method of Malkin and Shurbagy.[7]

Dry hydrogen chloride was passed into a mixture of elaidic acid (7 g.) and acetone-glycerol (15 g.) until the mixture liquefied (about 20 minutes). The mixture was diluted to a total volume of 50 ml. with ethyl ether and treated with concentrated hydrochloric acid (50 ml.). The precipitated product was crystallized from a 1:1 mixture of ethyl ether and petroleum ether as described under the preceding method; m. p. 58.5°. Mixed with the 1-monoelaidin prepared above, no melting point depression was observed.

For further identification each compound prepared by the two independent methods was hydrogenated to 1-monostearin, m. p. 81.5°. Mixed melting points with a 1-monostearin prepared from acetone-glycerol and stearyl chloride[8] showed no depression. Preliminary X-ray investigations show the 1-monoelaidin to have a diffraction pattern typical of all 1-monoglycerides examined to date.[9]

Preparation of 1-Elaidyl-2,3-dimyristin.—1-Monoelaidin (2 g.) was dissolved in a mixture of quinoline (10 ml.) and chloroform (10 ml.) and to this solution myristyl chloride (2.8 g.) was added slowly. The mixture was refluxed on a steam-bath for four hours. After the addition of ethyl ether (200 ml.), the solution was washed successively with cold 0.5 *N* sulfuric acid, 5% potassium carbonate solution, distilled water and dried over anhydrous sodium sulfate. The solution was filtered and the ether removed by distillation under reduced pressure. Fractional crystallizations from mixtures of ether and petroleum ether, and ether and 95% alcohol, yielded a product melting at 39.5°.

Anal. Calcd. for $C_{49}H_{92}O_6$: C, 75.72; H, 11.93. Found: C, 75.49, 75.61; H, 11.84, 11.79.

Other analytical constants together with the melting points of the saturated analogs obtained by a hydrogenation procedure described in a previous paper,[2] for this compound and 1-elaidyl-2,3-dilaurin, 1-elaidyl-2,3-dicaprin, 1-elaidyl-2,3-dicaprylin are listed in Table I.

Preparation of 1-Myristyl-2,3-dielaidin.—To a solution of 1-monomyristin (3.5 g.) in a mixture of quinoline (5 ml.) and chloroform (10 ml.), elaidyl chloride (8.5 g.) was added slowly. The mixture, after refluxing on a steam-bath for four hours, was dissolved in petroleum ether (200 ml.) and the solution washed successively with 0.5 *N* sulfuric acid, 5% potassium carbonate solution and distilled water. The solution was then dried over anhydrous

sodium sulfate and filtered. Crystallization occurred on cooling the solution to −20° overnight. Repeated fractional crystallizations from petroleum ether and finally 95% alcohol gave a product melting at 40.0°.

Other analytical constants and melting points of the saturated analogs obtained by hydrogenation for this compound and for 1-lauryl-2,3-dielaidin, and 1-capryl-2,3-dielaidin are also given in Table I.

Discussion

Bömer and Kappeller[12] reported a melting point of 44.8° for the 1-monoelaidin they prepared from elaidyl chloride and acetone-glycerol. Unfortunately, these investigators did not report the method by which they determined the melting point nor did they report other physical and chemical constants for the compound. Preliminary warming and cooling curves have established the existence of at least three forms for 1-monoelaidin. Form I melts at 58.5°, Form II at 44.0° and Form III at 17.6°. The melting point reported by Bömer is in good agreement with the melting point of Form II. This suggests, perhaps, that the melting point (44.8°) of the 1-monoelaidin prepared by these investigators was not that of the stable phase.

The mixed triglycerides, 1-elaidyl-2,3-distearin (m. p. 61.0°), and 1-elaidyl-2,3-dipalmitin (m. p. 51.0°) prepared from 1-monoelaidin were in good agreement with those previously reported by Bömer and Kappeller, as also were 1-stearyl-2,3-dielaidin (m. p. 49.5°) and 1-palmityl-2,3-dielaidin (m. p. 46.0°).

It will be observed from the data in Table I that the melting points of the 1-elaidyl-2,3-disaturated triglycerides are, on the average, approximately 20° lower than their fully saturated analogs, and, on the average, approximately 15° higher than the same triglycerides containing an oleyl in place of the elaidyl group. Data for the latter have been reported in a previous paper.[2] Thus, the melting point relationships show the mixed triglycerides containing one elaidyl group to be intermediate between those containing one oleyl group and one stearyl group, respectively, the other saturated acids in the molecule, of course, being the same.

The above relationship also holds true for the series of unsymmetrical monosaturated-dielaidins, except that the magnitude of difference in average melting point is larger between those glycerides containing two elaidyl and those containing two oleyl groups. The average difference in melting point is about 30°.

It may also be observed, in comparing the melting point data of the two series of triglycerides (Table I) that the double bond in the single elaidyl group has the greater influence on the melting point, particularly in lower members of the series. The converse seems to be true for the monosaturated-dielaidins, *i.e.*, the chain length of the elaidyl groups has the greater influence on the melting point.

The refractive indices of the new monoelaidyl-disaturated triglycerides and the monosaturated-dielaidins are measurably lower than the corresponding synthetic mixed triglycerides containing oleic acid. The change in refractive index with change in temperature ($dn/dt = 0.00038$) is approximately the same as that reported previously for other series.

Molecular weights and iodine values were used as criteria for purity in preference to combustion data. The carbon and hydrogen values, however, were determined for one compound as proof against errors or confusion.

Summary

Physical and chemical data are reported for seven new unsaturated synthetic glycerides, 1-elaidyl-2,3-dimyristin, 1-elaidyl-2,3-dilaurin, 1-elaidyl-2,3-dicaprin, 1-elaidyl-2,3-dicaprylin, 1-myristyl-2,3-dielaidin, 1-lauryl-2,3-dielaidin and 1-capryl-2,3-dielaidin.

Data are also reported for 1-stearyl-2,3-dicaprylin.

Specific Heats at Low Temperatures of Calcium Sulfite, Sodium Sulfite, and Manganese Dithionate Dihydrate[1]

BY K. K. KELLEY[2] AND G. E. MOORE[3]

As part of its program of supplying fundamental thermochemical data for substances of metallurgical interest, the Bureau of Mines has reported previously on the low-temperature specific heats and entropies of manganese[4] and eleven of its inorganic compounds.[4,5] The present paper adds another compound to this list, the dithionate-dihydrate, and also presents similar data for calcium and sodium sulfites, as these substances are of interest in connection with certain hydrometallurgical methods of extracting manganese.

This work represents the first measurements of low-temperature specific heats of any members of the two classes of substances concerned—sulfites and dithionates—and is of some interest from this viewpoint alone.

Materials

Calcium sulfite was prepared from C. P. calcium carbonate, low in alkali. The fine carbonate was suspended in a flask of water, previously boiled to remove air, and allowed to react with a rapid stream of sulfur dioxide at 80° in a system protected from contact with air. The reaction was continued until virtually all the carbonate was decomposed, as shown by intermittent tests. (The carbonate test consisted of removing a sample from the flask, acidifying with strong acid, and leading the evolved gas slowly through a concentrated iodine–potassium iodide solution to remove sulfur dioxide and then through barium hydroxide solution to detect carbon dioxide.) When the reaction was considered complete, the temperature was raised and the flask boiled dry while the sulfur dioxide stream was continued. At this point the product gave no test for sulfate. It was transferred to a high-vacuum system and heated five hours at 155°, after which a direct test for water gave 7.1%. (Röhrig's[6] claim that calcium sulfite may be dehydrated to hemihydrate at 80° and to the anhydrous salt at 100° is incorrect.) Heating was continued several hours longer at temperatures up to 245°, with but little additional removal of water. At about 275° water removal again commenced, and the temperature was raised slowly to 310° and held for two hours until evolution of water stopped. At this point 0.5% water remained in the material, and it was still free of sulfate. Seven hours of heating and pumping at 390–400° was finally required before the water content was reduced to a negligible quantity. During the latter process some sulfate was formed and some sulfite decomposed. Analyses were made for CaO, $SO_4^=$, CO_2, and H_2O. The results corresponded to 98.75% calcium sulfite, 0.9% calcium sulfate, 0.24% calcium oxide, 0.07% calcium carbonate, and 0.02% water, and it was felt that this product was about as good as could be obtained in any reasonable time. A 117.96-g. sample was used in the measurements.

Reagent-grade anhydrous sodium sulfite was used without further purification. Analyses gave 98.8% sodium sulfite and 0.90% sodium sulfate. It required 158.82 g. to fill the calorimeter.

Manganese dithionate is difficult to prepare in pure form, and after some preliminary experiments the following procedure was adopted. A suspension of reagent-grade manganese dioxide in a flask of water was cooled with ice–salt mixture and sulfur dioxide passed from a cylinder until reaction was complete. The sulfur dioxide flow was maintained slow enough to prevent the temperature in the flask from rising above 7°. The solution, containing mainly manganese dithionate but also some manganous sulfate, was filtered, diluted with water and treated with enough barium hydroxide solution to precipitate the sulfate and all the manganese. After filtering, the solution contained mainly barium dithionate, of which a fraction was crystallized out after low-temperature evaporation. The crystalline barium dithionate then was filtered off, redissolved in water, and titrated with reagent-grade manganous sulfate to precipitate barium sulfate and leave manganese dithionate in solution. This final solution was evaporated slowly under vacuum at 35° until a satisfactory yield of hydrated crystalline manganese dithionate was obtained. It was originally intended to dry these crystals to anhydrous form, but this was found to be impossible without considerable sacrifice of purity, because of the instability of manganese dithionate with respect to manganous sulfate and sulfur dioxide. Prolonged drying, for several weeks, at 35° in a warmed desiccator, first over concentrated sulfuric acid and then over phosphorus pentoxide, and finally under 10^{-4} mm. pressure at 45° for several hours, resulted in a sample of manganese dithionate-dihydrate that had decomposed only slightly. Under these conditions, dehydration ceased at the dihydrate point. Experiments on further dehydration at higher temperatures (up to 100°) resulted in too much decomposition. The product used in the measurements was analyzed and found to contain 99.0% $MnS_2O_6 \cdot 2H_2O$, 0.58% BaS_2O_6, and 0.42% $MnSO_4$. In computing the analytical results it was assumed that all $SO_4^=$ was present as manganous sulfate from decomposition of manganese dithionate, as the latter is much less stable than barium dithionate. The odor of sulfur dioxide was detectable over the preparation after standing in a sealed container, but the decomposition at room temperature is quite slow. This was shown by analyses for sulfate made before and after the specific heat measurements, which indicated no significant change. The specific heat measurements were made using a 123.18-g. sample.[7]

Measurements

The method and apparatus[8] used previously again were employed. The results of the specific heat measurements are listed in Table I and shown plotted against temperature in Fig. 1. The defined calorie (1 calorie = 4.1833 int. joules) is used throughout, and the molecular weight values in the headings of Table I are in accord with the 1941 international atomic weights. The calcium sulfite data have been corrected for the impurities previously listed, assuming the specific heats to be additive. The cor-

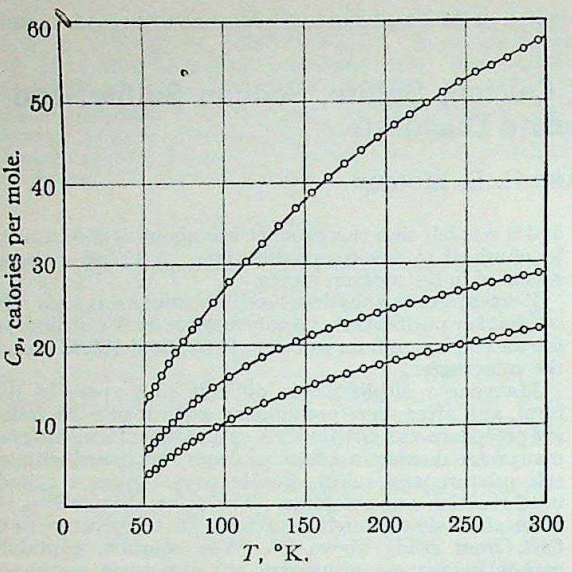

Fig. 1.—Specific heats of $CaSO_3$, Na_2SO_3, and $MnS_2O_6 \cdot 2H_2O$: upper curve, $MnS_2O_6 \cdot 2H_2O$; middle curve, Na_2SO_3; lower curve, $CaSO_3$.

rection amounted to 0.00 to 0.14%, depending on the temperature. Likewise, the sodium sulfite results were corrected for the 0.9% sodium sulfate content. In this instance, the correction varied from 0.07 to 0.16%. The impurity correction of the manganese dithionate-dihydrate data was the largest, on the average, of the three substances under consideration, 0.04 to 0.39%, depending on the temperature.

The two sulfites were measured in our best calorimeter, while the dithionate was measured in an older one that had been in use previously. This was considered advisable because of the possibility of the decomposition pressure of the dithionate reaching a value that would burst the container. This appears theoretically possible, according to available thermochemical data, but it did not occur because of the slowness of decomposition. It is believed that the measurements of calcium and sodium sulfites are accurate on the average to within 0.3% and those of the manganese dithionate-dihydrate to within 0.5%, the difference being attributable to the use of the older calorimeter for the last substance. The average deviation of the results from a smooth curve is considerably smaller than the error claimed, being less than 0.1%.

As is seen from Fig. 1, no abnormal behavior was noted for these compounds, and the course of their specific heat curves needs no discussion. There are no previous data with which to compare any of the present measurements.

Entropies at 298.16°K.

The entropies at 298.16°K. were calculated in the usual manner. Between 50.12° and 298.16°K., graphical integrations were made under the C_p against log T curves, $\int_{50.12}^{298.16} C_p \, d \ln T$. The entropy increments lying below 50.12°K. were obtained by extrapolation. This was accomplished by fitting the experimental data over the entire experimental range by the following series of Debye and Einstein functions

$$CaSO_3: \; C_p = D\left(\frac{201}{T}\right) + 2E\left(\frac{322}{T}\right) + E\left(\frac{720}{T}\right) + E\left(\frac{1316}{T}\right)$$

$$Na_2SO_3: \; C_p = D\left(\frac{175}{T}\right) + 3E\left(\frac{256}{T}\right) + 2E\left(\frac{860}{T}\right)$$

$$MnS_2O_6 \cdot 2H_2O: \; C_p = D\left(\frac{91.7}{T}\right) + 4E\left(\frac{197}{T}\right) + 4E\left(\frac{501}{T}\right) + 2E\left(\frac{857}{T}\right) + 2E\left(\frac{1205}{T}\right)$$

Only the first two functions are of significance in each instance in computing the extrapolated portion of the entropy. The results are listed in Table II.

TABLE II

ENTROPIES AT 298.16°K. (CAL./DEG. MOLE)

	$CaSO_3$	Na_2SO_3	$MnS_2O_6 \cdot 2H_2O$

sodium sulfate.[10] Thus, in these two instances, the effect on the entropy of removing one oxygen atom from a sulfate group to form a sulfite group is a decrease of about 1 unit. A difference of this order of magnitude reasonably may be expected between sulfates and sulfites of other metals, and this offers a means of estimating the entropy of the sulfite when that of the sulfate is known or *vice versa*.

The entropy of manganese dithionate-dihydrate may be subject to some correction because of unextracted magnetic entropy; but sufficient information on this point is not available at present, and it is not taken account of in the error assigned to the entropy value in Table II. In view of recent observations[11] on the approximate constancy of the entropy of water of crystallization, one would estimate the entropy of anhydrous manganese dithionate to be about 45 units at 298.16°K. and that of the hexahydrate to be about 110 units.

(11) Kelley and Moore, *ibid.*, **65**, 2340 (1943).

Summary

Low-temperature specific heat measurements, throughout the temperature range 51 to 298°K., have been made of calcium sulfite, sodium sulfite, and manganese dithionate-dihydrate.

The respective entropies at 298.16°K. are 24.2 ± 0.3, 34.9 ± 0.4, and 66.7 ± 1.0.

It is suggested that the difference in entropy between a sulfate and a sulfite group in a solid compound is about 1 unit at 298.16°K.

The Crystal Structure of Potassium Silver Carbonate, $KAgCO_3$[1]

BY JERRY DONOHUE[2] AND LINDSAY HELMHOLZ

Introduction.—The determination of the structure of potassium silver carbonate, which is colorless, was undertaken in conjunction with that of silver carbonate,[3] which is yellow, for the purpose of establishing the character of the silver-oxygen bond in those crystals, and discussing the difference in color in terms of the rule suggested by Pitzer and Hildebrand,[4] which states that the color of a compound formed from colorless ions is related to the amount of "covalent character" in the bond between these ions. Since the electronic structure of the carbonate group can readily be interpreted in terms of single bond double bond resonance, any effect of silver to oxygen covalent bond formation on the normal ionic configuration could be discussed in a relatively straightforward manner. Unfortunately an accurate structure of silver carbonate, in which appreciable covalent bond formation is suggested both by approximate distances and the rule of Pitzer and Hildebrand, is not yet available.

Experimental.—Potassium silver carbonate was prepared by the method of de Schulten.[5] Silver nitrate solution (0.25 *m*) was added dropwise to 50% potassium carbonate saturated with potassium bicarbonate. The yellow precipitate first formed turned white on standing. Complete solution takes place on heating. Slow cooling of this hot solution in a Dewar flask gives needle-like crystals, elongated in the *c* direction. The crystals prepared in this manner had all the properties described by de Schulten. Goniometric examination showed the crystals to be possibly orthorhombic, there being well-developed (100) and (110) faces ($a:b = 3.54:1$). Laue photographs showed the Laue symmetry D_{2h}-mmm, this establishing the orthorhombic symmetry.

Oscillation photographs were taken with the *c* axis vertical, using CuKα radiation. One oscillation photograph using Mo Kα radiation was taken for the purpose of obtaining more layer lines. The dimensions of the unit cell, as determined by indexing those photographs, were found to be $a_0 = 20.23$ Å., $b_0 = 5.75$ Å., $c_0 = 5.95$ Å. (all ±0.5%) ($a:b:c = 3.521:1:1.036$). Indexing of symmetric and asymmetric Laue photographs ($\lambda_{min.} = 0.24$ Å.) showed no first order reflections requiring a larger unit cell.

The number of molecules in the unit cell (using de Schulten's density value of 3.77 g./cc.) is calculated to be 7.66. Assumption of eight molecules in the unit cell gives a calculated density of 3.94 g./cc. de Schulten's value is low probably due to the fact that potassium carbonate clings tenaciously to the surface of the crystals as prepared. Attempts to measure the density also gave low values.

The intensities of the reflections on the oscillation photographs were estimated by means of the multiple film technique,[6] and by taking pictures of different exposure times over the same range. It was found necessary to correct the intensities for absorption; the correction factor was derived by integrating the expression for the path of beam through the crystal (assumed to be bathed by the beam) in accordance with the relation $I = I_0K|F|^2 e^{-\mu P} dp$ where I = the corrected intensity, I_0 = the incident intensity, K = the product of the Lorentz, polarization and temperature factors, F = the structure factor, μ = the absorption coefficient, and P = the path length of the beam through the crystal. The path length is expressed as function of: A, the width of the crystal; α, the angle through which the crystal has been rotated; and φ, the azimuthal scattering angle. Two cases are considered: (1) the incident and the emergent rays pass through the same crystal face, and (2) these two rays pass through different crystal faces. For case (1), the simplified expression is $I = I_0K|F|^2 \frac{A \sin\alpha}{\mu c}$, where $c = 1 + \frac{\sin\alpha}{\sin(\alpha - \varphi)}$. For case (2), the simplified expression is $I = I_0K|F|^2 \left(\frac{\sin(2\alpha - \varphi)}{\mu^2}\right)$. In

simplifying the integrated expressions, certain terms were found to be negligible because of the large value of μ (575).

The validity of the correction factors was checked by calculating the F values of certain reflections which appear when the crystal has been rotated through different angles, and hence appear on different films with different intensities. Some of these comparisons are shown in Table I.

TABLE I

(*hkl*)	Observed intensity	α	F, corrected
(132)	2.50	30°	20
	1.40	41°	18
(532)	4.15	12°	32
	1.50	63°	25
(752)	2.50	33°	17
	1.45	77°	16

Determination of the Structure.—The following regular absences, observed on the oscillation photographs: (hkl) with $h + k + l \neq 2n$, (hkO) with $h \neq 2n$ and $k \neq 2n$, $(h0l)$ with $h \neq 2n$ and $l \neq 2n$, and $(0kl)$ with $k \neq 2n$ and $l \neq 2n$, establish the space group uniquely as $D_{2h}^{27} - Ibca$.[7] The sets of positions for the space group $D_{2h}^{27} - Ibca$ are[7]

$(0\ 0\ 0;\ \tfrac{1}{2}\ \tfrac{1}{2}\ \tfrac{1}{2}) +$

8:	(a)	0	0	0;	0	$\frac{1}{2}$	$\frac{1}{2}$;	$\frac{1}{2}$	0	$\frac{1}{2}$;	$\frac{1}{2}$	$\frac{1}{2}$	0
	(b)	$\frac{1}{4}$	$\frac{1}{4}$	$\frac{1}{4}$;	$\frac{1}{4}$	$\frac{3}{4}$	$\frac{3}{4}$;	$\frac{3}{4}$	$\frac{1}{4}$	$\frac{3}{4}$;	$\frac{3}{4}$	$\frac{3}{4}$	$\frac{1}{4}$
	(c)	x	0	$\frac{1}{4}$;	$\bar{x}$	0	$\frac{3}{4}$;	x	$\frac{1}{2}$	$\frac{3}{4}$;	$\bar{x}$	$\frac{1}{2}$	$\frac{1}{4}$
	(d)	$\frac{1}{4}$	y	0;	$\frac{3}{4}$	$\bar{y}$	0;	$\frac{3}{4}$	y	$\frac{1}{2}$;	$\frac{1}{4}$	$\bar{y}$	$\frac{1}{2}$
	(e)	0	$\frac{1}{4}$	z;	0	$\frac{3}{4}$	$\bar{z}$;	$\frac{1}{2}$	$\frac{3}{4}$	z;	$\frac{1}{2}$	$\frac{1}{4}$	$\bar{z}$
16:	(f)	x	y	z;	x	$\bar{y}$	$\frac{1}{2}$	z;	$\frac{1}{2} - x, y, \bar{z}$;		$\bar{x}, \frac{1}{2} - y, z$;		
		$\bar{x}$	$\bar{y}$	$\bar{z}$;	$\bar{x}, y, \frac{1}{2} + z$;				$\frac{1}{2} + x, \bar{y}, z$;		$x, \frac{1}{2} + y, \bar{z}$.		

Into a unit cell of such a spatial symmetry must be placed 8 silver atoms, 8 potassium atoms, 8 carbon atoms, and 24 oxygen atoms.

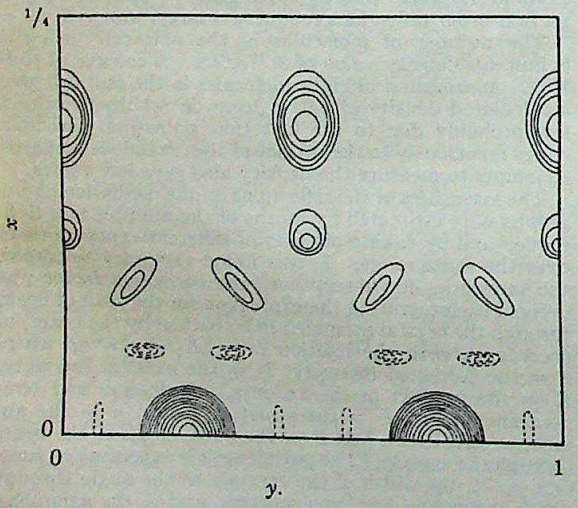

Fig. 1.—(x, y). Projection of electron density of 1/4 of the unit cell on (001). Contours are drawn at 12.5, 25, 37.5, 50, and at 100 to 800 in 100 unit intervals, in terms of an arbitrary scale.

The silver atoms must be assigned to the position 8(e) to account for the fact that reflections for which $l \neq 2n$ are exceedingly weak compared to those for which $l = 2n$. Positions 8(a) and 8(b) are excluded by the presence of strong reflections with h or k odd. With the silver atoms assigned to the positions 8(e), the signs of all the F_{hk0}'s can be determined. A Fourier projection on the xy plane made by using the 42 available $(hk0)$ reflections is shown in Fig. 1. The peaks at $x = 0, y = \frac{1}{4}$ and $x = 0, y = \frac{3}{4}$ are clearly those of the silver atoms. The next largest peak at $x \approx 0.185, y = \frac{1}{2}$ is due to the potassium atom superimposed on one oxygen atom of the carbonate group. The remainder of the carbonate group is also clearly shown. The peaks drawn in with dotted contours are believed to be spurious. No reasonable interpretation could be given to any of these spurious peaks. The Fourier projection places the potassium atoms, the carbon atoms, and eight oxygen atoms in the positions 8(c); the remaining sixteen oxygen atoms must fall into the general positions 16(f). There are thus in all seven parameters to be determined.

As a start in the parameter determination, the carbonate group was assumed to have the same configuration and dimensions as in calcite.[8] The intensities of the $(h00)$ reflections can thus be considered to be functions of two variables: the x parameter for the potassium atom, and the x parameter for the carbonate group. Using the eleven available $(h00)$ reflections, limits for these parameters were obtained by calculating and comparing F values in the usual way. Atomic scattering factors taken from the tables of Pauling and Sherman,[9] and a temperature factor with $\beta = 1.5$ were used in these calculations.

Using these x parameters, the z parameters for the silver atoms and the oxygen atoms in the general positions (O_{II}) can now be obtained in the same way from F values of (hkl) reflections. If $z_{O_{II}} = z_{Ag} + 0.250$ the silver atom is bisphenoidally surrounded by four oxygen atoms. Any other arrangement is chemically unreasonable, unless the silver atom is two coördinated, and this structure leads to improbable interatomic distances. The F values of the reflections of the type $h \neq 2n, k \neq 2n, l = 2$ were found to be very sensitive to small changes in the silver parameter, since its value is very close to $\frac{1}{8}$. The y parameter of O_{II} can now be calculated, because of the assumption made concerning the configuration and dimensions of the carbonate group. A check on the parameters of O_{II} is found in the F values for reflections of the type $h \neq 2n, k = 2n, l \neq 2n$, since none of the other atoms in the cell contribute to these reflections.

The final parameter values are

K	$x =$	-0.182		
C	$x =$	.122		
O	$x =$	.187		
Ag	$z =$	.128		
O_{II}	$x =$	.089	$y = 0.146$	$z = 0.378$

We believe it unlikely that any of the potassium

[a] Not observed because of experimental arrangement.

or silver parameters are in error by as much as ±0.002, since variation of this magnitude leads to serious discrepancies between observed and calculated F values. The oxygen and carbon parameters may be in error by more than this amount if there is a distortion from the assumed configuration of the carbonate group. However, a big distortion is rather unlikely.

Calculated and observed F values are shown in Table II.

Discussion

A projection of a portion of the unit cell on (100) is shown in Fig. 2. The silver atoms are surrounded by four oxygen atoms at 2.42 ± 0.05 Å. The potassium atom has nine close oxygen neighbors, one at 2.65 ± 0.08 Å., and four each at 2.88 Å. and 3.00 Å. all ±0.05 Å. The shortest potassium to oxygen distance is the only coördination the potassium atom has in that direction.

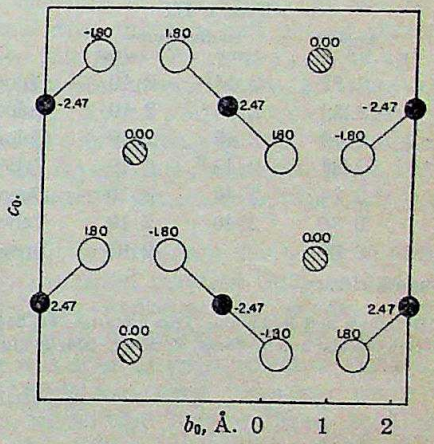

Fig. 2.—Projection of a portion of the unit cell on (100). Numbers give heights of atoms in Å. above plane of diagram ($x = 1/2$). Black circles represent carbon atoms, open circles, oxygen atoms and shaded circles, silver atoms. In this projection, the positions of the potassium atoms coincide with those of the carbon atoms.

The oxygen atoms in the positions 8(c) are octahedrally coördinated; in addition to being bonded to the carbon atom in the carbonate group, they are surrounded by five potassium atoms (one at 2.65 Å., two each at 2.88 Å. and 3.00 Å.) in such a way as to form a deformed octahedron. The oxygen atoms in the general positions have a more nearly triangular coördination, being close to two silver atoms (at 2.42 Å.), in addition to the carbonate group bond. Their next nearest neighbor is a potassium atom, at 2.88 Å.

Although we have made an assumption concerning the internal structure of the carbonate group, we feel that any significant deviation from the normal configuration would have been detected. Since the X-ray data indicate that such deviation is unlikely, it is probable that the carbonate group has its usual structure[8] in this crystal.

It is seen that the carbonate groups are tipped about 42° out of a plane parallel to (001). The bind-

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

ing between the silver atoms and the oxygen atoms is staggered in such a way that there are strong forces in both the *b* and *c* directions. This is in agreement with the observed growth of the crystals.

A preliminary report on the structure of silver carbonate[3] follows: Laue and rotation pictures showed the crystals to be monoclinic with $a_0 = 4.83$ Å., $b_0 = 9.52$ Å., $c_0 = 3.23$ Å., $\beta = 92.7°$, $z = 2$ (calcd. 1.99). The probable space group is C_2^2-$P2_1$. Patterson and Fourier analysis of (*hk*0) data gives positions for the silver atoms and probable positions for the carbonate groups. The silver atoms are surrounded by deformed tetrahedra of oxygen atoms at about 2.3 Å. The binding is somewhat similar to that in potassium silver carbonate, there being a staggered arrangement of bonds between the silver and oxygen atoms.

The table given by Helmholz and Levine[10] can now be extended:

TABLE III

Compound	Ag–O,[a] Å.	Radius Sums Ionic	Radius Sums Covalent	Color
$AgClO_3$[11]	2.51	2.46	2.19	Colorless
Ag_2SO_4	2.50	2.46	2.19	Colorless
$KAgCO_3$	2.42	2.46	2.19	Colorless
Ag_3PO_4	2.34	2.46	2.19	Yellow
Ag_3ASO_4	2.34	2.46	2.19	Deep red
Ag_2CO_3	2.30	2.46	2.19	Yellow
Ag_2O	2.06		2.02	Brown-black

[a] Average distance.

(10) L. Helmholz and R. Levine, THIS JOURNAL, **64**, 354 (1942).
(11) I. Naray-Szabo and J. Pocza, *Z. Krist.*, **104**, 28 (1942).

The correlation between the color and the bond distance is in reasonable accord with the rule of Pitzer and Hildebrand.[4] In view of the nature of the absorption process,[12] it seems probable that the *change* in absorption when, for example, silver is substituted for sodium in salts of these acids, rather than the color of the silver salt itself, should serve as a criterion for the amount of covalent character, in crystals of the type considered here. The apparent discrepancies in Table III of potassium silver carbonate and silver arsenate can be explained on this basis, and would lead, in the case of silver arsenate, to the reasonable conclusion that the tendency of the arsenate group to share electrons is greater than that of the phosphate group.

Summary

The crystal structure of potassium silver carbonate has been determined. The crystal is orthorhombic holohedral, with $a_0 = 20.23$ Å., $b_0 = 5.75$ Å., $c_0 = 5.95$ Å. The space group is D_{2h}^{27}-*Ibca*. The Ag-O bond distance was found to be 2.42 Å., and this is discussed in relation to other silver salts, including silver carbonate, for which a preliminary structure is given. The application of the rule of Pitzer and Hildebrand to the probable nature of this bond is also discussed.

Normal and Pseudo Structures of 8-Benzoyl-1-naphthoic Acid and Derivatives[1,2]

BY H. E. FRENCH AND J. E. KIRCHER

An earlier paper from this Laboratory[3] gave evidence for both the symmetrical and the unsymmetrical forms for 1,8-naphthalyl dichloride. This work has now been extended to the 8-benzoyl-1-naphthoic acid and certain of its derivatives.

8-Benzoyl-1-naphthoic Acid.—This acid was prepared by the method of Mason.[4] Upon crystallization from ethanol, 70% acetic acid, or chloroform, we obtained a product melting at 110°, as reported by Mason. From xylene, cyclohexane or toluene, the substance melted at 129–130°, checking the melting point reported by Knapp.[5] A sample of the 110° melting material heated to 90° for four hours under a watch glass was found to melt at 154°. From all of these samples, material of melting point 110° or 129–130° could be obtained by crystallization from the proper solvent.

Absorption curves were plotted for the acids melting at 110° and 129°, in chloroform solution, and for the 129° variety after refluxing in cyclohexane solution for twenty-four hours. The curves were all of the same form, with maximum and minimum points in the same regions. These maximum and minimum points are given in Table I. These curves for the acid are similar to the curve for diphenylnaphthalide, and bear no resemblance to the curve for dibenzoylnaphthalene which shows only one minimum and one maximum. Data for these curves are also given in Table I.[6]

Diphenylnaphthalide, ditolylnaphthalide and naphthalic anhydride, all of which have a ring structure across the 1,8 positions, were found to

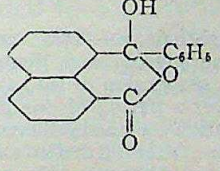
Normal ester	2700	2946				
Diethyl naphthalate	2665	2950				
1,8-Dibenzoyl-naphthalene	2754	2910				

Absorption spectra measurements were made in cyclohexane solution unless otherwise noted.

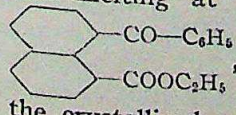
show a blue fluorescence under ultraviolet light, while the ethyl ester of 8-benzoyl-1-naphthoic acid and 1,8-diethylnaphthalate, which do not possess this closed structure, appear gray-white under the ultraviolet lamp. The samples of 8-benzoyl-1-naphthoic acid of various melting points all showed the blue fluorescence, as did 8-toluyl-1-naphthoic acid.

It is concluded from the evidence of absorption spectra and ultraviolet fluorescence that the acid in solution is very largely, if not completely, in the form of the cyclic compound of the structure

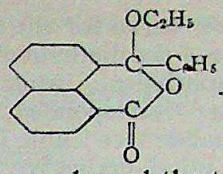


Ethyl Derivatives of 8-Benzoyl-1-naphthoic Acid.—Mason[4] prepared the acid chloride by the action of thionyl chloride on the acid of melting point 110°. The chloride was crystallized from benzene, and melted at 125–127°, and gave with ethyl alcohol an ethyl derivative melting at 166°. We repeated these reactions and obtained results which corresponded to those of Mason.

We also obtained an ethyl derivative by the action of the silver salt of the acid on ethyl iodide. This ethyl derivative melted at 134°. A mixture of the two ethyl derivatives gave a melting point depression of 15°. Without question the derivative melting at 134° was the normal ester,



, and the product obtained from the crystallized acid chloride and ethyl alcohol possessed some other structure, probably that of



the pseudo ester . Analyses for carbon and hydrogen showed the two compounds to be isomeric.

The normal ester, melting at 134°, gave the gray-white fluorescence of the open compounds, under the ultraviolet light, while the pseudo ester, melting at 166°, showed the blue fluorescence characteristic of the closed structure across the 1,8 positions.

Experiment with a known mixture showed that nearly quantitative separation of the two isomers could be accomplished by chromatographic adsorption on alumina from a benzene–petroleum ether solution. The crude product from the reaction of ethyl alcohol on the recrystallized chloride was dissolved in the benzene–petroleum ether mixture and passed through the column of alumina. As in the case of the known mixture, the isomer melting at 134° was adsorbed in the first layer, and fluoresced gray-violet, while the isomer melting at 166° was adsorbed in the second layer, and fluoresced light blue. In these experiments the high melting ester predominated.

In certain experiments the chloride was prepared by the usual reaction but, instead of crystallizing from benzene, the excess of thionyl chloride was distilled off and the brown oil remaining was treated with absolute alcohol. The reaction here was very vigorous, quite unlike those in which the recrystallized acid chloride were used. When chromatographed, the same two ethyl derivatives were obtained, but with the low melting form predominating. The acid chloride used in these experiments was prepared in some cases from acid melting at 110° and in other cases from acid melting at 130°. The results, however, corresponded throughout as shown in the following table.

TABLE II

ETHYL DERIVATIVES OF 8-BENZOYL-1-NAPHTHOIC ACID

M. p., °C., acid	Reagent for chloride	M. p., °C., chloride	% ratio of isomers m. p. 166°/m. p. 134°
110	$SOCl_2$	oil	15/85
110	$SOCl_2$	oil	5/95
110	$SOCl_2$	125	87/13
130	$SOCl_2$	oil	23/77
130	PCl_3	oil	33/67
130	$SOCl_2$	125	96/4

The recrystallized acid chloride with benzene and aluminum chloride gave diphenylnaphthalide in yields of from 25 to 50% of theoretical. No dibenzoylnaphthalene could be isolated from any of these reactions. When the acid chloride was used in the form of an oil, only hydrogen chloride and tars were obtained.

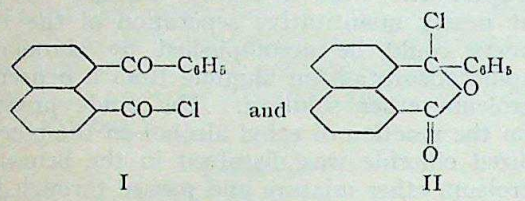
The absorption curve for the true ester corresponded to those of the diethylnaphthalate and the 1,8-dibenzoylnaphthalene, while the curve for the pseudo ester corresponded to that for the diphenylnaphthalide (see Table I). It is evident, then, that the ethyl derivative melting at 134° is the true ester and the one melting at 166° is the pseudo ester.

8-Benzoyl-1-naphthoyl Chloride.—As shown in Table II, the ratio of pseudo ester to the true ester in the reaction between the acid chloride and ethyl alcohol, can be practically inverted at will. There seems to be no doubt as to the existence of two chlorides represented by the formulas



I II

As pointed out in an earlier section of this paper, these chlorides differ in physical properties, one being an oil and the other a crystalline solid, as well as in the rates with which they react with ethyl alcohol. The recrystallized compound, no doubt represented by Formula II, yields diphenylnaphthalide in the Friedel–Crafts reaction, while the isomeric compound yields only tars and hydrogen chloride under the same conditions. The absorption curve for the chloride recrystallized from benzene was plotted and the maximum and minimum points are given in Table I. These points occur in the regions which characterize both the closed structures, such as diphenylnaphthalide, and the open structures, such as diethylnaphthalate. Results from the Friedel–Crafts reaction suggest the presence of the closed structure chiefly.

Experimental

The 8-benzoyl-1-naphthoic acid and its chloride were prepared by the method of Mason.[4] The diphenylnaphthalide was prepared as previously described.[3]

8-Benzoyl-1-ethyl Naphthoate.—Five grams of benzoylnaphthoic acid was dissolved in an excess of ammonium hydroxide after which the excess of ammonia was removed by boiling. To the neutral solution was added a slight excess of silver nitrate solution, and the white silver salt was filtered and dried.

The silver salt was placed in a 250-cc. conical three-neck flask equipped with reflux condenser and stirrer, and 17 cc. of ethyl iodide was added slowly. A vigorous reaction took place with the precipitation of silver iodide. After the reaction had subsided, the mixture was refluxed for thirty minutes. The silver iodide was repeatedly extracted with 20 cc. portions of boiling ethyl alcohol. On concentration of the solution the ester crystallized as white needles, m. p. 134°; yield, nearly quantitative.

Anal. Calcd. for $C_{20}H_{16}O_3$: C, 78.94; H, 5.26. Found: C, 78.43; H, 5.49.

8-Benzoyl-1-ethyl Naphthoate from the Acid Chloride.—Four grams of benzoylnaphthoic acid was treated with 4 cc. of thionyl chloride. After the initial vigorous reaction, the mixture was heated over a water-bath for thirty minutes, when the excess of thionyl chloride was distilled off, leaving an oily residue. To the residue 100 cc. of absolute alcohol was slowly added, whereupon a vigorous reaction took place. The solution was refluxed for an hour and then concentrated to 50 cc., and the white crystalline product filtered off. This solid material was then dissolved in benzene and chromatographed on alumina, after the addition of enough petroleum ether (b. p. 70–80°) to make the solution nearly saturated. The first major layer fluoresced gray-violet with only a small band showing a blue fluorescence. The gray-violet band was treated with alcohol and the material which crystallized melted at 128–130°. Repeated crystallizations from alcohol brought the melting point up to 134°; average yield 60%. *Anal.* Calcd. for $C_{20}H_{16}O_3$: C, 78.94; H, 5.26. Found: C, 79.22; H, 5.50. From the small layer showing blue fluorescence, the 3-phenyl-3-ethoxynaphthalide was obtained in about a 10% yield on extraction with alcohol.

3-Phenyl-3-ethoxynaphthalide.—The chloride of benzoylnaphthoic acid was prepared and crystallized from benzene as directed by Mason. The chloride was then treated with absolute ethyl alcohol, approximately 10 cc. per gram of chloride being used. There was practically no evolution of heat. The mixture was refluxed for approximately an hour. The chloride went into solution with some difficulty. Upon cooling the pseudo ester crystallized in colorless crystals melting at 166°. The average yield from several runs was about 60%. *Anal.* Calcd. for $C_{20}H_{16}O_3$: C, 78.94; H, 5.26. Found: C, 78.91; H, 5.43. In addition to the pseudo ester small amounts of the normal ester, melting at 134°, were also obtained.

1,8-Diethyl Naphthalate.—The silver salt of naphthalic acid was prepared by adding a slight excess of silver nitrate in aqueous solution to a solution of the sodium salt of the acid. A considerable excess of ethyl iodide was added as described in the preparation of 8-benzoyl-1-ethyl naphthoate. After the initial reaction had subsided the mixture was refluxed for one hour. The precipitated silver iodide was heated with ethyl alcohol and filtered, then washed repeatedly with 20 cc. portions of alcohol. The combined alcoholic solutions were concentrated and diluted with water. Upon cooling, the ester crystallized as white crystals, m. p. 54°.

1,8-Dibenzoylnaphthalene.—Two grams of 9,10-diphenylacenaphthene glycol[7] was dissolved in 50 cc. of dry benzene and a suspension of lead tetraacetate in benzene was added over a period of one hour, at room temperature. The solution was then refluxed for thirty minutes on the water-bath. After filtration the benzene was removed under reduced pressure. The solid material thus obtained was crystallized from dilute ethyl alcohol. The pure product melted at 186°.

Summary

1. 8-Benzoyl-1-naphthoic acids having melting points of 110, 129, and 154° have been obtained as allotropic forms. They are readily interconverted. The evidence points to the pseudo acid structure for the compound in solution.

2. The normal and pseudo ethyl derivatives of the acid as well as two forms for the acid chloride have been prepared.

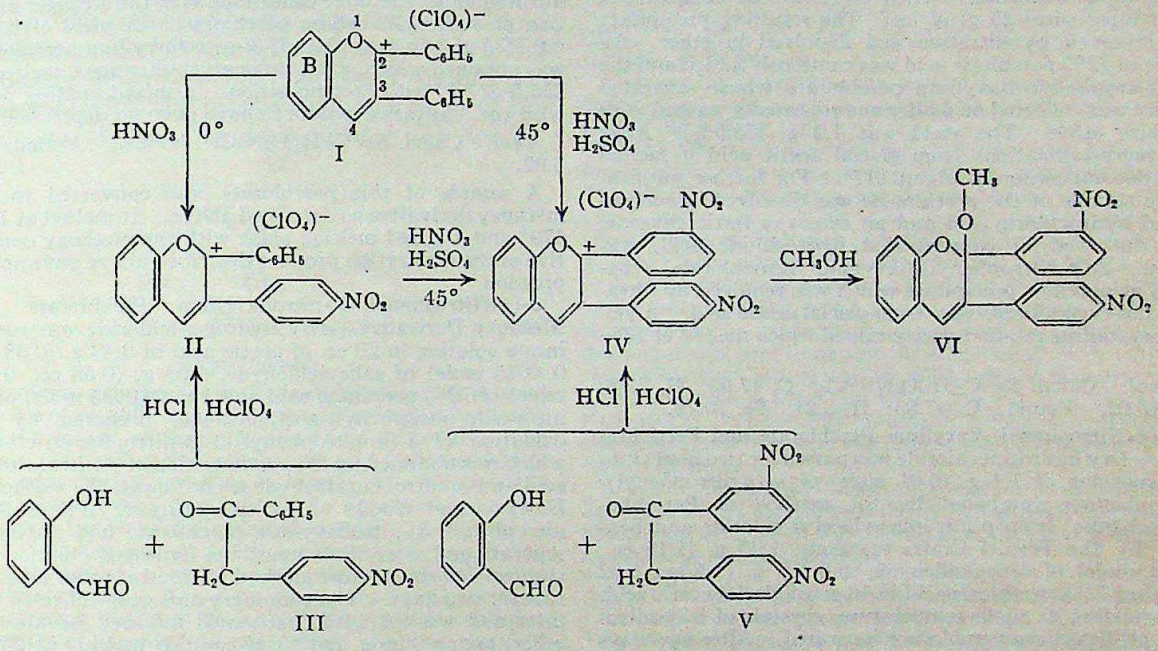
Benzopyrylium Salts. IV. Nitration of 2,3-Diphenyl-benzopyrylium Perchlorate

BY R. L. SHRINER AND ROBERT BRUCE MOFFETT

One of the most interesting reactions of flavylium salts is their behavior on nitration. Le Fevrè[1] showed that nitration of flavylium perchlorate produced the 3′-nitro derivative. In the present investigation the nitration reactions have been extended to a study of 2,3-diphenyl-benzopyrylium perchlorate (I) in order to establish the orientation of the substituents and relative ease of substitution in the two phenyl groups.

Treatment of 2,3-diphenyl-benzopyrylium perchlorate (I) with fuming nitric acid at 0° produced a 53% yield of the mono-nitro derivative (II). The latter was best purified and characterized by conversion to its ferrichloride. The structure of II was established by synthesis from salicylaldehyde and α-(*p*-nitrophenyl)-acetophenone (III). The perchlorates and ferrichlorides of the two samples of compound II were identical.

When the original perchlorate (I) was treated with concentrated nitric and sulfuric acids at 45° a 93% yield of a dinitro derivative was obtained. Exactly the same product could be obtained by nitration of the mono-nitro derivative (II). The structure of this dinitrodiphenyl-benzopyrylium perchlorate was shown to be that represented by formula (IV) by synthesis from salicylaldehyde and α-(*p*-nitrophenyl)-*m*-nitro-acetophenone (V). The three samples of compound IV were shown to be identical by analyses, mixed melting points and conversion to the same methoxy derivative (VI).



The above experiments show that under mild conditions of nitration a nitro group is introduced into the *para* position of the phenyl group in position 3 of the flavylium salt (I) and that under more drastic conditions an additional nitro-group is introduced in the meta position of the phenyl group in position 2.

The position taken by a group entering the benzene ring is fundamentally dependent on the charge of the atom already attached to the ring.[2] If the charge is zero or negative the entering group goes into the ortho or para position whereas a considerable positive charge sends the entering group to the meta position. The results of the present nitration experiments are in agreement with the carbonium structure for these salts[3] which in the present case is represented by formula I. Using the approximation method of Latimer and Porter[2a] the charge on carbon atom 2 is about +1.2 whereas the charge on carbon atom 3 is about 0.

It is remarkable that no nitration products were obtained with substituents in Ring B of formula I. Examination of the reaction mixtures showed that no additional nitro derivatives were produced in these experiments with 2,3-diphenyl-

benzopyrylium perchlorate. The nitration of other benzopyrylium salts is being studied in an effort to locate such substitutents since it is important in connection with other possible resonance structures of I.

Experimental

Nitration of 3-Phenylflavylium Perchlorate at 0°.—To 10 cc. of yellow, fuming nitric acid cooled in an ice–salt bath was added slowly with shaking 2 g. of 3-phenylflavylium perchlorate. When solution was complete, it was poured onto 25 g. of ice. The resulting precipitate was removed by filtration and dissolved in ether. An excess of 72% perchloric acid was cautiously added and the 3-(*p*-nitrophenyl)-flavylium perchlorate which separated at once was collected on a filter and repeatedly washed with absolute ether. The yield was 1.2 g. (53.5%). After two recrystallizations from glacial acetic acid it melted with decomposition at about 217°. For further purification a sample of the perchlorate was dissolved in concentrated hydrochloric acid and an excess of ferric chloride, also dissolved in concentrated hydrochloric acid, was added. 3-(*p*-Nitrophenyl)-flavylium ferrichloride separated as a yellow precipitate which was removed by filtration and crystallized twice from glacial acetic acid. A yellow crystalline product was obtained which melted at 136–137°.

Anal. Calcd. for $C_{21}H_{14}O_3NFeCl_4$: C, 47.95; H, 2.68; Fe, 10.62. Found: C, 47.89; H, 3.21; Fe, 10.78.

3-(*p*-Nitrophenyl)-flavylium Perchlorate and Ferrichloride.—Dry hydrogen chloride was passed for two hours into a suspension of 1.4 g. (0.01 mole) of α-(*p*-nitrophenyl)-acetophenone (prepared by the method of Petrenko-Kritschenko[4] from *p*-nitrophenylacetyl chloride and benzene by the Friedel–Crafts reaction), 1.35 g. (1.15 cc., 0.011 mole) of salicylaldehyde, and 2.7 g. (1.5 cc., 0.02 mole) of 72% perchloric acid in 40 cc. of glacial acetic acid. On standing at room temperature, crystals of 3-(*p*-nitrophenyl)-flavylium perchlorate separated. After two days the crystals were collected on a filter, washed with absolute ether, and recrystallized from glacial acetic acid yielding 4.0 g. (93.5%) of yellow crystals, which after a second recrystallization melted at 235–237° with decomposition.

Anal. Calcd. for $C_{21}H_{14}O_7NCl$: N, 3.28. Found: N, 3.28.

A sample of this perchlorate was converted to the ferrichloride as described above yielding yellow crystals of 3-(*p*-nitrophenyl)-flavylium ferrichloride which melted at 137–138°. When mixed with the ferrichloride from the nitration product no depression of the melting point occurred.

Anal. Calcd. for $C_{21}H_{14}O_3NFeCl_4$: C, 47.95; H, 2.68; Fe, 10.62. Found: C, 47.77; H, 2.90; Fe, 10.66.

Nitration of 3-Phenylflavylium Perchlorate at 45°.—Ten grams of 3-phenylflavylium perchlorate was dissolved in 40 cc. of concentrated sulfuric acid, cooled in an ice–salt bath, and 40 cc. of cold concentrated nitric acid was slowly added with shaking and cooling. This solution was warmed for five minutes at 45° and then poured onto ice. The resulting precipitate was removed by filtration, dissolved in ether, and an excess of 72% perchloric acid was cautiously added. The 3-(*p*-nitrophenyl)-3′-nitroflavylium perchlorate which separated was collected on a filter and repeatedly washed with absolute ether. The yield was 11.5 g. (93%) of a light yellow crystalline powder which melted at about 145–150° with decomposition. Repeated recrystallization either from glacial acetic acid containing a little perchloric acid, or from a mixture of acetic acid and nitromethane, yielded a product which melted at 258–258.5° with decomposition.

Anal. Calcd. for $C_{21}H_{13}O_9N_2Cl$: N, 5.93. Found: N, 5.90.

A sample of this perchlorate was dissolved in methanol by refluxing. When cooled, pale yellow crystals of the methoxy derivative separated, which after recrystallization from methanol with the aid of norite yielded pale yellow crystalline plates melting at 177.5–178.5°.

Anal. Calcd. for $C_{22}H_{16}O_6N_2$: N, 6.93. Found: N, 7.08.

Nitration of 3-(*p*-Nitrophenyl)-flavylium Perchlorate.—Two grams of 3-(*p*-nitrophenyl)-flavylium perchlorate was nitrated under the same conditions as in the stronger nitration of 3-phenylflavylium perchlorate. A yield of 2.1 g. (90.7%) of 3-(*p*-nitrophenyl)-3′-nitroflavylium perchlorate was obtained which, after three crystallizations, melted at 255.5–257.5° with decomposition. A mixed melting point with the dinitration product above gave no depression.

Anal. Calcd. for $C_{21}H_{13}O_9N_2Cl$: N, 5.93. Found: N, 5.92.

A sample of this perchlorate was converted to the methoxy derivative as described above. It melted at 178–179° and a mixed melting point with the methoxy derivative of the dinitration product described above gave no depression.

3-(*p*-Nitrophenyl)-3′-nitroflavylium Perchlorate and Methoxy Derivative.—Dry hydrogen chloride was passed into a solution in 20 cc. of acetic acid of 0.43 g. (0.38 cc., 0.0035 mole) of salicylaldehyde, 0.96 g. (0.58 cc., 0.007 mole) of 72% perchloric acid and 1 g. (0.0035 mole) of *m*-nitro-α-(*p*-nitrophenyl)-acetophenone, prepared by the oxidation of 1-(*m*-nitrophenyl)-2-(*p*-nitrophenyl)-ethanol which was obtained by the condensation of *p*-nitro-α-toluic acid and *m*-nitrobenzaldehyde according to the method of Harrison and Wood.[5] After two hours, crystals of 3-(*p*-nitrophenyl)-3′-nitroflavylium perchlorate had started to separate and after three hours the hydrogen chloride was stopped and the mixture allowed to stand at room temperature for two days. The yellow crystals were collected on a filter and washed with acetic acid followed by absolute ether, giving 0.99 g. (60%) of crystals melting at 254.5–255.5° with decomposition. After recrystallization from glacial acetic acid containing a little perchloric acid the compound melted at 257–258.5° with decomposition. Mixed melting points with both the perchlorates from the stronger nitration of 3-phenylflavylium perchlorate and from the nitration of 3-(*p*-nitrophenyl)-flavylium perchlorate gave no depressions.

Anal. Calcd. for $C_{21}H_{13}O_9N_1Cl$: N, 5.93. Found: N, 6.02.

A sample of this perchlorate was converted to the methoxy derivative as described above. It melted at 178–179° and mixed melting points with both the methoxy derivative from the stronger nitration of 3-phenylflavylium perchlorate and the methoxy derivative from the nitration of 3-(*p*-nitrophenyl)-flavylium perchlorate gave no depression.

Anal. Calcd. for $C_{22}H_{16}O_6N_2$: N, 6.93. Found: N, 6.85.

Summary

Mild conditions of nitration introduced a nitro-group in the para position of the phenyl group in position 3 of 2,3-diphenylbenzopyrylium perchlorate. More vigorous nitration conditions introduced an additional nitro-group in the meta position of the phenyl group in position 2. The structures of the nitration products were established by syntheses.

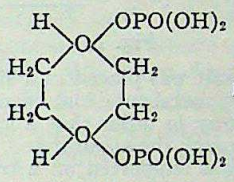
NOTES

Dioxane Diphosphate

By Erich Baer

Dioxane readily forms coördination compounds with several types of organic and inorganic substances. The oxonium salts of sulfuric acid[1] and perchloric acid[2] for example are well known. A phosphate, however, has not been described.[3] In the following the preparation and some of the properties of dioxane diphosphate[4] (I) are reported.



I

Experimental

The dioxane diphosphate (I) is easily obtained in good yields from an 88% aqueous solution of orthophosphoric acid by any one of the following three procedures. (a) Dioxane (one mole) and phosphoric acid (two moles) are mixed and crystallization is induced. The temperature of the mixture rises immediately to approximately 60°. To increase the yield of dioxane diphosphate the mixture is cooled. (b) Dioxane and phosphoric acid in separate containers are kept in a vessel under reduced pressure and at room temperature. The evaporating dioxane is absorbed by phosphoric acid and dioxane diphosphate precipitates. Any excess of absorbed dioxane, which decreases the yield of diphosphate,[5] can be readily removed *in vacuo*. (c) A dry current of air saturated with dioxane at 85° is bubbled through phosphoric acid kept at 100 to 120° until an excess of dioxane has passed into the reaction mixture. The product on cooling thickens to a crystalline sludge.

To isolate the very hygroscopic dioxane diphosphate from the crude reaction mixture obtained by any one of the above methods, the mother liquor is removed either by spreading the thick paste on porous clay plates in a desiccator or by filtering with suction using the rubber sheet technique.[6] The product is dried in a high vacuum over sodium hydroxide. The oxonium salt crystallizes in prisms and is obtained in yields as high as 84%; m. p. 83–87°[7] (sintering at 78°). A recrystallization from ether (10 g. of substance in 20 cc. of dry ether at −60°) does not change this melting point. The diphosphate is readily soluble at 25° in several solvents: water (giving a strongly acid solution), ethyl alcohol, *n*-butyl alcohol, cyclohexanol, benzyl alcohol, acetone, cyclohexanone, acetic acid, ether, dioxane, glycol dimethyl ether, ethyl acetate, trimethyl phosphate, and very slightly soluble or insoluble in benzene, cyclohexane, petrol ether, chloroform and bromoform. Dioxane diphosphate is unstable in water. Its aqueous solution gives all the usual reactions of phosphoric acid and loses dioxane on concentration. The dissociation of the molecular compound in organic solvents has not yet been investigated. *Anal.* Calcd. $C_4H_{14}O_{10}P_2$ (284): C, 16.9; H, 4.93; P, 21.82. Found: C, 16.9; H, 4.84; P, 21.80.

Dioxane diphosphate when kept dry is stable at room temperature. It remains apparently unchanged when heated for a short time in a glass vessel to 150°. Above 175° the substance rapidly turns dark brown and gives off fumes which when condensed form a colorless liquid. This distillate consisting mainly of dioxane [b. p. (756 mm.) 100°, $n^{25}D$ 1.4190] also contains an appreciable amount of acetaldehyde[8] [2,4-dinitrophenylhydrazone m. p. 147°,[9] from chloroform]. If a dry mixture of one mole of dioxane diphosphate with either 2.2 moles of Na_2HPO_4[10] or 1.1 mole of K_3PO_4[10] or 1.1 mole of anhydrous Na_3PO_4[10] is heated in an oil-bath to approximately 120 to 130° dioxane distils over in almost the theoretical yield. After redistilling the dioxane over metallic sodium, its refractive index and boiling point are $n^{25}D$ 1.4190, b. p. (751 mm.) 99.5–100.5°. The readily obtainable molecular compound should prove to be a valuable intermediate for the purification of dioxane.

Dioxane diphosphate, which is soluble in many organic liquids, may perhaps be used as a substitute for crystalline phosphoric acid, when a dry solution of phosphoric acid in an organic solvent is required.

(2) C. Smeets, *Natuurw. Tijdschr.*, **19**, 12 (1937).

(3) In spite of an intensive search of the literature no record of the substance could be found. A coördination compound of dioxane with a substituted phosphoric acid, the dioxanate of dimeric glyceraldehyde-1-bromide-3-phosphate has been used successfully where other methods failed to obtain this phosphate in an analytically pure state (Baer and Fischer, *J. Biol. Chem.*, **150**, 226 (1943).

(4) Patent applied for.

(5) Dioxane diphosphate is readily soluble in dioxane.

(6) L. F. Fieser, "Experiments in Organic Chemistry," 2d. ed., 1941, p. 321.

(7) The melting point was taken in a sealed tube. According to Kelley and McCusker (This Journal, **65**, 1307 (1943)) an unsharp melting point seems to be normal for a molecular compound containing a volatile component.

(8) The distillation of dioxane with a small amount of sulfuric acid yields dioxane containing acetaldehyde (Faworski, *loc. cit.*).

(9) Purgotti, reports a m. p. of 147° for acetaldehyde 2,4-dinitrophenylhydrazone, *Gazz. chim. ital.*, **24**, I, 565 (1894).

(10) A slight excess over the amount which is needed to convert all phosphoric acid into NaH_2PO_4 or KH_2PO_4.

The Preparation of Certain Phenolic Esters[1]

By Erwin Baumgarten, Howard G. Walker and Charles R. Hauser

Phenolic esters have been prepared from the sodium salt of the phenol in aqueous solution and the acid anhydride,[2] from the phenol and anhydride in the presence of the sodium salt of the acid from which the anhydride is derived,[3] and from the phenol and acid chloride in the presence of pyridine with[4] or without[5] an inert solvent. For the preparation of the rather large quantities of certain phenolic esters required in another investigation, the method involving the acylation of the phenol with the acid chloride in pyridine

has been found very satisfactory. By this method three new phenolic esters have been prepared on a one to three mole scale.

Ethyl 4-Phenylphenyl Carbonate.—To a solution of 510 g. (3 moles) of 4-phenylphenol in 720 ml. of pyridine (dried over potassium hydroxide pellets) in a 2-liter reaction flask, carrying a reflux condenser, dropping funnel and mercury-sealed "Hershberg" stirrer, there was added, with stirring at 0°, over a period of 30 minutes, 365 g. (3.4 moles) of ethyl chlorocarbonate. A bulky precipitate formed. Stirring was continued for thirty minutes after addition was complete. The reaction mixture was stirred to a paste with 500 ml. of water and filtered under suction; the precipitate was washed with three 200-ml. portions of ice-water prior to fusion *in vacuo*. The fused material was recrystallized from 800 ml. of 95% ethanol. There was obtained 430 g. (60%) of ethyl 4-phenylphenyl carbonate, m. p. 73.2–74.3°. A sample, recrystallized repeatedly from methanol, melted at 73.9–75.0°.

Anal.[6] Calcd. for $C_{15}H_{14}O_3$: C, 74.36; H, 5.82. Found: C, 73.90; H, 5.88.

4-Phenylphenyl Isobutyrate.—The acylation of 255 g. (1.5 moles) of 4-phenylphenol in 360 ml. of pyridine by means of 180 g. (1.7 moles) of isobutyryl chloride as described for ethyl 4-phenylphenyl carbonate gave 294 g. (82%) of 4-phenylphenyl isobutyrate, m. p. 73.2–74.8°. A sample, recrystallized repeatedly from methanol, melted at 74.2–74.8°.

Anal.[6] Calcd. for $C_{16}H_{16}O_2$: C, 79.97; H, 6.71. Found: C, 80.53; H, 6.80.

Phenyl Isobutyrate.—A solution of 94 g. (1 mole) of phenol in 240 ml. of pyridine was acylated by means of 128 g. (1.2 moles) of isobutyryl chloride essentially as described above. After reaction was complete, the mixture was diluted with water and ether to produce two clear phases. The aqueous phase was extracted with ether and the combined ether phases were dried over anhydrous sodium sulfate followed by "Drierite." After removal of the solvent at atmospheric pressure, the residue was distilled through an eight-inch Vigreux column. Fractions boiling at 60–110° (55 g.) and 110–112° (131 g.) were obtained. The lower boiling fraction was distilled up to 105° at 25 mm. and the residue combined with the fraction boiling at 110–112°. Distillation of the mixture gave 4 g. of a fore-run, b. p. 105–111° at 25.5 mm., and 144 g. (87%) of phenyl isobutyrate, b. p. 111–112.2° at 25.5 mm. A mid-fraction (b. p. 112° at 25.5 mm., const.) was analyzed.

Anal.[6] Calcd. for $C_{10}H_{12}O_2$: C, 73.15; H, 7.37. Found: C, 72.84; H, 7.32.

The Preparation of 1- and 2-Phenylpyrrole

BY F. F. BLICKE AND J. L. POWERS

Recently we have been able to synthesize relatively large quantities of 1- and 2-phenylpyrrole by means of the procedures reported below.[1]

The apparatus used for the preparation of 1-phenylpyrrole consisted of two round, cast-iron shells with flanges which were clamped together by means of eight short bolts fitted with wing nuts (only two bolts are shown in the drawing); several "cranite" asbestos gaskets placed between the shells prevented leakage.[2] Each of the shells was sixteen inches in diameter and three inches high at the point at which the pipe was attached. Two iron pipes, one inch in diameter, were screwed into the shells as shown in the diagram. The upper, outlet pipe was attached by rubber tubing to a Pyrex glass tube (combustion type) about six feet long which served as a condenser. At the beginning of the process it was found necessary to cool the condenser with wet cloths, but during the end of the operation it was essential, in some instances, to warm the glass tube with a flame to prevent the condensed material from clogging the tube.

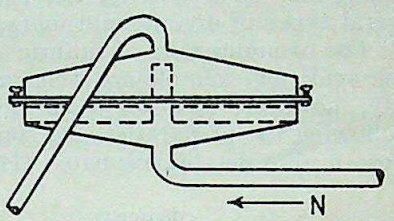

Fig. 1.

The mucic acid salt was placed in a shallow galvanized iron tray. A short, metal tube had been inserted through the center of the tray in order that a stream of nitrogen could be passed through the apparatus.

The apparatus was supported on a tripod, and heated from below with eight Meker burners. Since it was found that rubber tubing attached to the burners melted in a short time, due to the intense heat, it was necessary to unscrew the side arms from the burners and replace them with threaded iron pipes about eighteen inches long.

The upper shell of the apparatus was covered with several removable layers of heavy asbestos, and the whole apparatus was surrounded with a large sheet of the same material.

1-Phenylpyrrole.—In order to prepare the required aniline salt of mucic acid, an intimate mixture of 1116 g. of aniline and 1260 g. of mucic acid was placed in a large evaporating dish, 60 cc. of water added, and the mixture stirred and heated on a steam-bath until it became solid. The material was then pulverized and air-dried.

The salt (396 g.) was placed in the apparatus and the distillate was collected in a 2-liter, round-bottomed flask which contained 110 cc. of concd. hydrochloric acid and 400 cc. of water. The aniline dissolved and the insoluble pyrrole was obtained as a brown, crystalline material. After one-half hour the reaction was complete. The crude material was subjected to steam distillation. The phenylpyrrole separated in the distillate in the form of colorless crystals while a tarry residue remained in the distillation flask. The average yield was 60 g. (42%). The product melted at 58°,[3] and boiled at 230–234°.

2-Phenylpyrrole.—A five-foot length of Pyrex combustion tubing was bent, twenty inches from one end, at a 75° angle, and placed in a combustion furnace. To facilitate the flow of the product through the tube, one end of the furnace was raised about two inches above the level of the laboratory table. Fifty grams of 1-phenylpyrrole were put into a 125-cc. distillation flask in which the usual side arm had been replaced by another 10 cm. long and 9 mm. in thickness, sealed close to the bulb and fitted to the tube by a cork. The tube was heated to a dull red heat, and the pyrrole was distilled through the tube at such a rate that about thirty minutes were required to empty the distillation flask. Since the rearrangement was not complete, the product was distilled through the hot tube two more times.

The material was fractionated, and the recovered 1-phenylpyrrole was subjected to the rearrangement process. From 200 g. of 1-phenylpyrrole there was produced 127 g. (63%) of 2-phenylpyrrole; b. p. 272–278°.[4] A completely colorless product could be obtained only by distillation under reduced pressure; b. p. 151–154° (5 mm.).

(1) Other methods described during the last few years are those of Allen, Gilbert and Young (*J. Org. Chem.*, **2**, 230 (1937)) and of Adkins and Coonradt (THIS JOURNAL, **63**, 1566 (1941)).

(2) When new gaskets are used, the bolts must be tightened again after the apparatus has become hot.

(3) Köttnitz (*J. prakt. Chem.*, [2] **6**, 148 (1873)) found 62°.

(4) Piutti and Testoni (*Gazz. chim. ital.*, **28**, 1905 (1895)) found 271–272°.

But even this material soon turned pink when exposed to air. However, after several recrystallizations of the vacuum-distilled product from 70% alcohol the pyrrole was obtained in a form which remained colorless; m. p. 128–129°.[5]

(5) The melting point has been reported to be 129° (ref. 4).

Reactions of *t*-Butyl Cinnamate and *t*-Butyl Benzoate with Phenylmagnesium Bromide[1]

BY FRED FROSTICK, ERWIN BAUMGARTEN AND CHARLES R. HAUSER

Kohler and Heritage[2] showed that methyl cinnamate undergoes both 1,2- and 1,4-addition with phenylmagnesium bromide yielding a mixture of products. We have found that *t*-butyl cinnamate (in which the carbonyl group is relatively hindered) undergoes apparently only 1,4-addition yielding *t*-butyl β,β-diphenylpropionate.

$$C_6H_5CH{=}CHCOOC(CH_3)_3 \xrightarrow{C_6H_5MgBr} (C_6H_5)_2CHCH_2COOC(CH_3)_3$$

To a stirred solution of phenylmagnesium bromide, prepared from 5.6 g. (0.23 mole) of magnesium and 46.1 g. (0.23 mole) of bromobenzene in 100 ml. of dry ether, was added during twenty minutes 23.5 g. (0.115 mole) of *t*-butyl cinnamate.[3] The reaction mixture refluxed gently and a precipitate formed. After refluxing for three hours, the mixture was poured into an ice-cold saturated ammonium chloride solution. The ether layer was shaken with cold 10% sulfuric acid, and then with cold 5% potassium hydroxide solution. After drying with anhydrous sodium sulfate followed by "Drierite," the solvent was distilled, finally using the water aspirator. The solid residue (29.5 g.) was recrystallized from petroleum ether (b. p. 30–60°), yielding 15 g. (44%) of essentially pure *t*-butyl β,β-diphenylpropionate. Four recrystallizations yielded a product melting at 55.5–55.6°.

Anal.[4] Calcd. for $C_{19}H_{22}O_2$: C, 80.85; H, 7.86. Found: C, 80.93; H, 7.60.

The product was further identified by hydrolysis in the presence of concentrated hydrochloric acid to β,β-diphenylpropionic acid, which, after recrystallization from acetone–water mixture, melted at 152–154° (reported, 155°).[5]

Analogous to methyl or ethyl benzoate, *t*-butyl benzoate has been found to undergo the "normal" carbonyl addition reaction with phenylmagnesium bromide, yielding triphenylcarbinol. Some benzoic acid (which might have resulted from hydrolysis of the ester) was also isolated. Neither isobutene nor *t*-butylbenzene was found; these products would have resulted had the elimination or substitution reaction occurred.

To a stirred solution of phenylmagnesium bromide (prepared from 0.5 mole each of magnesium and bromobenzene in 150 ml. of ether), contained in a reaction flask equipped with a U-tube immersed in a dry ice-bath, was added during one-half hour 0.3 mole of *t*-butyl benzoate[6] in 100 ml. of ether. After standing overnight the reaction mixture was refluxed for five hours. The liquid condensed in the U-tube did not absorb an appreciable amount of bromine in carbon tetrachloride solution, indicating that no significant amount of isobutene was formed. After decomposition of the reaction mixture with ammonium chloride, the ether solution was shaken with bicarbonate (from which was isolated a 10% yield of benzoic acid), dried and the solvent distilled. The residue was subjected to steam distillation until oily material (containing diphenyl but apparently no *t*-butylbenzene) ceased to pass over, and then recrystallized from alcohol, yielding triphenylcarbinol (41%), m. p. 159–162°.

In a similar experiment, carried out with *t*-butyl benzoate and methylmagnesium iodide, no isobutene appeared to be formed.

Nature of Carotenes in Alfalfa

BY A. R. KEMMERER AND G. S. FRAPS

According to Beadle and Zscheile,[1] spinach and some other plants contain appreciable amounts of "neo-β-carotene," stereoisomer of β-carotene, which can be produced by heating β-carotene in petroleum ether. This pigment is the same as that termed pseudo-α-carotene by Gillam and El Ridi,[2] and neo-β-carotene B, by Polgár and Zechmeister.[3] Kemmerer and Fraps,[4] by chromatographic analysis with calcium hydroxide, found, besides β-carotene and this "neo-β-carotene" in plants, another pigment which they termed "carotenoid X." "Carotenoid X" did not possess vitamin A potency, while "neo-β-carotene" had one-half the potency of β-carotene. Polgár and Zechmeister,[4] by various treatments of β-carotene, secured about twelve neo-β-carotenes including neo-β-carotenes B and U. Since the identification of the carotenes in plants is of both practical and scientific importance, both the "neo-β-carotene" and "carotenoid X" in alfalfa were studied.

Neo-β-carotene B was prepared by refluxing a solution of 20 mg. of crystalline carotene in 100 ml. of hexane for one hour.[4] The solution was chromatographed on calcium hydroxide and the neo-β-carotene B was separated and extracted. Then it was purified by another chromatographic treatment. This pigment is just below the β-carotene band in the chromatogram. Neo-β-carotene U was prepared by dissolving about 10 mg. of crystalline carotene in petroleum naphtha (Skellysolve F), adding a small crystal of iodine, and allowing the solution to stand an hour.[4] The neo-β-carotene U was separated and purified by absorption on calcium hydroxide. The neo-β-carotene U is just above the β-carotene in the chromatogram.

"Carotenoid X" and "neo-β-carotene" were prepared from alfalfa leaf meal by extraction with alcholic potassium hydroxide and petroleum naphtha (Skellysolve F) and chromatographic separation on calcium hydroxide.[3]

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Solutions of neo-β-carotene U and "carotenoid X" were mixed and subjected to chromatographic analysis on calcium hydroxide. There was no separation of bands, showing that the two pigments were identical. By a similar experiment neo-β-carotene B and "neo-β-carotene" from alfalfa were found to be identical.

Direct comparisons of the absorption of light by the preparations were made by means of a quartz spectrograph. In petroleum naphtha (Skellysolve F) solutions, photographed at different settings of the photometer, "carotenoid X" and neo-β-carotene U both had absorption maxima at 468 and 443 mμ; "neo-β-carotene" from alfalfa and neo-β-carotene B likewise had the same absorption curve with maxima at 473 and 446 mμ.

The pigments were also compared by dissolving approximately equal quantities in hexane, treating with iodine and analyzing the product by chromatographic separation on calcium hydroxide. The colorimetric ratio of the pigments formed from neo-β-carotene U was, unknown pigment: neo-β-carotene U: β-carotene: neo-β-carotene B: neo-β-carotene E = 2:22:42:29:5 and from "carotenoid X" of alfalfa = 3:23:46:24:4. For neo-β-carotene B the ratio was, 2:25:45:28:0 and for neo-β-carotene from alfalfa 1:22:43:34:0. The ratios of stereoisomers produced by this treatment were nearly the same in the two comparisons, another evidence of the identity of the carotenes compared from alfalfa. The same carotenes have been found in the chromatographic analysis of other plants (spinach, collards, grasses, etc.).

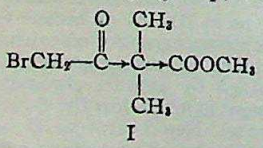
The Action of Sodium Cyanide on Methyl γ-Bromo-α,α-dimethylacetoacetate

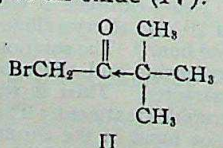
BY C. F. KOELSCH

The reaction of sodium cyanide with an α-halogenated ketone usually leads to the formation of a β-ketonitrile; for example, bromopinacolone yields pivaloylacetonitrile.[1] A few α-haloketones, however, furnish α,β-oxidonitriles; for example, desyl chloride yields α,β-epoxy-α,β-diphenylpropionitrile.[2]

On the basis of the polarizations indicated in formulas I and II, it was anticipated that methyl γ-bromo-α,α-dimethylacetoacetate (I) might not parallel bromopinacolone (II) in its behavior toward sodium cyanide, but might suffer attack at its carbonyl group, leading to an oxide (IV).

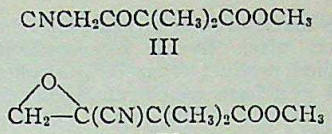


I



II

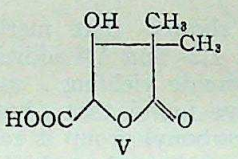
The reaction had been studied long ago[3,4,5] and the product had been assigned structure III. But a survey of the old data indicated that the properties of the product were more in accord with structure IV.



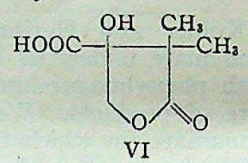
III

IV

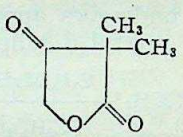
In the present work it was demonstrated that IV is correct. This was done by showing that the hydrolysis product of the nitrile, previously considered to be formed through hydration of the enol of III and formulated as V, actually is VI. The hydrolysis product was identical with the acid obtained by adding hydrogen cyanide to VII and hydrolyzing the resulting cyanohydrin, procedures which can lead only to VI.



V



VI



VII

2,4-Diketo-3,3-dimethyltetrahydrofuran[6] (VII), b. p. 200–210° (740 mm.) or 103–107° (16 mm.), was obtained in 86% yield when 25 g. of methyl γ-acetoxy-β-keto-α,α-dimethylbutyrate[7] was boiled for two hours with 5 g. of 10 molar alcoholic hydrogen chloride (contrary to the statement of Conrad and Gast,[6] the acetoxy ester was unchanged after it had been kept for three months; it also was unaffected when it was heated with potassium carbonate). When 1.3 g. of VII was shaken for fifteen minutes with a solution of 0.6 g. of sodium cyanide and 0.8 ml. of hydrochloric acid in 4 ml. of water, it furnished an oily cyanohydrin. This was removed with ether and boiled for one hour with 6 ml. of 20% hydrochloric acid; when the solution was cooled, it deposited 0.5 g. of VI, colorless prisms from water, m. p. 213–217° alone or mixed with the compound obtained from I by the procedure of Lawrence.[3] When it was boiled with methanol and sulfuric acid, VI gave a methyl ester that melted at 104–105° alone or mixed with Lawrence's ester.

Recognition of the correct structure (IV) for the nitrile previously considered to be III necessitates changes in the structures of substances derived from this compound. Simple esters, etc., need not be specifically mentioned here, but the following revisions must be pointed out. "3-Acetoxy-4,4-dimethyl-5-ketotetrahydro-furoic acid"[4] is actually 3-acetoxy-4,4-dimethyl-5-ketotetrahydrofuran-3-carboxylic acid; "4,4-dimethyl-5-ketotetrahydrofuroic acid"[4,5] is actually 4,4-dimethyl - 5 - ketotetrahydrofuran - 3 - carboxylic acid; "ethyl α′-chloro-β-hydroxy-α,α-dimethylglutarate"[3] is actually ethyl α-chloromethyl-α-hydroxy-β,β-dimethylsuccinate; "α,α-dimethyl glutaconic acid"[5] is actually[8] α,α-dimethylitaconic acid. Some doubt now attaches to the structures formerly assigned[3] to homologs of III and V, *viz.*, ethyl γ-cyano-β-keto-α-ethyl-α-

Observations on the Rare Earths. L.[1] The Separation of Erbium from Yttrium by Fractional Precipitation of the Ferrocyanides[2]

BY THERALD MOELLER AND H. E. KREMERS

Yttrium and erbium oxide mixtures which accumulate during bromate fractionations of the yttrium earths are usually further separated by basicity methods, although the very favorable solubility difference between the ferrocyanides of these elements[3,4] renders ferrocyanide fractionation more rapid. In spite of the gelatinous nature of the precipitates, comparatively pure yttrium material has been prepared by this procedure,[5,6,7,8] and Prandtl,[9] using large quantities of nitric acid to promote crystallinity, has obtained erbium oxide of high purity. The lack of specificity in Prandtl's directions suggested a further study of the problem, and the resulting modified procedure gives consistently reproducible results, is rapid, and is free from undesirable oxidation of the ferrocyanide.

Experimental

Ferrocyanide Precipitation.—Erbium–yttrium chloride solutions were prepared in 3 *N* hydrochloric acid to contain 2% rare earth oxide and 10% ammonium chloride. To these solutions at room temperature, sufficient 20% potassium ferrocyanide solution (calculated as the trihydrate) to precipitate about one-half the rare earth material was added slowly with constant stirring. Experimentally, about 15 ml. precipitated the equivalent of 1 g. of rare earth oxide from material analyzing 85–100% Er_2O_3 and 20 ml. for lower erbium concentrations. Slow precipitation began only after complete addition of the ferrocyanide. After several hours, the precipitates were removed by suction filtration on qualitative paper.

Recovery of Rare Earth Materials.—Part of the iron was removed from the precipitates by boiling the solids with 50% sodium hydroxide, diluting, and filtering. After ignition of these hydroxides, the remainder of the iron was removed by oxalate precipitation of the rare earths from chloride solutions. The ferrocyanide mother liquors gave iron-free oxides after two precipitations with oxalic acid.

Fractionation of Erbium–Yttrium Mixtures.—Erbium–yttrium mixtures showing no absorption lines for holmium or thulium were fractionated by the above procedure. Each fractionation was followed by means of spectrophotometric analyses (based upon the 489 and 653 mμ erbium absorption bands)[10] of oxides recovered from both precipitates and mother liquors. Oxides of approximately the same composition were combined and refractionated.

The fractionation of 43 g. of a mixture (ER-18) containing 57% Er_2O_3 gave 4.8 g. of 89% Er_2O_3, 2.1 g. of 86% Er_2O_3, 5.9 g. of 80% Er_2O_3, 6.8 g. of 62% Er_2O_3, 6.7 g. of 38% Er_2O_3, and 15 g. of an oxide mixture low in erbium after twenty-eight fractional precipitations (five series with five or six fractions in each).

A series of fractions (ER-34) obtained from a urea separation[11] and a previous ferrocyanide fractionation and consisting of (1) 6.9 g. of 87% Er_2O_3, (2) 5.9 g. of 80% Er_2O_3, (3) 13.8 g. of 59% Er_2O_3, (4) 20.3 g. of 27% Er_2O_3, and (5) 45 g. of 17% Er_2O_3 yielded ultimately 3.14 g. of 98.5% Er_2O_3 (two precipitations of fraction (1)); 1.3 g. of 94% Er_2O_3, 2.35 g. of 93% Er_2O_3 and 2.8 g. of 80% Er_2O_3 (four precipitations of fractions (2), (3), and (4), respectively); and 5.6 g. of 48% Er_2O_3 (three precipitations of fraction (5)). In addition, 5.0 g. of 65% Er_2O_3, 17.6 g. of 44% Er_2O_3, and 9.5 g. of 27% Er_2O_3 were recovered from the final mother liquors.

Success of the ferrocyanide procedure is dependent upon the complete removal of iron, since even traces of iron yield gelatinous blue precipitates which nullify the effects of crystallinity in the rare earth ferrocyanides. Although some unavoidable loss is inherent in the oxalate precipitations, the speed and efficiency of the method recommend it.

Acknowledgment.—The authors wish to express their appreciation to Dr. C. J. Rodden of the National Bureau of Standards for the analysis of an erbium oxide sample used in the calibration of our spectrophotometer.

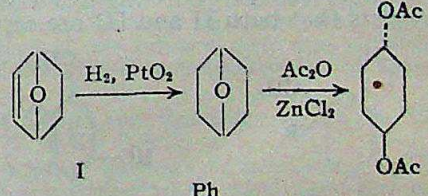
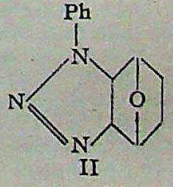
3,6-Epoxycyclohexene from Furan and Ethylene[1]

BY WALTER NUDENBERG AND LEWIS W. BUTZ

3,6-Epoxycyclohexene (I) has now been prepared by the procedure and with the apparatus previously employed in similar preparations.[2] It has been characterized as indicated below.



I



II

Into a mixture of 30–35 g. of furan and a few crystals of hydroquinone ethylene was introduced in two or three portions with intermittent shaking up to an initial pressure of 1100–1200 lb. per sq. in. at room temperature. The bomb was heated to 155° and kept at 150–155°, the pressure dropping and ultimately becoming constant after six-

teen hours. After cooling the bomb, the gas was allowed to escape through a trap cooled by solid carbon dioxide, and the deposited furan was returned to the reaction mixture. The whole was distilled in three fractions: the first, of unreacted furan, 14–16 g.; the second, b. p. 40–118°, chiefly furan, 1.5 g., the third, a colorless liquid, b. p. 118–122°, 1.2–1.5 g. This last was 3,6-epoxycyclohexene, b. p. 118–119°, $n^{20}D$ 1.4629; yield, 5–8% on the furan consumed.

The triazoline derivative, formula II,[3] was prepared by mixing a few drops of phenyl azide with a similar quantity of epoxycyclohexene and allowing the resulting yellow solution to crystallize in the ice box overnight. Repeated crystallization from ethyl acetate gave fine white needles, m. p. 166–167° (cor.) (after drying over phosphorus pentoxide).

Anal.[4] Calcd. for $C_{12}H_{13}ON_3$: C, 67.0; H, 6.1; N, 19.5. Found: C, 67.1; H, 6.1; N, 19.5.

The epoxycyclohexene (4.5 g.) in 12 ml. of methanol was hydrogenated using 50 mg. of Adams catalyst. Distillation of the residue remaining after removal of the catalyst and methanol gave a fraction b. p. 110–120°. This material was refluxed, without further purification, with acetic anhydride and several crystals of zinc chloride for two hours. The excess acetic anhydride was distilled off and the remaining brown oil poured into hot water. Crystallization did not occur. The oil was extracted with ether, the solution dried and the ether evaporated. The residual oil on standing deposited crystals, m. p. 102–103.6°, from aqueous ethanol. A mixture with authentic ester,[5] m. p. 102–104°, also melted at 102–103.6°.

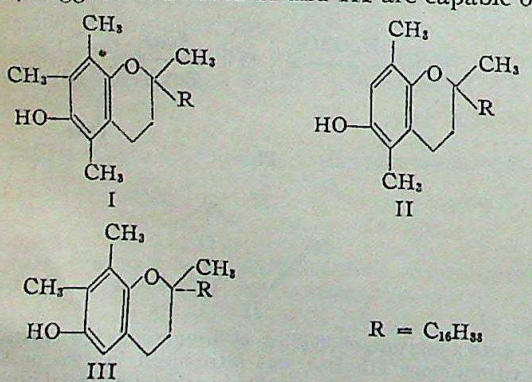
Coupling of Gamma Tocopherol and Failure of β-Tocopherol to Couple with Diazonium Salts

BY MARY LOUISE QUAIFE

Inspection of the structural formulas of α-tocopherol (I), β-tocopherol (II), and γ-tocopherol (III) suggests that both II and III are capable of



coupling with diazonium salts.[1] We have found that γ-tocopherol couples readily, but the beta isomer, surprisingly, does not. Consequently, III can be determined in the presence of I and II. This note describes the reaction upon which the procedure is based and also experiments showing the failure of β-tocopherol to couple.

γ-Tocopherol is determined by photometric estimation of the red dye produced by its reaction with diazotized *p*-nitroaniline in aqueous alcohol solution at *p*H of about 6. The dye, extracted with Skellysolve H, gives a stable color with absorption maxima at 530 mμ and 380 mμ. Over the range of quantity of γ-tocopherol employed in the analysis (0.2 to 0.5 mg.) absorption at either wave length is proportional to concentration. It is measured at 520 mμ for convenience. The method has been applied to estimation of γ-tocopherol content of tocopherol concentrates with results as shown in Table I. Total tocopherols were determined by the method of Emmerie and Engel.[2]

TABLE I

γ-TOCOPHEROL CONTENT OF VEGOL (CONCENTRATE OF NATURAL MIXED TOCOPHEROLS) FRACTIONS (DUPLICATE ANALYSES)

Sample	γ-Tocopherol, %	% total tocopherols	Ratio of γ- to total tocopherol; % γ-
Vegol (C)	2.8	4.3	65
	3.1	4.5	69
Vegol (I)	16.3	26.3	62
	17.8	26.7	67
Vegol (II)	21.4	42.0	51
	19.7	42.3	47
Vegol (III)	9.0	40.2	22
	9.5	40.2	24

When the procedure was applied to natural β-tocopherol, it required 12 mg. to give absorption at 520 mμ, equivalent to that given by only 0.05 mg. of γ-tocopherol. Since in this case the *p*H was about 6, the ability of β-tocopherol to couple with benzenediazonium chloride was tested over a *p*H range of 4.5 to 11. The test procedure was similar to that used in the analytical method except for increased amounts of β-tocopherol. Control series were run using equal amounts of γ-tocopherol as well as aqueous alcohol blanks. The resultant Skellysolve extracts of the reaction mixtures of the tocopherols (0.4 mg./cc.) and of the blank had colors as shown in Table II.

TABLE II

COLORS OF COUPLING PRODUCTS OF TOCOPHEROLS AND BENZENEDIAZONIUM CHLORIDE

*p*H	Blank	β-Tocopherol	γ-Tocopherol
4.5	Colorless	Colorless	Colorless
9.0	Light yellow	Light yellow	Deep orange
11.0	Light yellow	Light yellow	Deep orange

Absorption spectra over the range of 310 to 620 mμ of the reaction products at *p*H 9 show no difference in absorption between the Skellysolve extracts of the β-tocopherol reaction mixture and the blank. The γ-tocopherol azo dye formed at *p*H 9 had a density of 1.7 at 475 mμ, the peak of absorption.

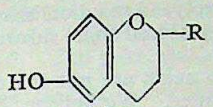
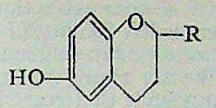
This difference in coupling ability of γ- and β-tocopherols suggests possible fixation of the bond structure in the benzenoid nucleus of the tocopherols according to IV instead of V. The sub-



IV



V

stituted tetralins, which have a ring system similar to that of the tocopherols, are considered to have a double bond between the rings. The observed difference in the tocopherol isomers may also be related to the Mills–Nixon effect.[3,4]

The advice of Dr. C. F. H. Allen is gratefully acknowledged.

COMMUNICATION NO. 56
FROM THE LABORATORIES OF
DISTILLATION PRODUCTS, INC.
ROCHESTER, NEW YORK RECEIVED DECEMBER 7, 1943

The Alkylation of Isopropylmalonic Ester Using Sodium Triphenylmethide[1]

BY J. C. SHIVERS, B. E. HUDSON, JR., AND CHARLES R. HAUSER

The difficulty of alkylation of secondary alkyl malonic esters, for example, isopropylmalonic ester, by the ordinary procedure using sodium ethoxide[2] in alcoholic solution has been ascribed to the incomplete formation of the sodio derivative.[3]

$$RCH(CO_2C_2H_5)_2 + NaOC_2H_5 \rightleftarrows [RC(CO_2C_2H_5)_2]Na + C_2H_5OH$$

Wallingford and co-workers[3b] found that, by substituting an alkyl carbonate for alcohol as a reaction medium and distilling all alcohol produced from the reaction with sodium ethoxide, certain secondary alkyl malonic esters could be alkylated. We have found that alkylation of isopropylmalonic ester may be achieved by using the stronger base, sodium triphenylmethide, in an inert solvent. The yields of alkylation product with ethyl iodide and isopropyl iodide were 73 and 23%, respectively.

$$(CH_3)_2CHCH(CO_2C_2H_5)_2 + NaC(C_6H_5)_3 \longrightarrow Na[(CH_3)_2CHC(CO_2C_2H_5)_2] + HC(C_6H_5)_3$$

$$RI + Na[(CH_3)_2CHC(CO_2C_2H_5)_2] \longrightarrow (CH_3)_2CHC(CO_2C_2H_5)_2 + NaI$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad |$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad R$$

Crossley and Le Sueur[2b] found that ethylisopropylmalonic ester (R = ethyl, prepared by isopropylating ethylmalonic ester using sodium ethoxide) undergoes alkaline hydrolysis to form partly ethylisopropylmalonic acid and partly ethylisopropylmalonic acid ester, which on decarboxylation gives ethyl ethylisopropylacetate. We have found that di-isopropylmalonic ester (R = isopropyl) undergoes alkaline hydrolysis only with difficulty yielding di-isopropylmalonic acid ester, which undergoes decarboxylation with difficulty.

Experimental

Diethyl isopropylmalonate (b. p. 217–218°)[4] was prepared in 56% yield essentially according to the directions given in "Organic Syntheses"[5] for the preparation of diethyl *n*-butyl malonate.

Diethyl Ethylisopropylmalonate.—To sodio-isopropylmalonic ester, prepared from 42.0 g. (0.205 mole) of the ester and 0.205 mole of an ether solution of sodium triphenylmethide,[6] was added 32 g. (0.205 mole) of ethyl iodide. After standing for seven days, the ether solution (above the thin layer of sodium iodide crystals) was transferred by means of nitrogen pressure to a flask and the solvent distilled through a column up to 40°. More ethyl iodide (11.6 g.) in 100 cc. of dry benzene was added to the residue and the mixture was refluxed eighteen hours. On working up the mixture there was obtained 35 g. (73%) of diethyl ethylisopropylmalonate, b. p. 118–120° (15 mm.) (234–236° at atm. pres.).[2b]

Refluxing diethyl ethylisopropylmalonate ten hours with 95% alcoholic potassium hydroxide and decarboxylation of the resulting malonic acid gave a 48% yield of ethylisopropylacetic acid, b. p. 104–105° (15 mm.). Neutral equivalent, calculated for $C_7H_{14}O_2$: 130.18. Found: 131.28. With aniline the acid gave the anilide, melting at 118–119°. (*Anal.*[7] Calcd. for $C_{13}H_{19}ON$: N, 6.83. Found: N, 6.53). No attempt was made to isolate ethyl ethylisopropylacetate obtained by Crossley and Le Sueur.[2b]

Diethyl Di-isopropylmalonate.—Sodio-isopropylmalonic ester was prepared by the decolorization of 0.1 mole of sodium triphenylmethide solution with 20.2 g. (0.1 mole) of isopropyl malonic ester, and practically all of the ether was distilled from the mixture in an atmosphere of nitrogen. To the residue was added 10 cc. of dry benzene followed by 21.2 g. (0.125 mole) of isopropyl iodide in 40 cc. of benzene. After standing overnight, the mixture was refluxed twenty-four hours, additional (4.3 g.) isopropyl iodide was added, and the mixture refluxed for twenty-four hours longer. On working up the mixture there was obtained 5.6 g. (23%) of diethyl di-isopropylmalonate, b. p. 122–124° (15 mm.).

Anal.[7] Calcd. for $C_{13}H_{24}O_4$: C, 63.90; H, 9.90. Found: C, 63.52; H, 9.79.

Long refluxing (eighteen to twenty-four hours) of diethyl di-isopropylmalonate with alcoholic potassium hydroxide yielded unchanged ester and ethyl hydrogen di-isopropylmalonate, m. p. 71–72°. Neutral equivalent, calculated for $C_{11}H_{20}O_4$: 216.3. Found: 213.6. The mono acid-ester on heating slowly decarboxylated to form a neutral material, b. p. 71–72° (15 mm.), which was apparently ethyl di-isopropylacetate (*Anal.* Calcd. for $C_{10}H_{20}O_2$: C, 69.72; H, 11.70. Found: C, 68.71; H, 11.31).[7]

Color Reactions for Certain Amino Acids

BY HENRY TAUBER

We have observed that certain amino acids are converted to chromogens when heated. Alcoholic extracts containing these chromogens become more deeply colored when alkali is added, but on subsequent acidification become colorless or much lighter in color.

The procedure has been as follows. Ten mg. of the amino acid in a dry Pyrex test-tube is heated over a burner until the first color change occurs, which may be to yellow or brown depending on the amino acid. Overheating should be avoided since it destroys the chromogens. After cooling, 3 cc. of ethyl alcohol is added and the solution boiled for thirty seconds and the resulting solution divided equally among three small test-tubes. To the first is added 0.2 cc. of 0.1 *N* sodium hydroxide, to the second 0.2 cc. of 0.1 *N* sulfuric acid, and to the third 0.2 cc. of water.

Twenty-one biologically important amino acids have been found to behave as follows: three (*dl*-alanine, *dl*-valine and *dl*-iso-leucine) when heated sublime completely, leaving no pigment or residue. Twelve (*l*-cystine, *l*-cysteine, glycine, *l*-hydroxyproline, *dl*-methionine, glutamic acid, *dl*-aspartic acid, *dl*-serine, *l*-proline, *d*-arginine-monohydrochloride, *dl*-lysine, and *d*-lysine) change to yellow, brown or black decomposition products without chromogenic properties. Six (phenylalanine, *l*-tyrosine, *l*-leucine, *l*-histidine, *l*-tryptophan and *dl*-threonine) form chromogens which react as follows when subjected to the above tests: *l*-tyrosine, *l*-tryptophan and *dl*-threonine turn reddish brown on heating, exhibit a light brown or reddish color in alcoholic solution, become more deeply colored on the addition of alkali and turn a light brown or, in the case of *l*-tyrosine, a yellow color on acidification. *l*-Histidine-monohydrochloride becomes light brown on heating, light yellow in alcoholic solution, deep yellow on the addition of alkali and almost colorless on acidification. *dl*-β or *l*-β-phenylalanine and *l*-leucine on heating partially sublime, turn yellow and give a yellow or light yellow color in alcoholic solution. This color turns to a deep yellow on addition of alkali and becomes almost colorless on subsequent acidification. In the case of the β-phenylalanines the alkaline alcoholic solution exhibits a greenish-yellow fluorescence which is particulary strong in ultraviolet light, without the addition of alkali.

This fluorescent pigment from phenylalanine has been isolated in a more concentrated form as follows. One gram of phenylalanine is heated in a large Pyrex test-tube and stirred with a thermometer until the temperature of the material reaches 250°. After cooling, the crystalline reaction mixture is extracted four times with 15-cc. portions of acetone. The deep yellow, fluorescent solution is concentrated to 10 cc., filtered and evaporated to dryness in vacuum. Ninety-five mg. of reddish-brown hygroscopic material is obtained. Dilute alcoholic solutions of this pigment show intense fluorescence in ultraviolet light but not in daylight. On the addition of alkali, however, deep greenish-yellow fluorescence is shown in daylight. In acetone the fluorescence is much stronger than in alcoholic solution. The pigment gives a much more intense xanthoproteic reaction (deep orange-red) than phenylalanine. After acetone extraction of the pyrolyzed reaction mixture there is left 550 mg. of white material and some substance is lost owing to sublimation.

We are aware that these amino acids are not the only compounds that react in this manner. We believe, however, that these observations are interesting enough to warrant recording. Especially remarkable is the strongly fluorescent compound that forms on the pyrolysis of phenylalanine.

Substituted α-Amyl-cinnamylaldehydes

BY A. WEIZMANN

α-Amyl-cinnamylaldehyde is, because of its jasmin-like odor, manufactured industrially from heptanal and benzaldehyde.[1] It seemed possible that the same synthesis with substituted benzaldehydes, which by themselves exhibit pleasant odors, would give especially valuable products. This was, however, not the case. 4-Methoxy-, 3,4-methylene-dioxy- and 3,4-dimethoxy-α-amyl-cinnamylaldehydes have been synthesized and studied; the first of them has been described briefly before.[2] The substituted benzaldehydes proved less reactive than benzaldehyde itself in this condensation, as in other similar cases.[3] In all these experiments, a mixture of pyridine and piperidine proved a more convenient catalyst, than the commonly used potassium hydroxide. Vanillin did not react at all with oenanthal under these conditions.

Experimental

4-Methoxy-α-amyl-cinnamylaldehyde.—A mixture of heptanal (12 g.), anisaldehyde (14 g), pyridine (100 cc.) and piperidine (10 cc.) was heated on the water-bath for eight hours, poured out into ice-cold dilute sulfuric acid and extracted with ether. The product was twice distilled at 0.3 mm.; b. p. 145°; yield, 10 g.

Anal. Calcd. for $C_{15}H_{20}O_2$: C, 77.6; H, 8.6. Found: C, 77.6; H, 9.0.

The semicarbazone separated from a mixture of the aldehyde (1.5 g.), semicarbazide hydrochloride (0.75 g.) and potassium acetate (0.6 g.) in aqueous alcohol at room temperature. It formed needles, m. p. 143–145°, when crystallized from propyl alcohol. Calcd. for $O_{16}H_{23}O_2N_3$: N, 14.5. Found: N, 14.3.

3,4-Dimethoxy-α-amyl-cinnamylaldehyde.—Veratraldehyde (13 g.) and heptanal (9.5 g.) were condensed by heating for eight hours in presence of pyridine (50 cc.) and piperidine (5 cc.). The condensation product had b. p. 165° (0.6 mm.).

Anal. Calcd. for $C_{16}H_{22}O_3$: C, 73.3; H, 8.4. Found: C, 73.4; H, 8.7.

The semicarbazone, prepared as above, was recrystallized from propyl alcohol and formed needles, m. p. 175°.

Anal. Calcd. for $C_{17}H_{25}O_3N_3$: C, 64.0; H, 7.8; N, 12.7. Found: C, 64.4; H, 8.4; N, 13.0.

NEW COMPOUNDS

Some Aryl and Aralkyl Ureas

In connection with a study of the hypnotic properties of aryl ureas carried out by a pharmacological group in these Laboratories, a number of halogenated unsymmetrical aryl alkyl ureas have been prepared. Data on these and on some related unhalogenated ureas and symmetrically substituted ureas are presented in Table I.

Preparation of Secondary Amines.—The 3-chloro and bromo anisyl methyl and homo anisyl methyl amines (leading to ureas XVI–XIX) were prepared by halogenation of N-methyl anisyl and N-methyl homo anisyl amines in hydrochloric acid solution (XXIV in hydrobromic acid).

Whereas non-halogenated aromatic secondary amines are readily prepared by alkylation with alkyl halides, isolation of the secondary amine as the nitrosamine followed by reduction with stannous chloride, the alkyl bromides and iodides are unsuitable for reaction with halogenated aromatic amines,[1] the halogen being removed or displaced with resulting complications. By use of alkyl sulfates and alkyl toluene-sulfonates the desired alkyl groups can be introduced satisfactorily.

Ethylation was accomplished by stirring the primary amine with ethyl sulfate and water on the steam-bath until the layers had disappeared after which the conventional nitrosamine procedure was followed.

The secondary propyl and butyl amines corresponding to ureas IV and VI were obtained by warming 1 mol of alkyl toluene sulfonate with 2 mols of primary amine for three hours at 110–120°. The partially cooled melts were sludged with benzene and the bulk of the primary amines separated as salts of *p*-toluenesulfonic acid. Addition to the filtrate of alcoholic hydrogen chloride equivalent to about half of the remaining base precipitated virtually all of the remaining primary amines, after which the hydrochlorides of the secondary amines could be separated without trouble. In some runs sulfonamide formation was encountered.

Preparation of Ureas.—The symmetrically substituted ureas XX and XXI were prepared from ethyl isocyanate and the appropriate aromatic bases.

The unsymmetrically substituted ureas I–XIX were formed by the reaction of nitro-urea with the corresponding secondary amines. This reaction is not complete with aromatic secondary amines having ortho-substitution. Ordinarily unreacted amine can be separated by partitioning between ether or benzene and about 6% hydrochloric acid. When, however, there is halogen substitution the basicity of the amine is too low for this separation. Steam-distillation from saturated sodium chloride solution (at about 110°) proved to be adequate for the removal of the unreacted amine and it was then possible to crystallize the secondary ureas reported here. The *n*-butyl derivative analogous to the ureas III and IV was not obtained in crystalline form. Tested physiologically as a crude preparation it showed considerable hypnotic activity.

The dibenzoyl urea XXII resulted from benzoylation of the known N-ethyl-N-*o*-ethyl phenyl urea either by the Schotten–Baumann method or by heating with benzoyl chloride in pyridine.

Di-*n*-butyl-*n*-propylamine

This compound was prepared by the hydrolysis of γ-di-*n*-butylaminopropylmagnesium chloride with aqueous hydrochloric acid, and by the interaction of 2 moles of di-*n*-butylamine and 1 mole of *n*-propyl iodide in a sealed tube at 120° for four hours, removing the residual secondary amine by shaking with benzoyl chloride and 10% sodium hydroxide.

Both methods gave an identical product, with the following constants: b. p. (754 mm.) 193°; b. p. (8 mm.) 73–75°; d^{20}_4 0.7622; $n^{25}D$ 1.4248.

The picrate crystallized easily from 95% alcohol or from ether; m. p. 115.8–116.2°.

The picrate was analyzed for C and H. Calculated for $C_{17}H_{23}N_4O_7$: mol. wt., 400.42; C, 50.99; H, 7.05. Found: C, 50.90; H, 6.77.

NATIONAL INSTITUTE OF HEALTH

RECEIVED DECEMBER 23, 1943

o-Phenylene Dioxyacetic Acid and its Ethyl Ester

The ethyl ester of *o*-phenylenedioxyacetic acid was prepared by refluxing dichloroethyl acetate with catechol in absolute ethanol solution in the presence of 2 moles of sodium and in an atmosphere of nitrogen until neutral to litmus. The reaction mixture was diluted with water, the ester extracted with ether, washed with sodium hydroxide solution and water, and isolated by fractionation; boiling point 115–117° at 12.5 mm.

Anal. Calcd. for $C_{10}H_{10}O_4$: C, 61.86; H, 5.15; mol. wt., 194. Found: C, 61.09; H, 5.70; mol. wt. (Rast), 191. The product gave no test for halogen nor phenolic hydroxyl.

The acid was prepared from its ester by hydrolysis with 1 *N* sodium hydroxide solution; melting point, 107–108° (uncor.) from ether–petroleum ether.

Anal. Calcd. for $C_8H_6O_4$: C, 57.84; H, 3.79. Found: C, 58.12; H, 3.91.

All attempts to effect direct preparation of *o*-phenylene dioxyacetic acid by condensation between catechol and dichloroacetic acid failed.

A New Ammine of Basic Copper Chromate

The salt which most commonly separates from ammoniacal copper chromate solutions is $Cu(NH_3)_4CrO_4$. Other ammines have been described.[1] However, from solutions deficient in chromium and containing a considerable excess of ammonium hydroxide, there separates a previously undescribed compound, having the composition $2CuO \cdot 4NH_3 \cdot CrO_3 \cdot H_2O$. In a typical experiment, the crystals were obtained by adding to a suspension of 14.3 g. of basic copper carbonate in 20 ml. of water, 20 ml. of a solution containing 220 g. of ammonium dichromate per liter; 50 ml. of concentrated ammonium hydroxide was added and the mixture shaken thoroughly. Solution was complete except for a few bluish flecks. On standing at room temperature for several days, crystals of the new compound will frequently deposit. Once a crop has been obtained, preparation of the material may be ensured by seeding the solution with the compound. Cooling should be avoided, as at low temperatures green needles of $Cu(NH_3)_4CrO_4$ tend to separate. The yield, after washing with ammonium hydroxide, alcohol and ether, and drying, is about 6 g. The crystals of the new compound are 0.05–1.0 mm. on a side, thickly tabular, almost cubic in habit, greenish-black by reflected light and deep blue-green by transmitted light. The material slowly loses ammonia on exposure to the air, and stoppered preparations have a noticeable odor. On ignition at low temperatures, the crystals decompose with mild deflagration. The crystalline substance becomes coated with an orange-brown discoloration on exposure to air, and water decomposes it to a yellow basic copper chromate. It is insoluble in alcohol, ether, benzene and carbon tetrachloride, and soluble in ammonium hydroxide and acids, being decomposed by the latter; d^{25}_4 2.49.

Anal. Calcd. for $2CuO \cdot 4NH_3 \cdot CrO_3 \cdot H_2O$: CuO, 46.09; NH_3, 19.73; CrO_3, 28.96; H_2O, 5.22. Found: CuO, 46.21; NH_3, 19.55; CrO_3, 28.92; H_2O, 5.33.

COMMUNICATIONS TO THE EDITOR

AN EQUATION OF STATE FOR SATURATED FLUIDS

Sir:

During a search for an equation of state for saturated fluids a simple relationship between pressure, temperature and specific volumes was found which seemingly is of general validity. In fact out of 59 substances tested only one, acetic acid, showed anomalous behavior. In this case the admittance of association, that is, double molecules, will explain the discrepancies. The test substances have molecular weights from 2 to 260, critical pressures from 2.3 to 218 atm., critical temperatures from −268 to +448° and critical densities from 0.03 to 1.15 g./cc.

Upon separating the roots of a more general, three constant, quadratic equation the following expression was arrived at

$$P = \frac{CT}{v_g + v_e + 2B}$$

where $C = R/M$ and $B = (CT_c/2P_c) - v_c$.

The symbols denote: p, the saturation pressure in atm.; T, the saturation temperature in °K. (ice point 273.16°K.); v_g and v_e the specific volume of saturated vapor and saturated liquid, respectively, in l. per gram; R, the gas constant (0.08206 for l., atm., g.-moles) and M, the molecular weight in grams (based on atomic weights of 1942). Subscripts c, indicate critical values.

The pressures calculated by the equation from corresponding v_g, v_e and T values are given for water from melting point to critical point. The critical data and constants for water are: T_c = 374.11°C., p_c = 218.167 atm., v_c = 3.1975 cc./g., C = 0.0045548 and B = 0.0035593.

TABLE I

T, °C.	p, atm. calcd.	lit.[1]	T, °C.	p, atm. calcd.	lit.[1]
0	0.0060307	0.0060273	200	15.910	15.332
20	.023089	.023042	220	23.800	22.897
40	.073126	.072748	240	34.356	33.044
60	.19742	.19656	260	48.049	46.322
80	.47070	.46740	280	65.290	63.343
100	1.0109	1.0000	300	86.583	84.776
120	1.9901	1.9595	320	112.34	111.40
140	3.6419	3.5669	340	143.09	144.14
160	6.2638	6.1032	360	180.59	184.26
180	10.216	9.896	374.11	(218.167)	218.167

Evidently the equation does not compare with the high accuracy afforded by several vapor pressure equations; however, the wide range of application, the great simplicity and the ease of calculation will render it useful for checking and supplementing experimental data. The agreement is considerably better for many of the substances tested and especially for the simpler gases such as helium, hydrogen, neon, nitrogen.

A complete report will be published later.

ELECTRON MICROSCOPE OBSERVATIONS OF CLAM MUSCLE FIBRILS

Sir:

Submicroscopic fibrils have been obtained from the adductor muscles of marine and fresh-water clams (Mya, Venus, Anodonta). In the dark-field microscope they appear as long, slender, needle-like fibrils. This fibrous protein has the solubility properties of myosin; it dissolves in 0.6 M potassium chloride to form a solution showing high viscosity and stream birefringence. Dilution with water produces a flocculent precipitate which can be redissolved in potassium chloride and which is apparently devoid of fibrils.

Electron micrographs show the fibrils to be very long and evenly contoured, having widths usually between 200 and 1000 Å., though sometimes less. In fibrils treated with osmic acid the density along the axis is not uniform but shows a periodic variation, producing a cross-striated appearance (Fig. 1). From measurements of 100 fibrils a distribution curve of "spacings" of this fiber axis repeat pattern was constructed. All the values lay between 290 and 470 Å., a surprisingly small range in view of the mechanical lability usually associated with muscle fibers. The most frequently occurring spacings were between 330 and 390 Å., the average value of all spacings being 360 Å.

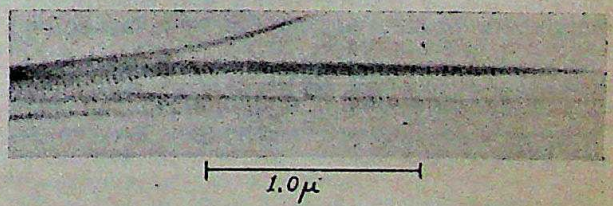

Fig. 1.—Electron micrograph of clam muscle fibrils, magnification × 27,000.

Subsequently Dr. R. S. Bear examined these muscles with X-rays and obtained diffraction evidence that the fiber-axis period in the intact dried muscle is 720 Å. It is improbable that this apparent difference is due to alterations produced in isolating the fibrils and preparing them for elec-

tron microscope examinations. More likely, the larger X-ray period reflects density differences not yet resolved with the electron microscope but which may become apparent when special methods are applied. The structural problem, which is of great interest in connection with the mechanism of contractility, is one which requires for its solution both electron microscope and X-ray diffraction data. Details of the analysis will be reported in due course.

SPIROPENTANE

Sir:

The authors have made a Raman spectroscopic study of the low-boiling products obtained in the debromination of pentaerythrityl bromide by zinc. The first reduction was carried out in aqueous methanol.[1] In addition to lines assignable to methylenecyclobutane (I) and to 2-methyl-1-butene (II) the Raman spectrum of the product showed lines at 581 and 1033 cm.$^{-1}$ which arose from about 1–5% of a third component (III). Examination of the spectra of various fractions obtained in the distillation of the reduction mixture indicated that the boiling point of III should be near 37°. By means of this information and the known Raman spectra and generalizations therefrom it was possible, at least tentatively, to conclude that III did not correspond to any compound known to the authors. It seemed quite probable that the lines belong to spiropentane.

It was reasoned that if this were spiropentane and if it could be formed at all by zinc in aqueous methanol, in spite of the preponderance toward rearrangement, there should be other conditions, under which III would form in larger proportion. This proved to be the case. When the reduction was carried out by zinc in molten acetamide in the presence of sodium iodide and sodium carbonate[2] the product showed the same low-boiling substances but the compound responsible for the 581 and 1033 cm.$^{-1}$ lines was now a major component—approximately 40%.

Isolation of the pure compound involved removal of the accompanying olefins, first by repeated extraction with saturated aqueous silver nitrate, then with saturated aqueous silver perchlorate and finally by reaction with bromine. None of these reagents noticeably affected the new compound. The final, purified product has an odor similar to chloroform; b. p. 38.3–38.5°; n^{20}D 1.4117. *Anal.*[3] Calcd. for C_5H_8: C, 88.17; H, 11.83. Found: C, 87.91; H, 11.53. Its spectrum is given in Table I.

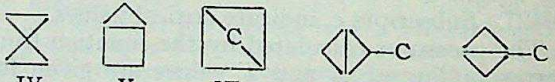
TABLE I

RAMAN SPECTRUM OF SPIROPENTANE

$\Delta\nu$, cm.$^{-1}$	I^a	$\Delta\nu$, cm.$^{-1}$	I^a
305	4	1397	5
581	16	1426	10
613	4	2836	0.4
779	4	2881[b]	
872	30	2991	100
1033	50	3065	30
1150	1		

[a] Intensities measured on Gaertner microdensitometer. [b] Intensity too low to measure.

Raman spectra considerations, boiling point, and non-reactivity with bromine conclusively eliminated acetylenes, diolefins and monocyclic olefins and left only the possibility that the compound was one of the following dicyclic hydrocarbons



IV V VI VII VIII

The authors favor formula IV because, 1, the product is formed in greater amount when conditions are less favorable to rearrangement and 2, the Raman pattern in the 2800–3100 cm.$^{-1}$ region indicates that all the hydrogens present are attached to cyclopropane rings and none either to cyclobutane rings (V, VI) nor to carbon in a methyl group (VII, VIII).

NEW BOOKS

How to Solve Problems in Qualitative Analysis. By JOSEPH A. BABOR, Associate Professor of Chemistry, The College of the City of New York, and J. KENNETH W. MACALPINE, Assistant Professor of Chemistry, New York University. Thomas Y. Crowell Company, 432 Fourth Avenue, New York, N. Y., 1943. iv + 93 pp. 14 × 21 cm. Price, $0.75.

The increasing importance of mathematical operations in chemistry has been producing a variety of "problem-solving" books, and this one is among the first dealing with qualitative analysis. Chapters composed of definitions, explanatory matter, examples and problems for the student, are presented under the titles: 1. Mathematical Operations, 2. Concentration of Solutions, 3. Weak Electrolytes, 4. Solubility-Product Principle, 5. Ionization Constant and Solubility Product, 6. The Water Equilibrium; Hydrolysis, 7. Complex Ions. The average sophomore student will have been exposed already to much of this material, but a lot of it will not have been retained. Diligent use of this condensed pamphlet will serve to revive and polish a student's faded comprehension into practically workable form.

ALLEN D. BLISS

Proteins, Amino Acids and Peptides as Ions and Dipolar Ions. By EDWIN J. COHN and JOHN T. EDSALL, Harvard Medical School. (A. C. S. Monograph Series.) Reinhold Publishing Corporation, 330 West Forty-second St., New York, N. Y., 1943. xviii + 686 pp. 15.5 × 235 cm. Price, $13.50.

At the present time, the outstandingly important general problem in the chemistry of natural products is the determination of the structure of proteins. Through the work of Emil Fischer and his predecessors, it has long been recognized that proteins consist of complicated condensation products of amino acids linked by peptide bonds, but of the ordinal distribution of these component units, and the effects of fine structure upon physicochemical properties, our knowledge is almost entirely conjectural. This state of affairs is ascribable to the complexity of the problem rather than to any neglect, for during the past decades much effort has been devoted to its elucidation.

The appearance of this treatise, written by a group of investigators who themselves have added, by observation and interpretation, to our knowledge of the physicochemical behavior of proteins, is therefore particularly welcome. Chapters on special aspects of the subject have been contributed independently or in collaboration with one of the authors by John D. Ferry, John G. Kirkwood, John W. Mehl, Hans Mueller, L. J. Oncley, and George Scatchard. No attempt has been made to present a systematic discussion of protein chemistry in all its phases, nor to describe experimental procedures.

The first half of the book deals with amino acids and peptides, consideration of which is an essential preliminary to the theoretical treatment of proteins. In an introductory chapter, Cohn and Edsall survey the modern theoretical views of dipolar ions and indicate the application of these to proteins. The second chapter, by Edsall, consists of a discussion of spectroscopic properties of dipolar ions; mere mention is made of the author's elegant demonstration that Raman spectra afford cogent evidence, supported by infrared and ultraviolet spectra, of the dipolar character of amino acids. In Chapter 3, Scatchard applies concentrated thermodynamics and simple electrostatic theory to dipolar systems. Chapter 4, by Edsall, relating to acid–base equilibria, contains a lucid description of Brönsted's theory as applied to amino acids and discusses in detail the ionization data of various types of amino acids and peptides; this discussion is continued in the fifth chapter, entitled Some Relations between Acidity and Chemical Structure, also by Edsall, who includes here a pertinent outline of the resonance theory. In Chapter 6, Edsall gives a comprehensive survey of work on the dielectric constants and dipole moments of dipolar ions; in Chapter 7 he discusses apparent molal volume, heat capacity, compressibility and surface tension of dipolar ions in solution. Chapter 8, by Edsall and Scatchard, relates to solubility in water and organic liquids, and includes a brief section on hydrogen bonding. Chapter 9, by Cohn and Edsall, treats of interactions between organic solvents and dipolar ions, as estimated from solubility ratios, in reference to the respective importance of the hydrophilic and hydrophobic groups in the amino acid molecule; the impressive volume of data permits the detection of striking quantitative trends in solubility relations. Chapter 10, by Cohn, is devoted to interactions between amino acids, peptides and related substances, and their effect on the activity coefficient. In Chapter 11, the same author considers the effect of interactions between ions and amino acids or peptides upon solubility, and discusses the theory of salting-out and salting-in. Chapter 12, by Kirkwood, is devoted to theoretical interpretation of the properties of solutions of dipolar ions which are characteristic of their electrical structure.

The second half of this volume bears the general title "The Size, Shape and Electric Charge of Protein Molecules." In Chapter 13, Edsall considers the structural basis of the protein molecule as inferred from analysis and from the action of proteolytic enzymes. Here the absence of clear-cut evidence of precise structure, in the organic chemist's sense of the word, combined with the inordinately complicated nature of the molecule, renders the author's task of summary difficult in the extreme; he has, however, so marshalled the pertinent facts as to present as clear a picture as seems humanly possible.

The succeeding chapters are devoted to more detailed discussion of restricted avenues of approach. In Chapter 14, Edsall considers the evidence concerning the peptide chain afforded by X-ray diffraction studies, discusses the structure of the "fibrous" and the "globular" proteins, gives a few paragraphs to the virus proteins, and concludes with brief sections on the cyclol hypothesis and on the deductions from Patterson projections. Chapter 15, by Cohn, consists of a survey of the natural amino acids, the special methods by which some of these are estimated in protein hydrolysates, and the amino acid composition of a few proteins. Chapter 16, by Cohn and Edsall, deals with the density of proteins and the molal volumes of their constituent amino acid residues. The osmotic pressure of proteins in solution and the deductions as to molecular weight are discussed in Chapter 17 by Edsall and Cohn. In Chapter 18, Edsall and Mehl take up the problems of translational diffusion and Brownian movement of proteins; in the succeeding chapter Edsall discusses sedimentation and diffusion in centrifugal fields and the results of ultracentrifugal studies on proteins.

Chapter 20, by Edsall, is devoted to the important subject of behavior of proteins as acids and bases. In the discussion of net charge and total charge in proteins, the author admits that his reasoning involves the addition or removal of protons and of no other ion, but he adheres to the custom of referring to the "binding" of "acid" and "base." This reviewer hopes that in future editions the authors will, in their theoretical treatment of the charges on dissolved proteins, exercise their world-wide authority and abandon this convention in favor of a terminology which suggests the participation of hydrogen or hydroxyl ions, and not that of undissociated molecules.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

In Chapter 21, Edsall discusses the determination of viscosity and double refraction of flow in protein solutions and the interpretation of the resulting information with respect to the shape of protein molecules. Chapter 22, by Oncley, is devoted to consideration of the estimation of electric moments and relaxation times by means of the dielectric constants of protein solutions. In Chapter 23, Cohn takes up the theory of the solubility of proteins and Edsall discusses the application of the phase rule to their solubility relations, a procedure of practical value in establishing criteria of homogeneity of protein preparations. In Chapter 24, Cohn and Ferry discuss the detection of interactions of proteins with ions and dipolar ions by determining the relations between solubility and various physical and chemical properties; salting-in and salting-out are here considered. Chapter 25, by Mueller, is devoted to the theory of electrophoretic migration, a subject of increasing practical importance in medicine as well as in protein chemistry.

The volume closes with an appendix containing factual information, a general subject index and tabular indexes of data in the text for certain important amino acids, peptides and proteins.

Like the other monographs in this series, this book is admirably edited and printed. It is, however, not easy reading for the general student, and probably few specialists exist who could take the whole work in their stride. The treatise has great educational value, for investigators as well as for students. It is, moreover, but one of the fruits of the close association, over more than fifteen years, of the unique group of experts in the authors' laboratory, where "freed from the necessity of considering practical applications" they could "make the excursion into the chemistry of protein prototypes which forms the background of this book. . . . ."

HANS T. CLARKE

Treatment of Experimental Data. By ARCHIE G. WORTHING, University of Pittsburgh, and JOSEPH GEFFNER, Weirton Steel Company. John Wiley and Sons, Inc., 440 Fourth Ave., New York, N. Y., 1943. ix + 342 pp. Illustrated. 15.5 × 23.5 cm. Price, $4.50.

Bringing to bear the resources of numerical mathematics for the treatment of experimental results is a relatively new procedure in some of the fields where experimental observations are gathered. The reviewer recalls asking a mature student some thirty years ago how he had obtained certain values which had obviously been subjected to a smoothing process. The reply was that "a curve had been drawn among the points." One may indeed sympathize with Professor Worthing when he refers to exasperations engendered over the years by the lack of knowledge on the part of the author of the methods by which experimental data may be fully digested and conveniently presented.

The material of the volume is the culmination in large part of a graduate course in the general treatment of a wide variety of observational material. Everyone who works with observational material, regardless of the particular field, will take a lively interest in the systematic and clear expositions for dealing with data. There are thirteen chapters of which the first three pertain to primary representations followed by one on methods of differentiation and integration. The practical applications and uses of Fourier series including a discussion of analyzers occupy one chapter, and then comes a very sensible presentation of the doctrine pertaining to normal frequency distribution, precision indexes and the technique of least square treatments of data. The concluding chapters contain a brief account of correlation and non-harmonic periodic functions, while an appendix giving the elementary expansion rules for determinants, useful tables, and a copious bibliography complete the volume.

The authors have incorporated a number of features which should prove particularly attractive to students and facilitate the book's use as a text. For example, all symbols used are listed along with ample information about their meaning before the first chapter and the fifth chapter (Fourier series). An abundance of illustrative material from widely different fields is used throughout, each chapter concludes with a summary and a series of problems, and the ensemble of material is knit together in simple direct language. The book is also illustrated with an unusually large number of figures. The authors have made an excellent contribution which will undoubtedly go far to promote the intelligent evaluation of experimental data in all fields of science.

Naturally the authors have had to exercise care not to overexpand the material. The reviewer believes, however, that George Rutledge's method of obtaining a derivative function (*Phys. Rev.*, **40**, 262 (1932)) is superior to that based on the Gregory–Newton formula, particularly for machine calculations. This remark holds also for Rutledge's interpolation formulae (*Trans. Am. Math. Soc.*, **31**, 807 (1929)). E. V. Huntington (*Am. Acad. Arts Sci.*, **63**, 421 (1929)) has also given convenient and extensive interpolation tables.

The printing, typography and form of the volume are excellent.

JOURNAL OF THE AMERICAN CHEMICAL SOCIETY

Published monthly by the American Chemical Society at Easton, Penna.

Editorial Office: Chemical Laboratory of Harvard University, 12 Oxford St., Cambridge 38, Mass.

Assistant to the Editor (Proof and Make-up): Allen D. Bliss, Department of Chemistry, Simmons College, 300 The Fenway, Boston 15, Mass.

Business Office: American Chemical Society, 1155 16th St., N.W., Washington 6, D. C.

Advertising Office: American Chemical Society, 332 West 42nd St., New York 18, N. Y.

The American Chemical Society and the Editors of the *Journal of the American Chemical Society* assume no responsibility for the statements and opinions advanced by contributors to THIS JOURNAL.

Remittances and orders for subscriptions and for single copies, notices of changes of address and new professional connections, and claims for missing numbers should be sent to the American Chemical Society, 1155 16th Street, N.W., Washington 6, D. C. Changes of address for the *Journal of the American Chemical Society* must be received on or before the 18th of the preceding month.

Claims for missing numbers will not be allowed (1) if received more than sixty days from date of issue (owing to the hazards of war-time delivery, no claims can be honored from subscribers outside of North America), (2) if loss was due to failure of notice of change of address to be received before the date specified in the preceding paragraph, or (3) if the reason for the claim is "missing from files."

Annual subscription—$8.50 to non-members, $3.00 to members. Postage to countries not in the Pan American Union, $1.50; Canadian postage, $0.50. Single copies—current issues $0.75, back numbers $0.80; special rates to members.

The American Chemical Society also publishes *Chemical Abstracts*, *Industrial and Engineering Chemistry* (Industrial and Analytical Editions), and *Chemical and Engineering News*. Rates on request.

NOTICE TO AUTHORS OF PAPERS

Manuscripts for THIS JOURNAL should be submitted to the Editor ready for publication, typewritten (double space), with 2–3 cm. margins, on a good quality, durable paper, preferably of 8.5″ × 11″ size. In addition to the original typewritten copy, one or more carbon copies should be submitted so that the time required for examination by the Editorial Board may thus be considerably shortened. Care should be taken that all pages in a manuscript, including tables (but not the diagrams) be numbered consecutively. In preparing manuscripts authors are requested to observe, for reasons of economy, the utmost conciseness consistent with clarity of presentation. The manuscripts should be addressed to specialists in their particular field rather than to the general reader. Extensive reviews of the literature cannot be accepted. When well-known or previously published procedures have been followed in the experimental work they should only be designated or referred to.

Form of Presentation.—There should be one or more introductory paragraphs setting forth the occasion, significance and main objectives of the investigation and the method of attack. This should be followed by the experimental results and a discussion of them, either *seriatim* or at their conclusion. Finally, there should be a brief summary of the main achievements of the investigation. Sometimes, particularly when the subject matter is involved and there are many details which, though essential for a successful repetition of the experiments, are unnecessary for the main account of the investigation, these details can with advantage be relegated to an appendix or supplement, just preceding the Summary. In intermediate cases it is often advisable to retain a single, straightforward presentation but to intercalate sections in fine print giving the experimental details of procedure. This has the great advantage of keeping the experimental details close to the more general statements based upon them and yet at the same time permitting the reader if he wishes to pass over this section without inconvenience.

It will be of great assistance to the Editor's Office if the style, arrangement and orthography of the manuscripts are made to conform to the usages of the JOURNAL as exemplified in its recent issues and as set forth in the following paragraphs.

Center headings should be employed sparingly; side headings should be indented and run into the text to which they apply, using period and dash. References to the literature and all footnotes regardless of their nature (except those in tables) should be numbered in one consecutive series, repetition of notes being avoided by using simply the superscript number corresponding to the original reference. They should follow immediately in separate lines the line of text containing the text words to which they refer, and may be set off by short rules above and below. The items in the references to the literature should conform to the uniform usages of the Journal as regards order and punctuation, and to the abbreviations as given by *Chemical Abstracts* in its "List of Periodicals Abstracted." The names of all simple compounds rather than their formulas should be used whenever they occur in the text. Periods of time (unless fractional) should be written in words and quantities of material in Arabic numerals, unless occurring at the beginning of a sentence. Letters used to represent quantities in mathematical expressions should be underscored to indicate that they are to be printed in italics, and Greek or other unusual characters should be written plainly or should be explained by annotations. Simple fractional expressions should be written with a slant line rather than in the conventional manner, so that only a single line of type is required. All subscripts and superscripts should be carefully made and placed (the degree sign ° or a small o should not be used to represent zero). For economy, except in unusual circumstances the abbreviations %, °A., cm., cc., ml., g., Å., m. p., f. p., b. p., cal., kcal., expt. and Fig., should be used rather than the words.

Figures and graphs should be carefully prepared line drawings on plain white drawing paper, blue drawing cloth or coördinate paper printed in blue only. The

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

original are preferable, but clear, well-prepared photographic prints or photostats are acceptable. Illustrations are most conveniently handled when made in the conventional 8.5″ × 11″ manuscript size; if they are of necessity larger, and therefore liable to damage in mailing, duplicate rough sketches or photographic prints of smaller size should be furnished for dispatch to the Referees. Diagrams should be designed to occupy a single column width and should therefore be tall rather than wide. Particular attention should be given to the correct proportions of the various parts of the figure, especially the experimental points, and if any letters, numbers, or legends must be placed on the diagram to their proportions also. In graphs the frame and actual curves should be ruled and inked more heavily than the coördinate lines, and these latter should not be too close together. Experimental points should always be given and should be indicated not by crosses but by circles or other symbols carefully drawn with drafting instruments. Where feasible it is often helpful to have the diameter of the circles indicate the precision of the measurements. The numbers and legends on coördinate axes are set up in type by the printer; the author, therefore, should place them in pencil outside the axes. The numbers and titles of figures should be placed below the diagrams, or on the back, or collected on a separate sheet. Small photographic prints should be mounted on cardboard and any composite series of photographic prints should be mounted in the order and arrangement desired. Each piece of illustration copy should be marked on the margin or back with the name of the author and brief title of the article (for identification purposes).

Tables.—Tables should not be used indiscriminately as they are much more expensive, line for line, than running text. If reasonably possible, they should be designed to occupy fully a single column (3 inches), which will take 50–75 characters and spaces. Tables occupying the full width can be used, but they are undesirable for the same reasons advanced with regard to page wide figures; their preparation should follow the same principles as for those of single width. Care should be taken to avoid any arrangement which unduly increases the depth of a table, and column heads should be made as small as possible, using abbreviations liberally. Lines of data should not be numbered nor run numbers given unless these numbers are needed for reference in the text. Columns should not be used to contain only one or two entries, nor should the same entry be repeated numerous times consecutively, since these cases may be taken care of more economically in footnotes, or by entries following the title of the table. Data should not be included in one column which are deducible easily by simple arithmetic from data in another column. Tables should be interspersed in the manuscript as near as possible to the places where they are referred to in the text, and need not be placed alone on separate sheets.

Formulas and Equations.—Empirical and structural formulas and mathematical and chemical equations should be arranged to fill adequately the width of a single column. This will often require a continuation of the equation in additional lines, and although this is a disadvantage it is in general preferable to intrusion into the adjoining column. Subscripts and superscripts, especially the latter, should be written with care and the conventional fractional arrangements should not be used in exponents. Organic structural formulas should be arranged to fill the space economically, and arrows should be used horizontally or vertically, not diagonally, wherever possible.

Notes do not differ fundamentally from Articles. They describe fragmentary or less complete studies and hence particular attention must be given to brevity and conciseness of presentation. Summaries are not included. They are collected in a special section near the end of each number of the Journal.

New Compounds.—This department is for brief accounts of new substances which do not appear of sufficient importance to justify separate publication and cannot be described appropriately as part of any other Article or Note. These accounts should report the preparation of the new compound succinctly, yet fully enough so that the operations can be duplicated. Significant properties, formulas and analytical data to establish the identity and purity of the substance should be given. Material appearing in this classification will not be accepted for subsequent publication.

Communications to the Editor are designed to afford prompt, brief, preliminary publication in our Journal of new and significant observations or discoveries. Their total length may in no case exceed 500 words or the equivalent. They will be given as rapid editorial consideration as possible, but at best it will usually be out of the question to include them in a given issue of the Journal if they arrive at the Editor's office later than the 20th of the preceding month. Communications like other contributions should be self-sustaining; that is, they should present experimental or other evidence adequate to establish the *prima facie* credibility of the results or conclusions stated or to permit their appraisal by an expert in the field although because of the 500-word limit a complete presentation cannot usually be expected. These requirements make Communications on many subjects impracticable, particularly those of an involved or theoretical nature.

Communications differ from ordinary Articles or Notes in that their publication does not prevent the re-publication of their subject matter in a later, more complete article in the Journal. In view of this special provision and their expedited publication, it is clear that the contribution made by the Communication should be of special interest or timeliness; mere abstracts of forthcoming articles cannot be accepted. Proof and reprint order will be sent to authors whenever possible, but as this cannot always be done, a memorandum as to the reprints desired should accompany the manuscript.

Microfilm Supplements.—By arrangement with Science Service material supplementary to articles in THIS JOURNAL, such for instance as extensive tables, graphs or calculations, can be distributed at small cost as American Documentation Institute Documents in the form of microfilms with images 25 mm. high on standard 35-mm. film or photoprints 6 × 8 inches legible to the unaided eye. Such material must, however, have been submitted to the Editor of the Journal and must have been approved by him for publication. Attention will then be called to these documents by means of footnotes at appropriate points in the text of the article concerned.

AMERICAN CHEMICAL SOCIETY

VOLUME 66 MARCH 9, 1944 NUMBER 3

[CONTRIBUTION FROM THE GATES AND CRELLIN LABORATORIES OF CHEMISTRY, CALIFORNIA INSTITUTE OF TECHNOLOGY, No. 943]

Contribution to the Stereochemistry of Cryptoxanthin and Zeaxanthin

BY L. ZECHMEISTER AND R. M. LEMMON

Although the *cis–trans* isomerization of β-carotene has been studied in detail,[1] the investigation of its hydroxy derivatives, cryptoxanthin, $C_{40}H_{55}$·OH, and zeaxanthin, HO·$C_{40}H_{54}$·OH, is limited. Only those stereoisomerization phenomena which result from the iodine catalysis or heating of solutions have been studied.[2] Those spectral alterations which are caused by the bending of the molecule and take place in a certain section of the ultraviolet region[3,4] have not yet been examined.

In earlier experiments only one stereoisomer of natural (all-*trans*-) cryptoxanthin, *viz.*, "neocryptoxanthin," was reported. Three stereoisomers of natural zeaxanthin, the neo-forms A, B and C, were studied more extensively. In contrast to "neocryptoxanthin," the neozeaxanthins were found to possess a stronger adsorption affinity than the all-*trans* compound. The present reinvestigation of the stereoisomerization of zeaxanthin by methods which among others included melting of crystals and refluxing in higher boiling solvents has revealed no new members of this stereoisomeric set. However, two new isomers of cryptoxanthin were observed and named in accordance with analogous members of the β-carotene set. The minor isomer, neo B, is adsorbed on the Tswett column below "neocryptoxanthin" (now termed neo A). Neocryptoxanthin U which is adsorbed above the all-*trans* pigment appears upon careful development with petroleum ether–acetone mixtures. Its characteristics in many respects are similar to those of neo-β-carotene U[1] and neo-α-carotene U,[4] which likewise possess increased adsorbability relative to their all-*trans* forms.

In the present paper we wish also to report on the changes which occur in dilute solutions of cryptoxanthin and zeaxanthin (1 to 10 mg. per 100 ml.) during exposure to intense sunshine.[5] Under such conditions a gradual bleaching takes place, the rate of which for some reason is considerably greater for zeaxanthin than for cryptoxanthin (Table I).

TABLE I

LOSS OF COLOR INTENSITY OF BENZENE SOLUTIONS OF CRYPTOXANTHIN AND ZEAXANTHIN ON EXPOSURE TO INTENSE SUNSHINE

Duration of insolation, min.	Loss of color intensity (% of the initial value) Cryptoxanthin	Zeaxanthin
15	6	21
30	17	39
45	26	63
60	36	88

This loss in colorimetric intensity is a result of three processes: first, stereoisomerization; second, structural conversion to other pigments; and third, cleavage to colorless or nearly colorless substances. A short exposure to sunshine causes a small amount of *trans*→*cis* isomerization. While this rearrangement is taking place, the other reactions begin. Finally, the cleavage becomes the predominant process. Therefore, the proper duration of the insolation must be established for each carotenoid in order to study its photoisomerization.

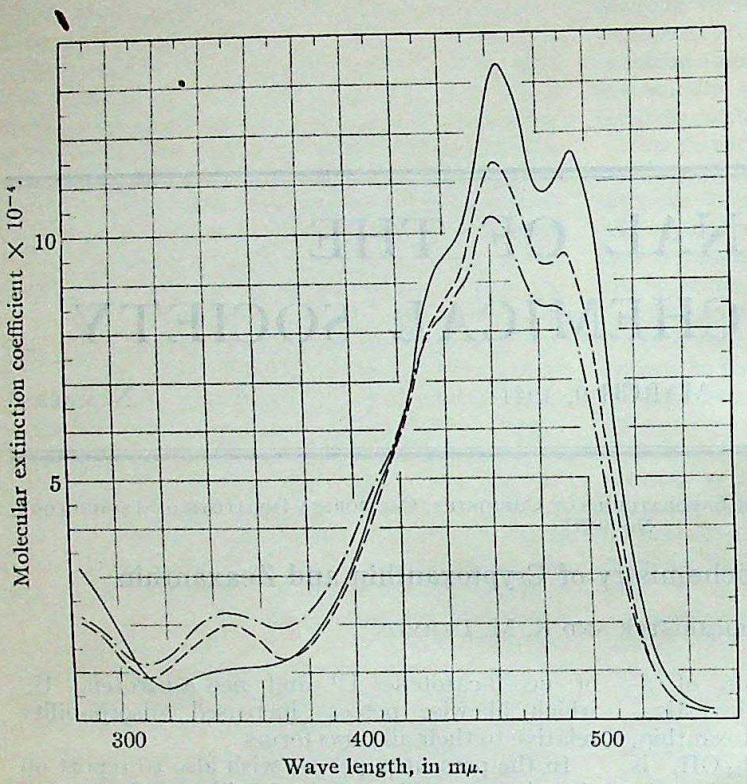

Fig. 1.—Molecular extinction curves of cryptoxanthin in benzene: —, fresh solution of the all-*trans* compound; ---, mixture of stereoisomers after refluxing for forty-five minutes; —·—·, after iodine catalysis at room temperature in light.

An insolation for forty-five minutes is adequate for cryptoxanthin; shorter exposures produce a slight stereoisomerization only. Zeaxanthin isomerizes to some extent in five minutes but an exposure of fifteen minutes was more satisfactory for the present stereochemical work. After thirty minutes of insolation most of the recovered pigment passed into the chromatographic filtrate under conditions under which any known member of the zeaxanthin set would have been adsorbed on the column.

The pigment mixture obtained upon insolation of zeaxanthin for fifteen minutes was composed of 48% unchanged all-*trans* compound, 11% neozeaxanthins, 12% minor zones, and 29% of a pigment which does not belong to the zeaxanthin set. The positions of the visual spectral bands of this latter pigment are approximately identical with that of the zeaxanthin bands. It is adsorbed between zeaxanthin and cryptoxanthin on the column. The investigation of this polyene, which was obtained in crystals in a yield of 17% from zeaxanthin, is not yet concluded.

We shall now consider the influence of *trans*→*cis* rearrangements on the spectral curves. As shown by Figs. 1 and 2, the molecular extinction curves of solutions which have been catalyzed with iodine resemble those of the carotenes in their essential features. There occurs upon catalysis a decrease of the extinction in the visible region which was observed earlier in heated solutions by Strain,[6] by Beadle and Zscheile,[7] and by White, Zscheile and Brunson[8]; partial spectral curves of some stereoisomers were given in those papers. We find that in the ultraviolet region a marked *cis*-peak appears at 348 mμ (in benzene). It must be stressed that light is required for *cis–trans* rearrangement of carotenoids induced by iodine[9]; neither cryptoxanthin nor zeaxanthin solutions showed a *cis*-peak when catalyzed in darkness. However, an irradiation with a lamp as short as five seconds developed a marked portion of the peak under conditions specified in the Experimental Part. The process is practically complete within two or three minutes.

The isolation of isomers from mixtures by chromatography permits the determination of the height of the *cis*-peak of each observed member of the set and, consequently, a tentative assignment of spatial structures.[4,5] The basis for the following discussion is given in Figs. 3, 4 and 5 as well as in Table II.

One *trans*→*cis* rotation usually shifts the longest wave length maximum of an all-*trans* carotenoid about 5 mμ toward the ultraviolet. Therefore, the neocryptoxanthins B and U are evidently mono-*cis*

Table II

Typical Spectroscopic Data for Some Members of the Stereoisomeric Cryptoxanthin and Zeaxanthin Sets in Benzene Solution (in the Sequence of Decreasing Adsorbability)

Member of the set	Diff. between the visually established longest wave length max. of the member and the all-*trans* form (mμ)	Mol. extinction coeff. at the *cis*-peak $E^{\text{mol.}}_{1\text{ cm.}} \times 10^{-4}$	Diff. between mol. ext. coeff. of the member and of all-*trans* form at *cis*-peak
	Cryptoxanthin		
Neo U	5	1.7	0.7
All-*trans*	0	1.0	0
Neo A	6.5	3.4	2.4
Neo B	4.5	4.6	3.6
	Zeaxanthin		
Neo A	5.5	4.4	3.7
Neo B	5.5	2.4	1.7
Neo C	8.5	3.9	3.2
All-*trans*	0	0.7	0

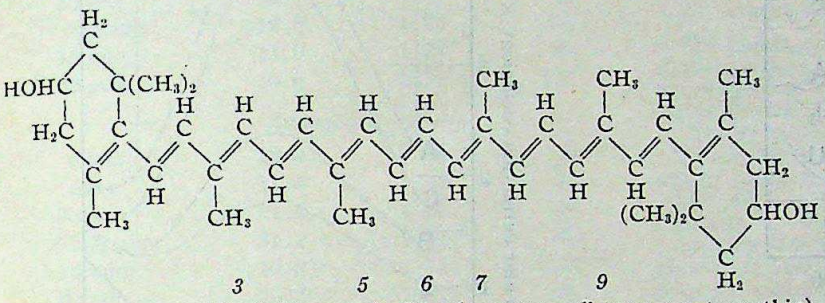
compounds. The very great difference in their *cis*-peaks suggests that the *cis* double bond is located in the center of the chromophore of neocryptoxanthin B but far from the center in that of neo U.[5] The most probable configurations are: neocryptoxanthin B = *6*-mono-*cis*-cryptoxanthin, and neocryptoxanthin U = *3*-mono-*cis*- or *9*-mono-*cis*-cryptoxanthin (see the formula). Neocryptoxanthin A seems to be a di-*cis* compound in which the central double bond is one of the *cis* bonds.



All-*trans*-zeaxanthin (with one hydroxyl group: all-*trans*-cryptoxanthin). The stereochemically effective double bonds[10] are numbered.

In the stereoisomeric zeaxanthin set the neo forms A and B are undoubtedly mono-*cis* compounds. On the basis of their *cis*-peaks the best assignment is: neozeaxanthin A = *6*-mono-*cis*-zeaxanthin and neozeaxanthin B = *5*-mono-*cis*-zeaxanthin. Neozeaxanthin C seems to be a di-*cis* isomer; it is possible that one of its *cis* double bonds is located in the center.

Experimental Part

Materials and Methods.—Cryptoxanthin solutions were chromatographed on calcium hydroxide (Shell Brand lime, chemical hydrate, 98% through 325 mesh) and those of zeaxanthin on calcium carbonate (Merck Heavy Powder). The visual spectral maxima were determined with an Evaluating Grating Spectroscope (Zeiss; light filter BG-7; 2 mm. thick). All pigments listed in the chromatograms below were tested spectroscopically before and after the addition of catalytic amounts of iodine. The spectra of cryptoxanthin and its isomers were taken in petroleum ether (b. p. 60–70°) and those of zeaxanthin and its isomers in benzene. The addition of iodine shifted spectra in the former set to 480, 449 mμ (± 1 mμ) and in the latter to 493, 460 mμ (± 1 mμ). The extinction curves were taken in a Beckman photoelectric spectrophotometer.[11] Solutions which had been catalyzed with iodine were irradiated from a distance of 60 cm. with a 3500° Mazda white fluorescent lamp (length of the tubes, 120 cm.). The solutions were placed in 25-ml. volumetric flasks (glass) in horizontal position on a white base. For insolation experiments transparent quartz test-tubes or small flasks were used which were filled with carbon dioxide. For more details concerning methods we refer to earlier reports.[12]

The cryptoxanthin and zeaxanthin samples were isolated from the berries of *Physalis alkekengi* and, after purification, were chromatographically homogeneous.

1. Cryptoxanthin

(a) ***cis–trans* Isomerization of Cryptoxanthin on Standing or Refluxing.**—Petroleum ether solutions of cryptoxanthin isomerize at room temperature in darkness to an extent of 1% within twenty-four hours.

A solution of 6 mg. of the pigment in 50 ml. of ligroin (b. p. 120°) was refluxed for thirty minutes in an all-glass apparatus in a slow stream of carbon dioxide. The chromatogram was developed on a column (20 × 3.5 cm.) with petroleum ether containing 10% acetone. (The figures on the left are the width of the zones in millimeters).

5	yellow, irreversible
65	colorless
22	orange, all-*trans;* 483.5, 452.5 mμ
2	almost colorless
14	yellowish orange, neo A: 477, 445.5 mμ
2	colorless
12	yellow, neo B: 479.5, 448 mμ

The loss of the initial colorimetric value was about 30%.

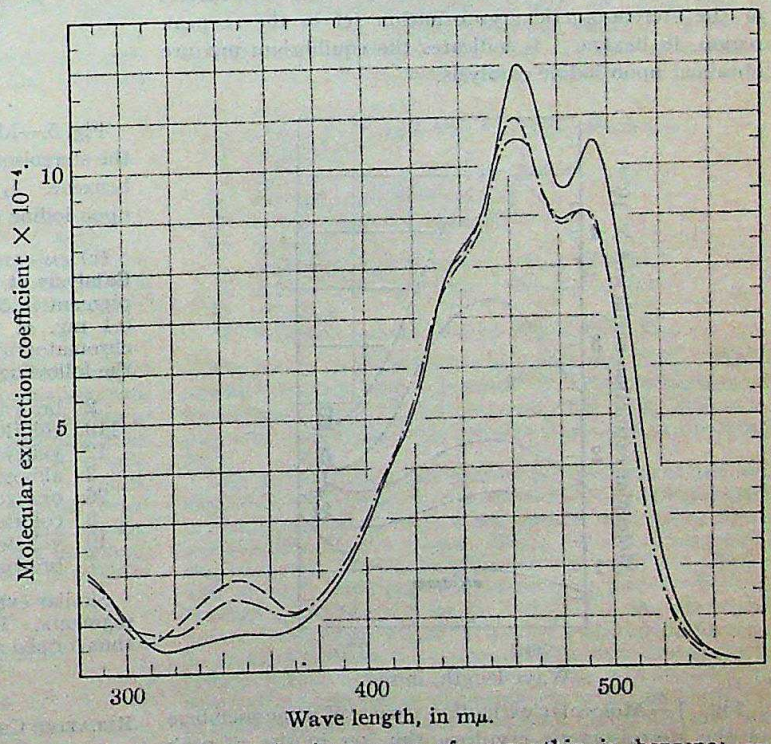


Fig. 2.—Molecular extinction curves of zeaxanthin in benzene: —, fresh solution of the all-*trans* compound; ---, mixture of stereoisomers after refluxing for forty-five minutes; and — · — ·, after iodine catalysis at room temperature in light. (The *cis*-peak obtained on refluxing is higher than that of the iodine equilibrium because much more neozeaxanthin A is contained in the refluxed solution than in the catalyzed mixture[2].)

The colorimetric ratio was, unchanged all-*trans:* neo A: neo B = 62:32:6.

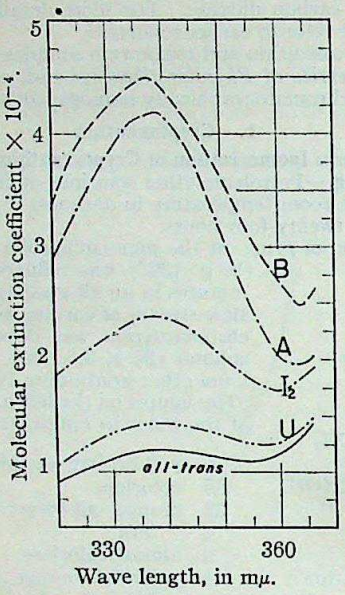

Fig. 3.—Molecular extinction curves of some members of the stereoisomeric cryptoxanthin set in the *cis*-peak region, in hexane. I_2 indicates the equilibrium mixture obtained upon iodine catalysis.

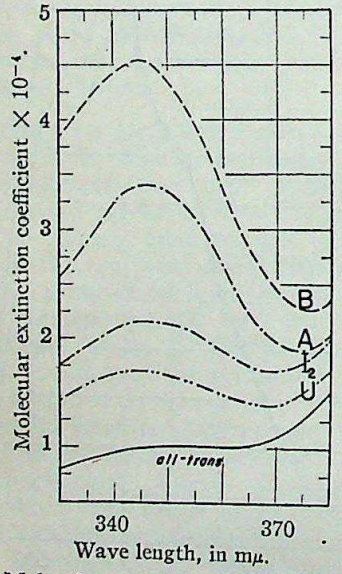

Fig. 4.—Molecular extinction curves of some members of the stereoisomeric cryptoxanthin set in the *cis*-peak region, in benzene. I_2 indicates the equilibrium mixture obtained upon iodine catalysis.

(b) *cis–trans* **Isomerization of Cryptoxanthin by Melting.**—Three milligrams of crystals was placed in a tube which was filled with carbon dioxide and then sealed. The tube was kept in a bath at 175° for fifteen minutes and then the melt was rapidly solidified in ice water. The petroleum ether solution of this material gave the following chromatogram (18 × 1.8 cm.) when the column was developed as in section (a).

1 brownish yellow, irrev.
75 colorless
15 yellowish orange, neo U: 478, 448 mμ
28 orange, all-*trans:* 483.5, 452 mμ
19 yellow, neo A: 477, 446 mμ
1 colorless
6 yellowish orange, neo B: 479, 448.5 mμ

The loss in the initial colorimetric value was 55%. The colorimetric ratio was, unchanged all-*trans:* neo U: neo A: neo B = 49:7:38:6.

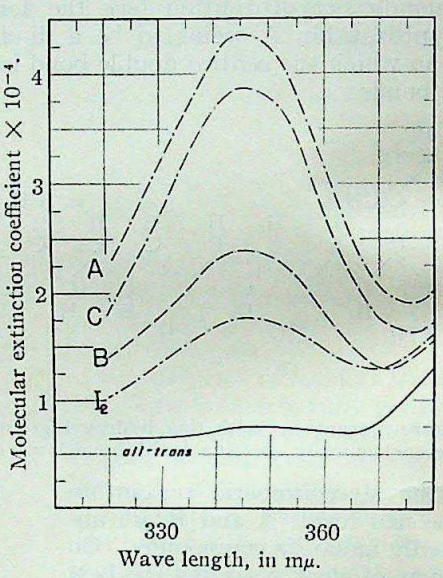

Fig. 5.—Molecular extinction curves of some members of the stereoisomeric zeaxanthin set in the *cis*-peak region, in benzene. I_2 indicates the equilibrium mixture obtained upon iodine catalysis.

(c) *cis–trans* **Isomerization of Cryptoxanthin by Iodine Catalysis at Room Temperature.**—A solution of 5 mg. of pigment in 30 ml. of petroleum ether was catalyzed with 0.1 mg. of iodine. An hour later the solution was chromatographed and, after development as above, gave the following zones (20 × 3.5 cm.).

2 brownish yellow, irrev.
110 colorless
12 yellowish orange, neo U: 478.5, 448 mμ
2 almost colorless
26 orange, all-*trans:* 483.5, 452.5 mμ
2 colorless
10 yellow, neo A: 477, 446 mμ
7 brownish yellow, neo B: 479.5, 449.5 mμ

Similar experiments were also carried out with the neo pigments. The relative colorimetric values of the zones thus formed are listed in Table III.

TABLE III

RELATIVE COLORIMETRIC VALUES OF CRYPTOXANTHIN AND SOME OF ITS STEREOISOMERS REVERSIBLY FORMED BY IODINE CATALYSIS AT 25° IN DIFFUSE DAYLIGHT

Starting material	Relative colorimetric values (% of the recovered pigment) neo U	all-*trans*	neo A	neo B
Neocryptoxanthin U	23	55	22	—
All-*trans*-cryptoxanthin	18	59	18	5
Neocryptoxanthin A	20	57	23	—
Neocryptoxanthin B	21	55	17	7

The influence of illumination on the iodine catalysis, especially on the *cis*-peak effect, is demonstrated in Table IV. In complete darkness no peak was observed one hour after the addition of iodine.

60 min.	10.1	1.74	100

(d) *cis–trans* **Isomerization of Cryptoxanthin by Insolation.**—A solution of 2 mg. of pigment in 30 ml. of petroleum ether was exposed for forty-five minutes to intense sunshine. The final temperature was 34°. The following chromatogram was obtained (18 × 1.8 cm.).

4 yellowish brown, irrev.
83 colorless
26 orange, all-*trans:* 483.5, 453 mμ
13 yellow, neo A: 478, 446.5 mμ

The loss of color was about 30% of the initial value. In the recovered pigment the colorimetric ratio was, all-*trans:* neo A = 86:14. In parallel experiments the presence of a small amount of neocryptoxanthin B was also noticed.

2. Zeaxanthin

(a) *cis–trans* **Isomerization of Zeaxanthin on Refluxing.**—The isomerization produced by refluxing benzene solutions has been described earlier.[2] When 5 mg. of zeaxanthin in 50 ml. of ligroin (b. p. 120°) was refluxed in darkness in an atmosphere of carbon dioxide, for thirty minutes, only small amounts of the usual main isomers, neo A and neo B, were formed whereas a considerable fraction was converted into pigments which do not belong to the zeaxanthin set. The following chromatogram was obtained on a carbonate column (20 × 3.5 cm.) after development with a mixture of equal volumes of petroleum ether and benzene.

8 pale yellow, irrev.
9 yellowish orange, neo A: 489.5, 457.5 mμ
5 almost colorless
6 yellowish orange, neo B: 490, 458 mμ
12 almost colorless
13 yellowish orange, irrev.: 489.5, 457.5 mμ
14 colorless
9 orange, all-*trans:* 494, 462.5 mμ
21 colorless
5 yellowish orange, irrev.: 491.5, 458.5 mμ

The loss in the initial color intensity was 57%. The colorimetric ratio was, all-*trans:* neo A: neo B = 73:14:13. About 35% of the total recovered pigment was distributed among the two irreversible zones whose spectra are listed. These pigments shifted their spectral bands upon addition of iodine in the expected manner but did not behave as dihydroxy compounds in the partition test.

(b) *cis–trans* **Isomerization of Zeaxanthin by Melting.**—A mixture of 5 mg. of crystals and 20 mg. of naphthalene was placed in a tube (filled with carbon dioxide). The sealed tube was kept in a bath at 160° for fifteen minutes and then rapidly cooled in ice water. The material was dissolved in cold benzene, diluted with petroleum ether, drawn into a column (20 × 3.5 cm.) and developed with a benzene–petroleum ether mixture (1:1).

22 almost colorless
6 yellowish orange, neo A: 489, 458 mμ
2 almost colorless
6 yellowish orange, neo B: 489, 457.5 mμ
6 colorless
4 yellowish orange, irrev.: 489.5, 457.5 mμ
5 colorless
5 yellow, neo C: 486, 454.5 mμ
9 colorless
13 orange, all-*trans:* 494.5, 462.5 mμ

The loss in color intensity was about 60%. Nearly ⅛ of the recovered pigment consisted of the irreversible zone which did not behave like a dihydroxy compound in the partition test. The colorimetric ratio was, all-*trans:* neo A: neo B: neo C = 56:17:17:10.

In another experiment, at 220° without naphthalene, almost complete bleaching occurred.

(c) *cis–trans* **Isomerization of Zeaxanthin by Iodine Catalysis at Room Temperature.**—The data published previously[2] have been confirmed. In addition, experiments showed no *cis*-peak in the presence of iodine within half an hour in darkness. The influence of irradiation on this process is illustrated in Table IV.

(d) *cis–trans* **Isomerization of Zeaxanthin by Insolation.**—A solution of 5 mg. of zeaxanthin in 50 ml. of benzene was exposed to intense sunshine for fifteen minutes. When this solution was developed with pure benzene on a column (20 × 3.5 cm.) the following zones resulted.

3 almost colorless
2 yellowish orange, neo A: 490.5, 459.5 mμ
2 colorless
2 yellowish orange, neo B: 490, 459 mμ
60 blurred, traces of pigment
10 orange, all-*trans:* 494, 462.5 mμ
13 colorless
4 yellowish orange, irrev.: 491.5, 458 mμ
8 yellowish orange, irrev.: 491.5, 458 mμ
26 colorless
2 yellowish orange, irrev.: 492.5, 460.5 mμ

The loss in the initial color intensity was 20%. The recovered pigment was composed of 48% unchanged all-*trans*-zeaxanthin, 11% neozeaxanthins A + B, 12% minor pigments, and 29% of the pigment contained in the 8 mm. zone.

The latter, irreversibly formed polyene was eluted with methanol, transferred into benzene and, after evaporation, crystallized from the minimum amount of benzene by the addition of excess methanol. When 100 mg. of zeaxanthin was insolated, the yield of the new recrystallized pigment was 17 mg. This pigment forms long plates which are tapered on both ends; m. p. 129–131° (cor., electrically heated Berl block; sealed tube filled with carbon dioxide). In the partition test the compound is intermediate between cryptoxanthin and the carotenes. The visually observed spectral maxima were: in petroleum ether, 482, 451 mμ; in benzene, 496.5, 463 mμ; in alcohol, 483.5, 452 mμ; and in chloroform, 495, 462 mμ. Except in alcohol solution, the addition of iodine caused a 2 to 4 mμ displacement of the maxima toward shorter wave lengths.

Summary

The *cis–trans* isomerization of cryptoxanthin and zeaxanthin has been investigated further. Earlier observations concerning neozeaxanthins were confirmed. Cryptoxanthin yielded two new stereoisomers, one of which is adsorbed above the all-*trans* compound on the Tswett column. In addition to previous methods, stereoisomerization also occurs upon the melting of

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

crystals or exposure of solutions to sunshine. Zeaxanthin is more photosensitive than cryptoxanthin. Extinction curves are given for fresh, refluxed, and iodine-catalyzed solutions. Cryptoxanthin and zeaxanthin develop *cis*-peaks at 348 mμ (in benzene); however, no peak was observed upon iodine catalysis in darkness. On the basis of optical data the most probable configurations are: neocryptoxanthin B = *6*-mono-*cis*-cryptoxanthin, and neocryptoxanthin U = *3*-mono-*cis*- or *9*-mono-*cis*-cryptoxanthin; neo A is a di-*cis* compound; neozeaxanthin A = *6*-mono-*cis*-zeaxanthin and neozeaxanthin B = *5*-mono-*cis*-zeaxanthin; neozeaxanthin C is probably a di-*cis* isomer.

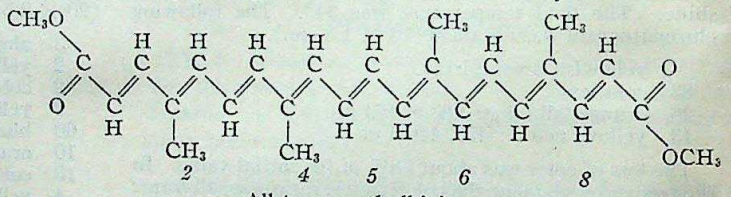
A Stereochemical Study of Methylbixin

BY L. ZECHMEISTER AND R. B. ESCUE

Bixin, $CH_3OOCC_{22}H_{26}COOH$, the main pigment in the seeds of the Annato tree (*Bixa orellana*, L.), was the first polyene for which stereoisomerism was demonstrated. Herzig and Faltis[1] in a single unreproducible experiment obtained from the seeds, instead of the well-known bixin, an isomer, termed "β-bixin," with higher melting point and greater stability than bixin, and with spectral maxima at longer wave lengths than those of bixin. Karrer and his associates[2] reported later that natural bixin can be converted into β-bixin by iodine, and they correctly interpreted this reaction as a *cis*→*trans* rearrangement. According to Kuhn and Winterstein[3] catalytic amounts of the halogen are sufficient to effect this transformation. Furthermore, they showed that both bixins yield the same dihydro compound, which is oxidized in air into β-bixin.

The following names have been used[4] for the two bixins and, in an analogous manner, for the two free carboxylic acids (norbixins) and the two dimethyl esters (methylbixins): ordinary bixin = natural bixin = *cis*-bixin = α-bixin = labile bixin = lower melting bixin = bixin II; isobixin = *trans*-bixin = β-bixin = stable bixin = higher melting bixin = bixin I.

Since no other isomer seems to have been described[5] and since the reversibility of the bixin isomerization by iodine catalysis so far as we know has not been claimed, we have re-investigated this field[6] by making use of some methods which were first applied to C_{40}-carotenoids.[7,8] Methylbixin was the most suitable starting material because of its greater solubility and markedly weaker adsorbability than that of bixin. Furthermore, because of its symmetrical molecule (see the formula) methylbixin can exist in only twenty stereoisomeric forms, whereas the corresponding number for bixin is thirty-two.[9,10]



All-*trans*-methylbixin

(The stereochemically effective double bonds are numbered.)

In the course of our experiments five members of the methylbixin set (and traces of other isomers) have been observed in chromatograms[11]; two new pigments, the neomethylbixins A and C, have been isolated as crystals. We designate

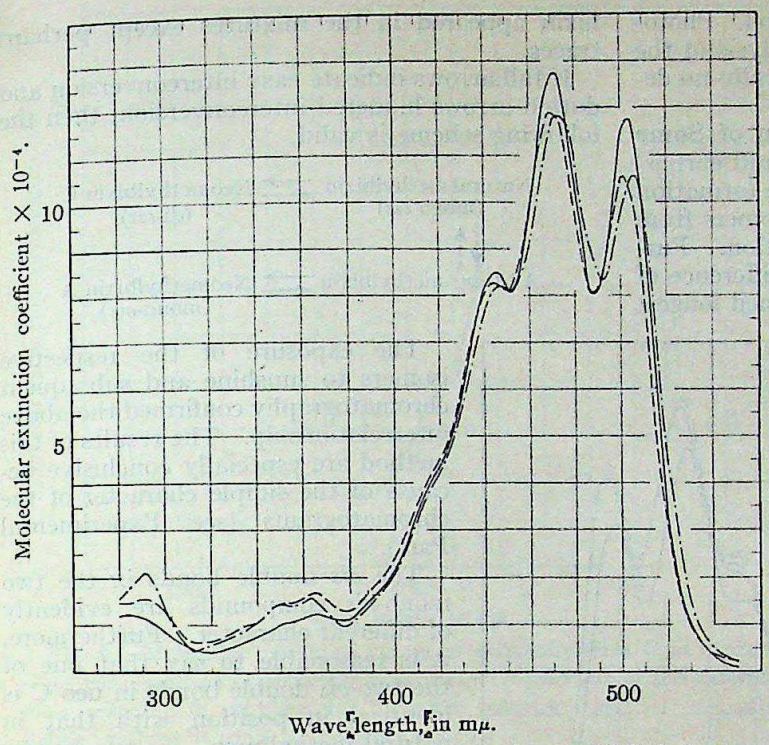

Fig. 1.—Molecular extinction curves of natural methylbixin in benzene: ——, fresh solution of natural methylbixin; – – –, mixture of stereoisomers after refluxing in darkness for forty-five minutes; and — · — ·, after iodine catalysis at room temperature in light.

(Table I) that stereoisomer whose double bonds have the same configuration as those in naturally occurring bixin (=norbixin II-monomethyl ester) as "natural methylbixin"; the methyl ester of β-bixin (=norbixin I-monomethyl ester) is termed "all-*trans*-methylbixin."

The position of natural methylbixin in chromatograms strongly reminds us of neo-β-carotene U, whereas the neo-forms A, B and C are adsorbed below the all-*trans* member in both sets.

Extinction curves of the bixins and methylbixins have been reported in the literature.[12] Figures 1 to 4 show the alterations of the curves of the four main isomeric methylbixins under the influence of refluxing and iodine catalysis. The iodine equilibrium curves obtained from the isomers are identical within experimental error. However, the curves taken after refluxing are not identical because under the conditions applied true equilibria are not reached.

A characteristic "*cis*-peak" appears in benzene solutions in each case at 363–364 mμ. As in the corresponding lycopene curve, the *cis*-peak maximum of methylbixin shows a fine structure. Natural methylbixin possesses only a slight peak and neo C a moderately high one, whereas neo A is responsible for the main effect observed in the iodine equilibrium mixture (Fig. 8).

Light is needed for the development of the *cis*-peak in the presence of iodine.[13] The extinction of all-*trans*-methylbixin remained practically unaltered in the *cis*-peak region when the catalyzed solution was kept in darkness; however, a five-second illumination caused a major effect (Fig. 5).

In the absence of catalysts, a fifteen-minute exposure to sunshine did not essentially alter the extinction curve of all-*trans*-methylbixin; natural methylbixin proved also to be relatively photo-stable under similar conditions. However, the configurations of the neo forms A and C are much more photosensitive (Figs. 6 and 7). The alterations which are represented in these curves are nearly

exclusively caused by stereoisomerization. Photometric measurements after iodine catalysis of the insolated solutions proved that practically no destruction of pigment had taken place.

Interrelationship and Configuration of Some Stereoisomers.—It has been pointed out earlier[8] that there is a high probability for the formation of substantial amounts of mono-*cis* isomers from an all-*trans* carotenoid by isomerization. Furthermore, it has been stated that a difference of about 5 mμ from the visually established longest wave length maximum of the all-*trans* member of the set corresponds to one *trans*→*cis* rotation.[7,8] On the basis of the spectra listed in Table I we assume that natural methylbixin and neomethylbixin A are mono-*cis* compounds, neo C is a di-*cis* and neo B probably a tri-*cis* (or tetra-*cis*) methylbixin.

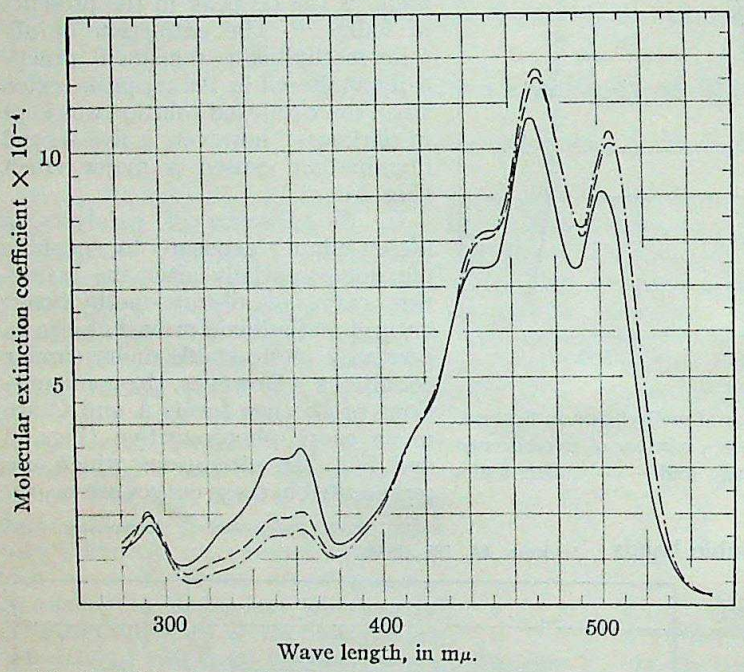

Fig. 3.—Molecular extinction curves of neomethylbixin A in benzene: ——, fresh solution of neomethylbixin A; – – –, mixture of stereoisomers after refluxing in darkness for forty-five minutes; and —·—·, after iodine catalysis at room temperature in light.

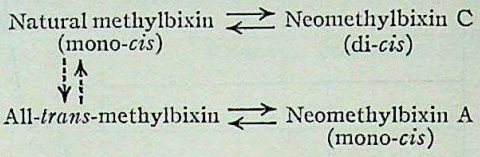
These conclusions which are based on optical data are in accordance with the following observations of another type. It is a characteristic feature of the methylbixin set that no all-*trans* pigment (except traces) is formed, in the absence of catalysts, from natural methylbixin upon refluxing and *vice versa*. The thermostability and photostability of the *cis* double bond in natural methylbixin are so great that the molecule undergoes a second *trans*→*cis* rotation and gives substantial amounts of neomethylbixin C instead of yielding any marked amounts of the all-*trans* pigment. On the other hand, the neomethylbixin A is easily formed when all-*trans* methylbixin is refluxed and *vice versa;* no natural methylbixin appeared in the mixtures except perhaps traces.

If full arrows indicate easy interconversion and dotted arrows hindered interconversion, then the following scheme is valid.



The exposure of the respective isomers to sunshine and subsequent chromatography confirmed the above interrelationship. The results of this method are especially conclusive because of the simple character of the chromatograms (see Experimental Part).

The *cis* double bonds in the two mono-*cis* compounds are evidently of different character. Furthermore, it is reasonable to say that one of the two *cis* double bonds in neo C is identical in position with that in natural methylbixin.

It has been pointed out[8] that in long conjugated systems a central mono-*cis* isomer is expected to show the highest *cis*-peak. As a rough approximation, the *cis*-peak effect of each member of the set can be taken proportional to the square of the distance between the center of the chromophore and the mid-point of the straight line between its ends. The values for the molecular extinction coefficients × 10^{-4} at the *cis*-peak wave length minus the corresponding value for the all-*trans* compound are

Natural methylbixin : 0.4	Neomethylbixin A : 2.8
All-*trans*-methylbixin : 0	Neomethylbixin C : 1.4

Figure 8 shows that neomethylbixin A must be interpreted as the 5-mono-*cis* and natural methylbixin as the 2-mono-*cis* isomer. The considerable peak of neo C indicates the presence of a central double bond and we suggest that this isomer is 2,5-di-*cis*-methylbixin. The curve of neo B is flat in the *cis*-peak region but because its lability and the difficulties of separation, no exact data can be given. The skeleton models of the four main stereoisomeric methylbixins are represented in Fig. 9.

The intensity of the principal absorption peak has already been used by Pauling[9,10] in the assignment with confidence of the all-*trans* structure to the natural C_{40}-carotenoids. Pauling pointed out, using the example of lycopene and neolycopene A for the discussion, that the integrated absorption coefficients should be approximately proportional

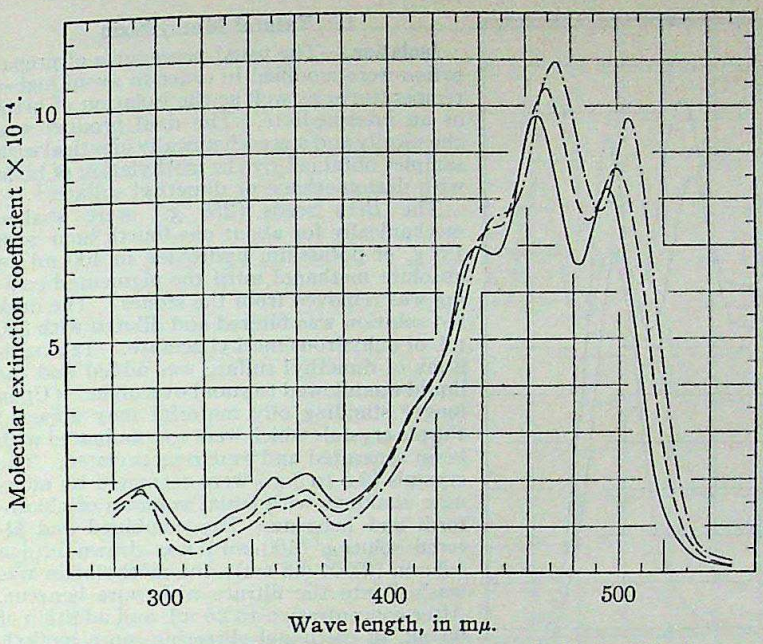

Fig. 4.—Molecular extinction curves of neomethylbixin C in benzene: ——, fresh solution of neomethylbixin C; – – –, mixture of stereoisomers after refluxing in darkness for forty-five minutes; and —·—·, after iodine catalysis at room temperature in light.

to the squares of the actual distances between the ends of the system. For the four members of the methylbixin set, we found experimentally that the maximum intensity ratios are, all-*trans*:natural: neo A:neo C = 1:0.93:0.80:0.82 while the ratios calculated on the basis of the models (with the single bond-double bond angles taken as 125°16′) are 1:0.87:0.82:0.79; the agreement is satisfactory, considering the experimental error and the approximate nature of the theory.

The configuration proposed for natural methylbixin is in contradiction with some results published (with reservation) by Karrer and Solmssen.[14] In a remarkable paper, these authors concluded, on the basis of the stereochemical relationship of some partial oxidation products, that natural bixin (or methylbixin) contains a *cis*-double bond in the 7-position. This double bond, however, belongs to the sterically hindered type.[9,10]

Some other data of the older literature are in very good accordance with the content of the present paper. Van Hasselt[5] found that two different methyl ethyl esters of "natural" norbixin can be prepared. Although he attributed this observation to a structural difference in the two molecule halves, it was shown by Karrer, *et al.*,[15] that the cause for the lack of symmetry is stereochemical and that a symmetrical structural formula must be given to norbixin. The existence of the two methyl ethyl esters shows independently of our configurational assignments that natural methylbixin cannot contain a centrally located *cis* double bond.

We believe that the experiments described below are in accordance with previous observations concerning the C_{40}-carotenoids and that they provide us with an enlarged basis for further conclusions. The experimental data for methylbixin indicate that, as was found also for the lycopene set,[8] the *trans* configuration around any double bond investigated is thermodynamically more stable than the *cis*.

Acknowledgment.—We wish to thank Professor Linus Pauling for valuable advice, furthermore Professor A. J. Haagen-Smit and Dr. G. Oppenheimer for microanalyses.

Experimental Part

Materials and Methods.—The designation "petroleum ether" refers to Skellysolve B (b. p. 60–70°). Calcium carbonate (Merck, Heavy Powder) was used as the adsorbent. Bixin is so strongly adsorbed on this material even from benzene solutions that a separation from methylbixin is easily accomplished. Ether or methanol does not completely elute these bixin adsorbates. For the separation of the methylbixin stereoisomers, development with a benzene–petroleum ether mixture (1:3) was used unless otherwise specified. These pigments can be conveniently chromatographed when dissolved in any mixture of benzene and petroleum ether if the former does not exceed 25%; a lower benzene content is distinctly advantageous since it secures a narrow pigment zone for the subsequent development. The best available eluent is acetone. Spontaneous crystallization may occur from petroleum ether solutions.

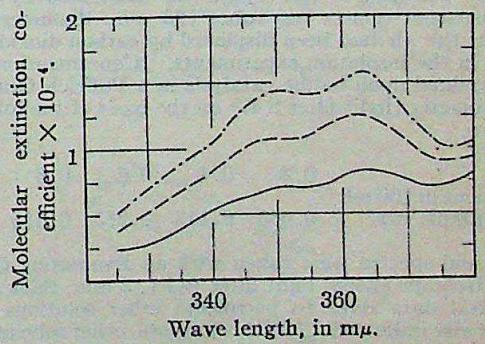

Fig. 5.—Influence of illumination on the development of the *cis*-peak effect in an iodine catalyzed solution of all-*trans*-methylbixin in benzene: ——, molecular extinction curve after standing for thirty minutes in darkness with iodine; – – –, after five seconds illumination; and —·—·, after thirty seconds illumination.

For melting point determinations the pigments were sealed in tubes filled with carbon dioxide. The samples were introduced into an electrically heated Berl block 20° below the melting point and the temperature was increased 2 to 3° per minute. The melting point values may be influenced by isomerization.

Refluxing experiments were carried out in darkness while a slow stream of carbon dioxide was introduced into the all-glass apparatus. In isomerization experiments by melting crystals, the pigments were sealed under carbon dioxide, kept fused in a dibutyl phthalate bath, and then

cooled rapidly in ice water. The iodine catalyzed solutions (contained in 25-ml. glass volumetric flasks) were exposed to diffuse daylight for thirty minutes or illuminated by a 3500° white fluorescent Mazda lamp (tube length, 120 cm.) at 60 cm. distance for fifteen minutes. This same procedure was used in the experiment illustrated by Fig. 5. Transparent quartz test-tubes (22 mm. diameter) from which the air had been displaced by carbon dioxide were used in the insolation experiments. Concentrations were determined upon iodine catalysis in a Pulfrich Gradation Photometer (light filter S 47) on the basis of the following values.

k	0.2	0.4	0.6	0.8	1.0
Pigment in 100 ml. benzene, mg.	0.065	0.145	0.215	0.315	0.390

Visual spectra were taken with an Evaluating Grating Spectroscope (Zeiss, light filter BG-7, 2 mm. thick). The spectral data refer to petroleum ether solutions unless otherwise indicated. For this purpose, other solvents were displaced from the column by washing with petroleum ether immediately before extrusion. Each pigment listed below in the chromatograms as a member of the methylbixin set shifted its maxima to visually observed 488, 455 mμ (±0.5 mμ) when catalyzed with iodine. The extinction curves were determined in a Beckman Photoelectric Spectrophotometer.[16]

All crystalline samples were dried in high vacuum. The concentration of solutions was established in many cases from the equilibrium curve (Table II) upon iodine catalysis with an accuracy of ±2.5%. Since the columns were developed with benzene-petroleum ether mixtures but the concentrations had to be established in pure benzene, the adsorbates were washed after cutting with petroleum ether (b. p. 28–38°). The latter was eliminated by means of a vacuum pump and the pigment was eluted with ice cold acetone and transferred into benzene.

1. Natural Methylbixin

Isolation.—The usual procedures of preparation were modified in order to avoid higher temperatures as well as the isolation of bixin as an intermediate. The final product was chemically and stereochemically identical with samples obtained by the methylation of bixin with diazomethane or dimethyl sulfate.

The *Bixa* seeds (250 g.) were shaken mechanically for about one-fourth hour with 1.5 g. of potassium hydroxide in 400 ml. of absolute methanol until the pigmented coating was removed from the stones. The dark red solution was filtered and diluted with 200 ml. of anhydrous methyl acetate. Ten milliliters of dimethyl sulfate was added and the liquid was allowed to stand overnight. (Upon longer standing oily material may appear.) Purple crystals which were contaminated with bixin separated and were remethylated. The crystals (2.5 to 3 g.) were extracted by alternate shakings with equal volumes of chloroform and benzene. The combined and filtered solution (100 ml.) was drawn into a column (23 × 4.8 cm); the methylbixin was washed into the filtrate with pure benzene. After concentration to 25 ml. and addition of 90 ml. of methanol glittering, pure methylbixin crystallized (Fig. 10). After cooling to −10° the crystals were filtered, washed with ice cold methanol and dried in high vacuum; m. p. 161–161.5° (cor.). The yield was 1.4 g. but it is dependent upon the quality of seeds.

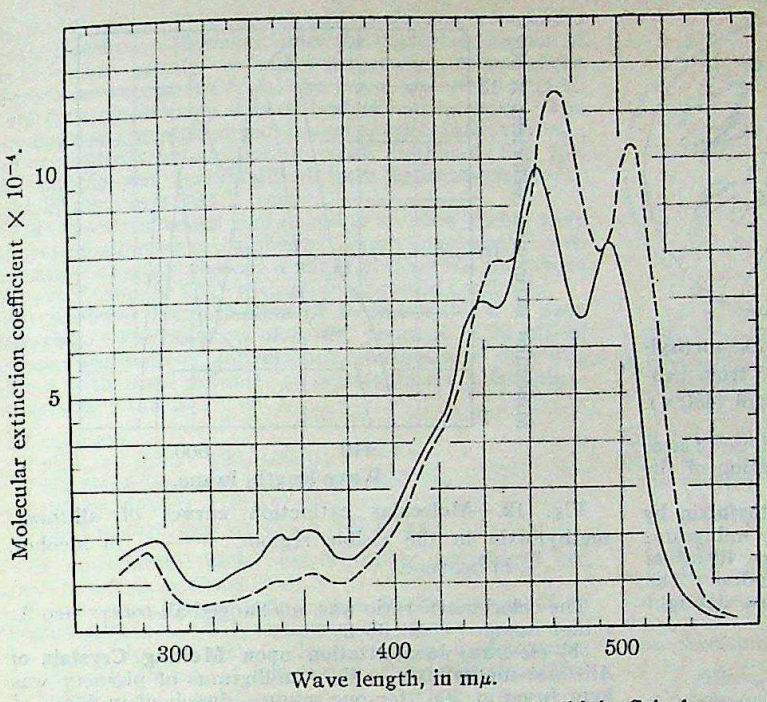

Fig. 7.—Photochemical isomerization of neomethylbixin C in benzene: ——, fresh solution of neomethylbixin C; and – – –, mixture of stereoisomers after fifteen minutes insolation.

The molecular extinction coefficients are compared with those of some other members of the set in Table II.

(a) ***cis–trans* Isomerization of Natural Methylbixin upon Standing and Refluxing.**—The extent of spontaneous isomerization in benzene–petroleum ether solution at 25° is about 3% in twenty-four hours. It must be remarked that even fresh solutions occasionally show a separation into blurred regions when chromatographed. The fractions could not be differentiated by any means, and extended development may cause them to recombine.

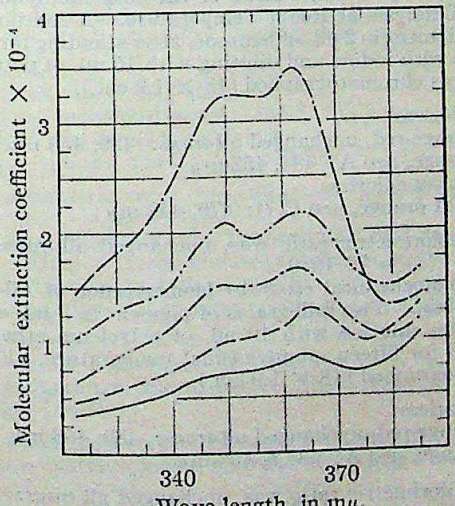

Fig. 8.—Molecular extinction curves of some members of the stereoisomeric methylbixin set in the *cis*-peak region in benzene: ——, all-*trans*-methylbixin; – – –, natural methylbixin; — · — ·, iodine equilibrium mixture; — · · —, neomethylbixin C; and · — · — ·, neomethylbixin A.

A solution of 5 mg. of methylbixin in 20 ml. of benzene was refluxed for an hour, concentrated to 2 ml., diluted with 15 ml. of petroleum ether, and chromatographed (size of column 18 × 1.9 cm.). (The figures on the left designate zone width in millimeters.)

25 colorless
34 orange-red, unchanged methylbixin: 486, 454 mμ

5 orange, neo A: 484, 452 mμ
5 almost colorless
25 light orange, neo C(?): 479, 448 mμ

The colorimetric ratio was, unchanged all-*trans:* neo A: neo C(?) = 72:19:9.

(d) **Photochemical** *cis–trans* **Isomerization of All-*trans*-methylbixin.**—Two milligrams of pigment in 3 ml. of benzene, after dilution with 10 ml. of petroleum ether, was insolated for fifteen minutes (final temperature, 31°) and chromatographed (18 × 1.9 cm.).

25 colorless
25 orange-red, unchanged all-*trans:* 489, 458 mμ
2 orange, neo A: 485.5, 453 mμ

The colorimetric ratio was, unchanged all-*trans:* neo A = 94:6.

3. Neomethylbixin A

Isolation.—A solution of 100 mg. of natural methylbixin in 10 ml. of benzene was catalyzed with 0.5 mg. of iodine and kept in daylight for thirty minutes at 25°. After dilution with 3 vol. of petroleum ether it was chromatographed (27 × 5.8 cm.). The broad orange layer located directly below the all-*trans* zone was eluted with acetone and rechromatographed immediately on a smaller column

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

(24 × 4.8 cm.). This chromatogram showed only traces of other isomers. However, since the uppermost section of the neo A zone usually contains considerable amounts of the all-*trans* isomer, about 1/5 of the main zone was rejected. A third chromatogram showed perfect homogeneity. The pigment was transferred into benzene, evaporated to 2 ml., and crystallized by addition of excess methanol (Fig. 13). The sample was recrystallized from benzene–methanol; yield, 20 mg.; m.p. 190–2° (cor.).

This isomer is much more soluble and less stable than natural or all-*trans*-methylbixin. Fresh solutions of even the purest crystals showed a slight contamination (about 3%, exceptionally 6%) with all-*trans*-methylbixin.

(a) *cis–trans* **Isomerization of Neomethylbixin A upon Refluxing.**—The solution of 3 mg. pigment in 20 ml. of benzene was refluxed for an hour, concentrated to 3 ml., diluted with three volumes of petroleum ether and chromatographed (18 × 1.9 cm.).

22 colorless
50 pink, all-*trans:* 490, 458 mμ
22 orange, unchanged neo A: 485, 453 mμ
2 yellow, neo B: 475, 447 mμ
9 light orange, neo C: 477.5, 447.5 mμ

The colorimetric ratio was, all-*trans:* unchanged neo A:neo B:neo C = 63:32:2:3.

(b) *cis–trans* **Isomerization upon Melting Crystals of Neomethylbixin A.**—Five milligrams of pigment was fused, kept at 195° for one minute, dissolved in 5 ml. of benzene, diluted with 15 ml. of petroleum ether and chromatographed (18 × 2.5 cm.).

20 yellow, irreversible
20 colorless
30 pink, all-*trans:* 488.5, 455.5 mμ
10 orange, unchanged neo A: 484.5, 453 mμ
15 greenish-yellow, neo B (+irreversible): 474, 447 mμ
22 yellow-orange, neo C: 479, 449 mμ

Irreversibly formed pigments passed into the chromatographic filtrate. The neo C zone showed some tendency to separate into three sections with blurred borders; however, an examination did not reveal any spectral differences.

The colorimetric ratio was, all-*trans:* unchanged neo A:neo B (+irreversible):neo C = 53:25:6:16.

(c) *cis–trans* **Isomerization of Neomethylbixin A by Iodine Catalysis at Room Temperature.**—Three milligrams of pigment in 5 ml. of benzene was catalyzed and chromatographed (18 × 1.9 cm.) after standing half an hour.

40 colorless
44 pink, all-*trans:* 490, 456.5 mμ
16 orange, unchanged neo A: 484.5, 453.5 mμ
2 yellow, neo B: 474, 446.5 mμ
28 yellow-orange, neo C: 478, 448.5 mμ

The colorimetric ratio was, all-*trans:* unchanged neo A:neo B:neo C = 64:25:2:9.

(d) **Photochemical** *cis–trans* **Isomerization of Neomethylbixin A.**—After a fifteen-minutes insolation of 3 mg. of pigment in benzene and dilution with 5 vol. of petroleum ether, the mixture was chromatographed (18 × 1.9 cm.).

60 colorless
33 pink, mainly all-*trans:* 490, 458 mμ
25 pinkish-orange, mainly neo A: 484.5, 453 mμ
1 yellow (traces)

Due to unsatisfactory separation, the following ratio is only approximately correct, all-*trans:* unchanged neo A = 45:55.

4. Neomethylbixin B

Small amounts of this isomer may be obtained by iodine catalysis or by refluxing neomethylbixin A solutions. Its extinction maxima were located at 490, 460 mμ, in benzene and shifted to 505, 472 mμ upon the addition of iodine. From one fusion experiment with natural methylbixin, a pigment of a different type was separated from the neo B zone. Its benzene solution showed four extinction maxima in the visual region (490, 461, 419 and 404 mμ), the two first being identical in position with those of neomethylbixin B. The addition of iodine did not produce the spectrum which is characteristic for the methylbixin set.

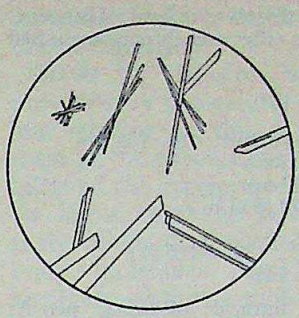

Fig. 13.—Neomethylbixin A, crystallized from benzene and methanol (430×).

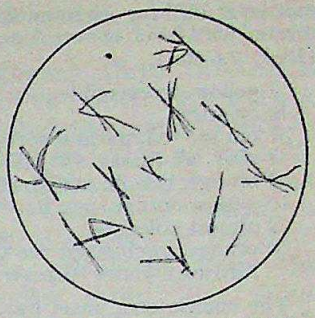

Fig. 14.—Neomethylbixin C, crystallized from benzene and methanol (430×).

5. Neomethylbixin C

Isolation.—A solution of 300 mg. of natural methylbixin in 100 ml. of benzene–petroleum ether (1:1) was refluxed for an hour, diluted with petroleum ether to 250 ml. and developed (30 × 8 cm.) with 2.5 liters of a 1:4 mixture. The development required three hours.

7 yellow (traces)
5 colorless
130 orange-red, unchanged natural methylbixin
1 colorless
2 pink
1 colorless
2 orange
1 yellow
60 bright orange, neo C

In order to augment the yields, the zone of unchanged methylbixin was eluted with acetone, transferred into benzene, refluxed again, and chromatographed. The natural methylbixin zone of this second chromatogram was submitted to a third refluxing and adsorption analysis after the addition of a 50-mg. portion of starting material.

The combined acetone eluates of the three zones of neo C were developed with benzene–petroleum ether (1:5) on a smaller column (27 × 5.8 cm.). Except for traces, the pigment was found to be homogeneous. It was transferred into petroleum ether and completely evaporated *in vacuo*. The red, oily residue was taken up in the minimum amount of benzene and transferred to a centrifuge tube; the solvent was evaporated with a carbon dioxide stream at 25°. When methanol was added gradually with stirring, an oily suspension appeared which crystallized upon scratching and cooling. Upon seeding, the crystals appear directly. After cooling to −10°, they were centrifuged and recrystallized (Fig. 14). The intensely colored mother liquors may be reworked. The yield of crude neomethylbixin C crystals was 50 mg.; however, this quantity decreased to 25–30 mg. upon recrystallization; m. p. 150–1° (cor.).

(a) *cis–trans* **Isomerization of Neomethylbixin C upon Refluxing.**—The benzene solution of 1 mg. pigment was refluxed for an hour, concentrated to 2 ml., diluted with 15 ml. of petroleum ether and chromatographed (18 × 1.9 cm.).

15 colorless

The colorimetric ratio was, natural: neo A: unchanged neo C = 21:2:77.

Summary

Besides "labile methylbixin," now named "natural methylbixin," and "stable" termed "all-*trans*-methylbixin," two other stereoisomers, neo A and C, have been isolated in crystals; several minor members of this set were observed in solution. The mutual conversion of the stereoisomers can be carried out by means of thermal methods, iodine catalysis or insolation. Natural and all-*trans*-methylbixin are practically not interconvertible by refluxing or exposure to sunshine. In contrast, the reversible formation of neo C from natural methylbixin and of neo A from the all-*trans* form takes place easily under similar conditions. On the basis of spectroscopic data, especially "*cis*-peak" measurements, configurations are suggested for the four main observed methylbixins.

The Serological Properties of Simple Substances. VI. The Precipitation of a Mixture of Two Specific Antisera by a Dihaptenic Substance Containing the Two Corresponding Haptenic Groups; Evidence for the Framework Theory of Serological Precipitation

BY LINUS PAULING, DAVID PRESSMAN AND DAN H. CAMPBELL

The framework theory (lattice theory) of serological precipitation and agglutination, first proposed by Marrack,[1] was shown by Marrack and by Heidelberger and Kendall[2] to account for many experimental observations. Because of its simplicity and its compatibility with the available information about intermolecular forces, this theory was incorporated in his general theory of the structure and process of formation of antibodies by one of the present authors.[3]

Strong support of the framework theory has been provided during the past two years by the results of extensive studies of the reactions of antibodies and simple substances,[4] based upon the observations by Landsteiner and Van der Scheer[5] of the precipitation of antibody by certain simple substances containing two haptenic groups. It was found[4] from experiments with about fifty substances that all of those (about twenty) containing two or more haptenic groups (azophenylarsonic acid groups) per molecule gave precipitates with antiserum homologous to this haptenic group, and that none of the monohaptenic substances gave a precipitate. This fact is most readily accounted for by the framework theory.

The argument might be made, however, that no more than one of the haptenic groups of a molecule of a polyhaptenic substance is involved in interaction with antibody molecules, and that the difference in precipitability of polyhaptenic and monohaptenic substances with antiserum is due to some difference in properties of these two classes of substances, such as a tendency to asso-

ciate into colloidal particles.[6] In order to test this point, we have carried out a new experiment, the results of which show that each of the two haptenic groups of a dihaptenic substance enters into specific combination with antibody in the formation of the precipitate.

The experiment[7] was made with use of two different antisera, one of which (anti-R serum) was prepared by injecting rabbits with azoprotein containing R groups (*p*-azophenylarsonic acid groups) and the other (anti-X serum) by injecting with azoprotein containing X groups (*p*-azobenzoic acid groups). A substance was used as precipitating antigen which had one R group and one X group per molecule. It was found that this RX substance does not give a precipitate with either anti-R serum or anti-X serum alone, but does give a precipitate with a mixture of these two antisera. Similar results were obtained also with another RX substance.

This striking experimental result corresponds exactly to the behavior predicted by the framework theory: according to this theory the RX substance cannot give a precipitate with anti-R serum because its molecules contain only one R group, and are hence univalent with respect to anti-R antibodies and so are unable to form a framework with them; and similarly it can not give a precipitate with anti-X serum. (Indeed, it is predicted, and verified by experiment, that this effectively monohaptenic substance can inhibit the precipitation of either anti-R serum or anti-X serum by corresponding polyhaptenic simple substances or azoproteins.) But the RX substance is effectively dihaptenic and bivalent with respect to a mixture of anti-R serum and anti-X serum, since each molecule can form two bonds, one with an anti-R antibody molecule and one with an anti-X antibody molecule; and accordingly a specific framework precipitate, containing equal numbers of the two kinds of antibodies, can be formed with the mixed antiserum.

Let us now ask to what extent this experimental result supports the framework theory—whether it might not be equally compatible with some other theory. The answer is that our experiment shows that both of the two haptenic groups R and X of the RX molecule enter into specific combination with antibody, that the molecule of precipitating antigen is hence truly bivalent, and that this bivalence is necessary for precipitation. This, however, is common to two theories—the framework theory, which requires that the antibody molecules, as well as the antigen molecules, be bivalent or multivalent, and an alternative theory, which is based on the assumption that a complex of a multivalent antigen molecule and two or more univalent antibody molecules is for some reason or other insoluble, and constitutes the precipitate.[8]

Basis for decision between these theories is provided by the results of two other experiments, one relating to the antibody–antigen molecular ratio in the precipitate and the other to the solubility of the precipitate in excess antibody. Since we know that the RX precipitating antigen is truly bivalent, the effective valence of the antibody molecules can be calculated from the antibody–antigen molecular ratio. The value found by analysis for this ratio is 0.7, which corresponds to an average effective antibody valence of $2/0.7 = 2.8$; for univalent antibody the molecular ratio would be 2. (The assumption is made here that the antigen molecules are not associated into complexes, which might then form a precipitate with antibody with use of only some of the haptenic groups. Evidence against association of this sort is furnished by the failure of the RX substances to precipitate with anti-R serum or anti-X serum alone.)

The second experiment is based on the following argument. If antibody molecules are univalent, and the precipitate consists of RX antigen molecules each of which has two attached antibody molecules, increase in antibody concentration, with amount of antigen held constant, would necessarily increase the amount of precipitate; decrease in the amount of precipitate, which could occur only by formation of a soluble complex, would not occur because the antigen molecules in the precipitate would be already saturated with antibody, and so could not increase their valence, and the antibody molecules could not decrease their valence (below the value 1) and remain attached to antigen. But a framework precipitate with multivalent antibody could dissolve in excess antibody by formation of soluble complexes, the effective valence of the antibody molecules in these complexes being less than that in the precipitate (1 instead of 2 or 3), and the antibody–antigen ratio being greater than that for the precipitate; according to the principles of chemical equilibrium, increase in the antibody concentration would then lead to solution of the precipitate. The observation that increase in the amount of mixed antiserum results in pronounced decrease in the amount of precipitate formed with the RX substance accordingly eliminates the theory of univalent antibody and provides further proof of the framework theory.

A detailed discussion of these experiments and of other experiments with the RX substance (hapten inhibition, etc.) is given below, following the section on experimental methods and results.

Experimental Methods and Results

The following substances containing groups R =

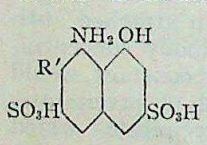
The substances R′X′ and RX′ are the "RX substances" referred to in the preceding discussion.

Preparation.—The substances R′R′ and R* have already been described,[4] and X′X′ and X* are described in a paper to be published soon.[9] The substance R′X′ was prepared by diazotizing 1.3 g. (0.0038 mole) of *p*-(*p*-aminophenylazo)-phenylarsonic acid, removing excess nitrite with urea, and coupling with 1.35 g. (0.0040 mole) of recrystallized "H-acid" in acetate buffer. The intermediate red compound was precipitated by addition of hydrochloric acid and washed twice with 500 ml. of water containing 10 ml. of 6 *N* hydrochloric acid and 3 g. of sodium chloride. The substance was then dissolved in sodium carbonate solution and added to a diazotized solution of 0.312 g. (0.0012 mole) of *p*-(*p*-aminophenylazo)-benzoic acid.[9] The product was precipitated with hydrochloric acid, dissolved in 500 ml. of sodium hydroxide solution, and reprecipitated with hydrochloric acid and sodium chloride and an equal volume of ethanol, leaving most of the remaining intermediate in solution. The process of solution and precipitation was repeated until the solution showed constant color, and sodium chloride was then removed from the product by extraction with 90% ethanol. Although the product was not crystallized, there is little doubt of its identity and purity; the method of preparation is based on the fact that at low *p*H substitution occurs in the 7 position of H-acid, ortho to an amino group, and not in the 2 position, ortho to a hydroxyl group, reaction at the latter position occurring in basic solution.



The RX′ compound was made by diazotizing 4.0 g. (0.020 mole) of *p*-arsanilic acid and adding it very slowly to 6.0 g. (0.019 mole) of chromotropic acid in solution with sodium carbonate (final *p*H 9). After one hour a diazotized and neutralized solution of 1.3 g. (0.005 mole) of *p*-(*p*-aminophenylazo)-benzoic acid was added and the *p*H was adjusted to 9. The product was purified in the way described above; this process removes any RR compound which is formed.

Anti-R, anti-R′, and anti-X sera were prepared as described elsewhere,[4,9] and the precipitation experiments were carried out in the usual way.[4] Several pools of antisera were tested; the same pools of anti-R and anti-X antisera were used for all of the quantitative experiments reported in this paper.

The substance RX′ was found not to precipitate with anti-X serum, anti-R serum, or anti-R′ serum, or with a mixture of anti-R′ serum and anti-X serum; it formed heavy precipitates with a mixture of anti-R serum and anti-X serum.

(9) David Pressman, Stanley M. Swingle, Allan L. Grossberg and Linus Pauling, paper to be submitted for publication in THIS JOURNAL.

The substance R′X′ gave no precipitate or only very slight precipitates with various pools of anti-X serum, anti-R serum, or anti-R′ serum; heavy precipitates were formed with mixtures of anti-R serum and anti-X serum and with mixtures of anti-R′ serum and anti-X serum. The quantitative experiments reported in Tables I to V were carried out with pools of sera which separately gave no precipitate with R′X′.

The failure of the substance RX′ to precipitate with a mixture of anti-R′ serum and anti-X serum is related to the fact[4] that anti-R′ serum in general does not precipitate with polyhaptenic substances containing R groups.

It was found that the substances RX′ and R′X′ act as monohaptenic substances in inhibiting the specific precipitation of R′R′ with anti-R′ serum or anti-R serum and of X′X′ with anti-X serum. Data showing the effect of haptens R* and X* on some precipitation reactions are given in Table II.

TABLE I

PRECIPITATION OF ANTIGENS R′R′, X′X′, R′R′ + X′X′, AND R′X′ WITH MIXTURES OF ANTI-R SERUM AND ANTI-X SERUM

Antigen solution, 2 ml.; mixed antiserum, 1 ml.; 1 hour at room temperature and 2 nights in refrigerator; *p*H of supernates 8.1.

Ratio anti-R serum: anti-X serum[a]	Antigen	Moles of antigen × 10^9 6	18	54	167	500
		Amount of precipitated antibody, μg.[b]				
93:7	R′R′	52	522	1134	721	162
	X′X′	0	0	0	0	0
	R′R′ + X′X′[c]	14	136	913	1070	564
	R′X′	48	60	72	60	60
62:38	R′R′	44	(261)	(446)	(169)	25
	X′X′	4	22	80	50	23
	R′R′ + X′X′[c]	8	104	439	481	236
	R′X′	22	158	792	821	623
17:83	R′R′	(12)	16	9	5	4
	X′X′	9	23	706	756	280
	R′R′ + X′X′[c]	9	12	137	1024	906
	R′X′	12	16	25	66	90

[a] The ratio 62:38 was selected as that for which the optimum concentrations of the antigens R′R′ and X′X′ are the same; the other ratios are 8 and 1/8 times as great, respectively. [b] Average of triplicate analyses, with mean deviation ±2%; duplicate analyses in parentheses. [c] In equimolal amounts, with totals as given above.

Discussion of Results and Comparison with Theory

The qualitative behavior of the substances RX′ and R′X′ in precipitation and in hapten inhibition, as described above, is just that predicted by the framework theory. The quantitative data given in Tables I and II are also in accord with this theory. In particular, there is some verification of the prediction of the framework theory that the precipitate with R′X′ should contain equal numbers of anti-R molecules and anti-X molecules; this would require that the amount of precipitate be small in case that either anti-R or anti-X serum be present in small amount, in agreement with observation.

It is also predicted, and verified by experiment, that precipitation of mixed antiserum with R′X′ can be completely inhibited by the presence of either hapten R* or hapten X*, whereas precipitation with a mixture of R′R′ and X′X′ is only partially inhibited by either of these haptens.

[a] Total moles of antigen used: R′R′, 50 × 10^{-9}; X′X′, 50 × 10^{-9}; R′R′ + X′X′, 100 × 10^{-9}; R′X′, 100 × 10^{-9}. [b] Average of triplicate analyses, with mean deviation ±2%; duplicate analyses in parentheses. [c] In equimolal amounts.

TABLE III

ANTIBODY–ANTIGEN MOLECULAR RATIO IN PRECIPITATES FORMED BY R′X′ ANTIGEN AND A MIXTURE OF ANTI-R SERUM AND ANTI-X SERUM

Ratio of antisera 62:38; equal volumes of antigen solution and mixed antiserum: 1.5 ml. of each for first series, 2.0 ml. for second; 1 hour at room temperature and 2 nights in refrigerator; *p*H of supernates 8.1.

Moles of antigen × 10^9	Amount of precipitated antibody[a]		Amount of precipitated antigen[a]		Molecular ratio, antibody/antigen[a]
	μg.	moles	μg.	moles	
100	1421	8.89 × 10^{-9}	10.8	11.7 × 10^{-9}	0.76
33	456	2.85	4.2	4.5	.63

[a] Average of triplicate analyses, mean deviation ±2% for antibody, ±2% for antigen, ±2% for ratio. Assumed molecular weight of antibody 160,000, of antigen 927.

TABLE IV

PRECIPITATION OF MIXTURES OF NORMAL SERUM AND ANTISERUM AT CONSTANT AMOUNT OF ANTIGEN

Antigen solution, 2 ml., containing either 5 × 10^{-9} moles of antigen R′R′ (series A) or 6.7 × 10^{-9} moles of antigen R′X′ (series B); mixture of antiserum and normal serum, 2 ml.; 1 hour at room temperature and 2 nights in refrigerator; *p*H of all supernates 8.1.

Antiserum concentration in mixture[a]	Amount of antibody precipitated, μg.[b]	
	Series A[c]	Series B[d]
1.00	39	39
0.67	35	106
.45	93	120
.30	128	109
.20	133	81
.13	120	47
.088	90	23
.059	51	6

[a] Anti-R serum (Series A) or 62:38 mixture of anti-R serum and anti-X serum (series B) diluted with normal rabbit serum to the extent indicated in this column. [b] Averages of triplicate analyses, with mean deviation ±3%. [c] Blank of anti-R serum and buffer, 5 μg.; blank of normal serum and antigen R′R′, 5 μg. [d] Blank of 62:38 antiserum mixture, 6 μg.; blank of normal serum and antigen R′X′, 5 μg.

An interesting feature of the data in Tables I and II is that the 62:38 mixture of antisera gives a larger amount of precipitate with the R′X′ antigen than with R′R′ and X′X′ together. This is presumably related to the fact that the amount of precipitate formed with antigen R′R′ (or X′X′) alone falls off very rapidly with decrease in the fraction of anti-R (or anti-X) antiserum in the mixture; for example, the amount of precipitate formed by X′X′ with the 62:38 mixture is only about one-ninth of that formed with the 17:83 mixture, although the first mixture contains nearly one-half as much anti-X antibody as the second. The amount of precipitate formed by antigens R′R′ and X′X′ together would be expected to be about equal to the sum of the amounts formed by these antigens separately, since the two precipitates are mutually independent. But a single precipitate is formed by R′X′, containing equal amounts of the two kinds of antibody, and accordingly the amount of precipitate would be expected to be about equal to that formed by R′R′ or X′X′ with a mixture containing double the amount of anti-R serum or anti-X serum as is, indeed, observed.

It has been noted in general that simple antigens, in contradistinction to protein antigens, are far from completely precipitated by antisera, and that the fraction of the antigen remaining in solution at the optimum region increases on dilution of the antiserum with normal serum or heterologous antiserum; this effect, as discussed above, is to be noted in Table I. We have not yet carried out a sufficiently detailed experimental study of these phenomena to justify an extended discussion of them.

A mathematical discussion based on the simplified model treated previously[4,10] can be carried out for the RX precipitation reaction, leading to results in general correspondence with experiment. Let A represent the R′X′ antigen, $B^{(1)}$ and $B^{(2)}$ the anti-R and anti-X antibodies, respectively, which are assumed to be bivalent and homogeneous, and $H^{(1)}$ and $H^{(2)}$ the haptens R* and X*, respectively. It is assumed that, in addition to the precipitate $A_2B^{(1)}B^{(2)}$, certain soluble complexes exist, and that their equilibrium constants of formation have the values given below; these values have been assigned on the basis of structural considerations, with inclusion of the entropy term arising from the symmetry numbers of the molecules.

$$A + B^{(1)} = AB^{(1)} \qquad 2K_1$$
$$A + B^{(2)} = AB^{(2)} \qquad 2K_2$$
$$2A + B^{(1)} = AB^{(1)}A \qquad K_1^2$$
$$2A + B^{(2)} = AB^{(2)}A \qquad K_2^2$$
$$2A + B^{(1)} + B^{(2)} = AB^{(1)}AB^{(2)} \qquad 4K_1^2K_2''$$
$$2A + B^{(1)} + B^{(2)} = AB^{(2)}AB^{(1)} \qquad 4K_1''K_2^2$$

$$\begin{aligned} H^{(1)} + B^{(1)} &= H^{(1)}B^{(1)} & 2K_1' \\ H^{(2)} + B^{(2)} &= H^{(2)}B^{(2)} & 2K_2' \\ 2H^{(1)} + B^{(1)} &= H^{(1)}B^{(1)}H^{(1)} & K_1'^2 \\ 2H^{(2)} + B^{(2)} &= H^{(2)}B^{(2)}H^{(2)} & K_2'^2 \\ A + B^{(1)} + H^{(1)} &= AB^{(1)}H^{(1)} & 2K_1K_1' \\ A + B^{(2)} + H^{(2)} &= AB^{(2)}H^{(2)} & 2K_2K_2' \end{aligned}$$

By straightforward solution of the equilibrium equations there is obtained for the case that no hapten is present a set of simultaneous equations

$$\beta_1^2(1 + K_1\alpha)^2 - \beta_1(B^{(1)}_{total} - B^{(2)}_{total}) - S(1 + K_2\alpha)^2/\alpha^2 = 0 \quad (1)$$

$$A_{total} - B^{(1)}_{total} - B^{(2)}_{total} - \alpha + \beta_1(1 - K_1^2\alpha^2) + S(1 - K_2^2\alpha^2)/\alpha^2\beta_1 = 0 \quad (2)$$

$$A_2B^{(1)}B^{(2)}(pp) = B^{(1)}_{total} - \beta_1(1 + K_1\alpha)^2 - s \quad (3)$$

These three equations are to be solved for three unknown quantities, the amount of precipitate $A_2B^{(1)}B^{(2)}(pp)$ and the two auxiliary variables α, the concentration of molecular species A in solution, and β_1, the concentration of molecular species $B^{(1)}$; the other quantities are the equilibrium constants K_1 and K_2, the solubility product $S = [A]^2[B^{(1)}][B^{(2)}]$ of the precipitate, and the solubility s of the precipitate as the complexes $AB^{(1)}AB^{(2)}$ and $AB'^{(2)}AB^{(1)}$, with $s = 4(K_1''K_2^2 + K_1^2K_2'')S$. A convenient method of solving the equations is to leave A_{total} undetermined, and to introduce numerical values of the other parameters; introduction in Equation 1 of a trial value of α permits solution for β_1, after which A_{total} may be evaluated from Equation 2 and $A_2B^{(1)}B^{(2)}(pp)$ from Equation 3.

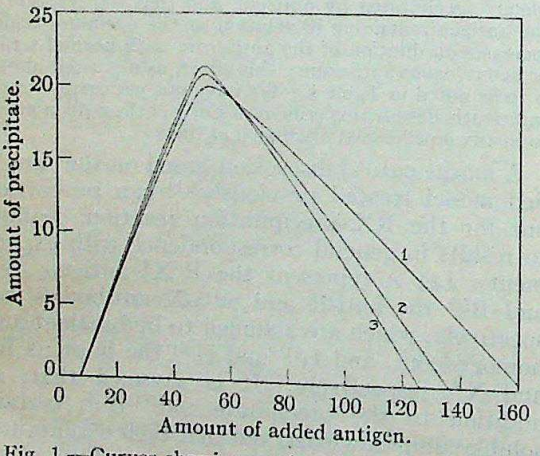

Fig. 1.—Curves showing results of theoretical calculations of amount of precipitate formed by antigen RX with an equimolal mixture of anti-R serum and anti-X serum, as function of amount of antigen: $B^{(1)}_{total} = B^{(2)}_{total} = 25$, $s = 2$, and $K_1 = K_1'' = 1$ for all curves; $K_2 = K_2'' = 0.2$ for curve 1, 1 for curve 2, and 5 for curve 3.

Curves showing dependence of amount of precipitate on amount of antigen with equal amounts of the two kinds of antibody present (Fig. 1) are similar to those for the precipitation of one kind of antibody by homologous dihaptenic antigen.[4] As the ratio of the amounts

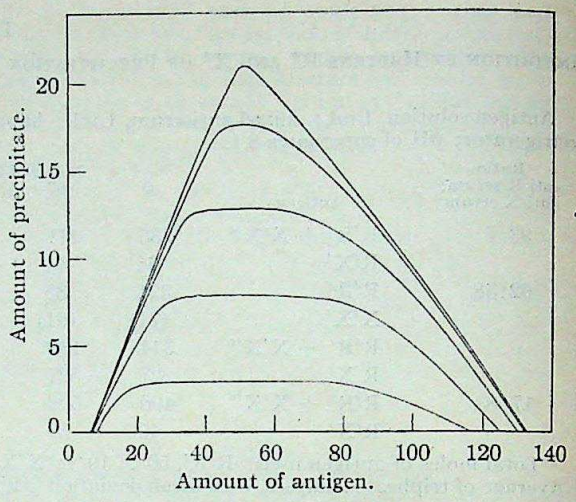

Fig. 2.—Curves showing calculated amount of precipitate as functions of amount of antigen RX for various relative amounts of anti-R and anti-X antibody. All curves are for $K_1 = K_1'' = K_2 = K_2'' = 1$ and $s = 2$. From top to bottom the curves correspond to the following pairs of values of $B^{(1)}_{total}$ and $B^{(2)}_{total}$: 25, 25; 20, 30; 15, 35; 10, 40; 5, 45.

of the two kinds of antibody is varied more and more from unity, the calculated curves of the amount of precipitate show broader and broader regions of approximate constancy (Fig. 2), resulting from the buffering action of the antibody present in excess, which combines with excess antigen to form a soluble complex, and thus interferes with the reaction of solution of the precipitate in excess of antigen; it is seen that the antigen concentration at which the amount of precipitate reaches its approximate maximum is determined by the amount of that kind of antibody which is present in smaller quantity, and that the antigen concentration at which the amount of precipitate begins to decrease is determined by the amount of the other kind of antibody. Experimental verification of these details of prediction cannot be expected until essentially homogeneous antibody solutions have been made by fractionation of antisera; however, the predicted general difference in nature is shown by the R'X' data given in Table I for the 93:7 mixture (broad region with nearly constant amount of precipitate) and the 62:38 mixture (rather narrow optimum region). Verification of the existence of the broad region of nearly constant amount of precipitate was obtained by the repetition of the experiment with the 93:7 mixture, with inclusion of points for smaller and larger amounts of the antigen R'X'; the amount of precipitated antibody was found to be constant (80 ± 10 μg.) over the range 18 to 500 $\times 10^{-9}$ mole of antigen, and to decrease for smaller and for larger amounts of antigen (34 μg. at 6.2 $\times 10^{-9}$ mole of antigen, 60 μg. at 1500 $\times 10^{-9}$).

When hapten of one kind is also present in the system, the equilibrium expressions may be com-

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

bined to form the set of simultaneous equations 4 to 7.

$$\beta_1^2(1 + K_1\alpha + K_1'\gamma_1)^2 - \beta_1(B_{\text{total}}^{(1)} - B_{\text{total}}^{(2)}) - S(1 + K_2\alpha)^2/\alpha^2 = 0 \quad (4)$$

$$\beta_1^2\{(1 + K_1'\gamma_1)^2 - K_1^2\alpha^2\} + \beta_1\{A_{\text{total}} - B_{\text{total}}^{(1)} - B_{\text{total}}^{(2)} - \alpha\} + S(1 - \Lambda_2^2\alpha^2)/\alpha^2 = 0 \quad (5)$$

$$H_{\text{total}}^{(1)} = \gamma_1 + 2K_1'\beta_1\gamma_1 + 2K_1'^2\beta_1\gamma_1^2 + 2K_1K_1'\alpha\beta_1\gamma_1 \quad (6)$$

$$A_2B^{(1)}B^{(2)}(\text{pp}) = B_{\text{total}}^{(1)} - \beta_1(1 + K_1\alpha + K_1'\gamma_1)^2 - s \quad (7)$$

Here $H_{\text{total}}^{(1)}$ is the total amount of hapten (of the first kind) added and $\gamma_1 = [H^{(1)}]$ is another auxiliary variable. A similar set of equations can be derived for the case that hapten of the second kind is present. Solution of these equations may be made by selecting a value of γ_1 and finding by successive approximations the values of α and β_1 which satisfy Equations 4 and 5, and then determining $H_{\text{total}}^{(1)}$ and $A_2B^{(1)}B^{(2)}(\text{pp})$ from Equations 6 and 7, respectively.

The calculated curves for hapten inhibition by either kind of hapten when equal amounts of antibodies of the two kinds are present are closely similar to those for the simpler systems previously treated.[4] However, an interesting effect is predicted to occur when one antiserum predominates in the mixture and a small amount of antigen is present: a normal inhibition curve, linear in amount of hapten added, is found from the equations for one hapten, whereas the other hapten, that homologous to the antibody present in the larger amount, is predicted to be ineffective in small amounts, and to produce inhibition of precipitation only after enough of the hapten has been added to neutralize the excess of antibody in solution; calculated curves are given in Fig. 3. To test this prediction experiments were carried out, in triplicate, for the 93:7 mixture with the R′X′ antigen (antigen solution, 2 ml., containing 200 × 10^{-9} moles of R′X′ antigen; mixed antiserum, 2 ml.; hapten solution, 2 ml.; one hour at room temperature and two nights in refrigerator; pH of supernates 8.1; mean deviation of triplicate analyses ± 2%); the results are shown in Fig. 4. It is seen that there is a small initial region for which inhibition by the R* hapten does not occur. (In the comparison of Figs. 3 and 4 it should be remembered that the curves for Fig. 3 are calculated for haptens of equal bond-strength constant K', whereas K' for hapten R* is considerably larger than that for X*.) It is likely that the predicted effect would be shown more strikingly by fractionated antibody solutions than by the heterogeneous antisera used in these experiments.

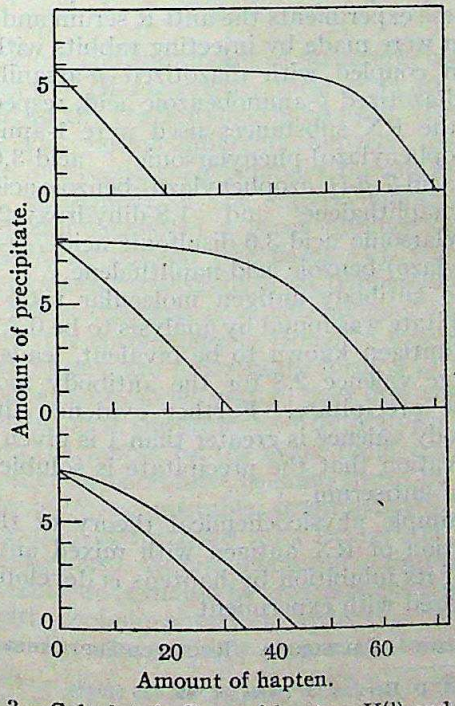

Fig. 3.—Calculated effects of haptens $H^{(1)}$ and $H^{(2)}$ on precipitation of antigen RX with an antiserum mixture containing four times as much anti-R antibody as anti-X antibody ($B_{\text{total}}^{(1)} = 10$, $B_{\text{total}}^{(2)} = 40$). From top to bottom the curves are for $A_{\text{total}} = 20$, 50, and 100; of each pair the curve at the left is for hapten $H^{(1)}$ and the other for hapten $H^{(2)}$.

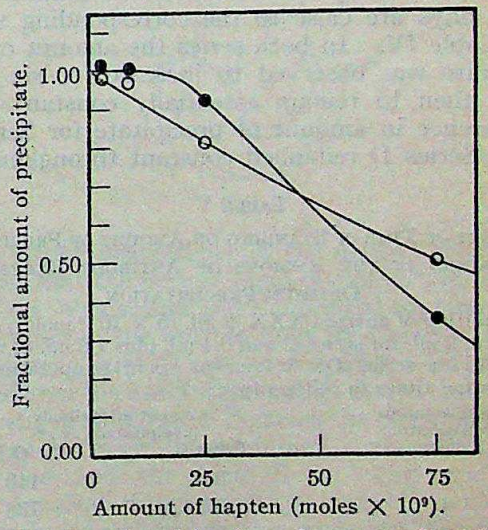

Fig. 4.—Experimental values of amount of precipitate formed by antigen R′X′ with 93:7 mixture of anti-R serum and anti-X serum in presence of hapten R* (solid circles) or hapten X* (open circles).

Experimental data bearing on the valence of the antibody molecules are given in Tables III and IV. The observed antibody/antigen molecular ratio of about 0.7 in both the equivalence zone and the region of antibody excess (Table III) corresponds, with antigen known to be bivalent, to 2/0.7 = 2.8 for the average valence of the antibody molecules in the precipitate.

The second of our arguments for the multivalence of antibody molecules is based on the solubility of antigen–antibody precipitates in

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

excess antibody. This phenomenon has been reported for many antigen–antibody systems, especially with horse antibody. We have observed it to occur with rabbit antibody and simple polyhaptenic antigens; the results of an experiment of this sort, with anti-R serum and the substance R′R′, are given in Table IV. In this table there are given also data for a similar experiment with the substance R′X′ and a mixture of anti-R serum and anti-X serum; the observed decrease in the amount of precipitate with increase in amount of antiserum can be accounted for only with the theory of multivalent antibody.

It is known that excess of one component causes decrease in the rate of precipitation of antibody and antigen, and the question may be asked as to whether the effect of excess antibody reported in Table IV might be due to failure of the reaction to be completed in the time allowed. An experimental test of this possibility was made, with the results given in Table V. Tubes were set up corresponding to the first and fifth experiments of Series A of Table IV, representing, respectively, the region of antibody excess (Series C) and the region of optimum precipitation (Series D). These tubes were allowed to stand for times ranging from two to fifteen days, and then were analyzed. The values obtained after two days are close to the corresponding values of Table IV. In both series the amount of precipitate was observed to increase for six days, and then to remain essentially constant. The difference in amount of precipitate for Series C and Series D remained constant throughout the period; from these results we conclude that the effect of excess antibody in decreasing the amount of precipitate is real, and is not due to a difference in the rate of precipitation.

TABLE V

EFFECT OF TIME OF STANDING ON AMOUNT OF PRECIPITATE OBTAINED IN THE REGIONS OF ANTIBODY EXCESS AND OPTIMUM PRECIPITATION

Solution of antigen XXX, 2 ml. (5×10^{-9} mole); anti-R serum, 2 ml. for series C and 0.4 ml. plus 1.6 ml. of normal serum for series D; 1 hour at room temperature and indicated times in refrigerator.

Time of standing in refrigerator, days	Amount of antibody precipitated (μg.)[a] Series C	Series D
2	34	110
4	37	138
6	78	150
8	59	156
10	27	138
15	62	131

[a] Averages of triplicate analyses with mean deviation ±2 μg. Values are corrected by subtraction of the blanks for serum and buffer, which ranged between 14 and 23 μg. The large values of the blank in comparison with those of Table IV (5 μg.) may be due to change in the antiserum during the period of three months between the experiments.

Solubility of the precipitate in excess of antiserum has been reported for a few systems, such as diphtheria toxin and horse antitoxin, but not for antigen–antibody systems in general. Theoretical considerations[3,11] indicate that solubility in antibody excess should occur for antigens with small valence (such as the dihaptenic substances of Table IV) but not for antigens with large valence, which would only with difficulty be saturated with antibody to form a soluble complex.

This work was carried out with the aid of a grant from The Rockefeller Foundation. Dr. Stanley Swingle and Mr. Allan L. Grossberg helped with the experimental work.

Summary

It has been found by experiment that substances of the type RX, containing two different haptenic groups, do not form precipitates with either anti-R serum or anti-X serum alone, but do form precipitates with a mixture of the two specific antisera. This provides proof of the effective bivalence of the dihaptenic precipitating antigen, and thus furnishes further evidence for the framework theory of antigen–antibody precipitation. In these experiments the anti-R serum and anti-X serum were made by injecting rabbits with sheep serum coupled with diazotized *p*-arsanilic acid and diazotized *p*-aminobenzoic acid, respectively, and the RX substances used were 1-amino-2-*p*-(*p*-azophenylazo)-phenylarsonic acid-3,6-disulfonic acid-7-*p*-(*p*-azophenylazo)-benzoic acid-8-hydroxynaphthalene and 1,8-dihydroxy-2-*p*-azophenylarsonic acid-3,6-disulfonic acid-7-*p*-(*p*-azophenylazo)-benzoic acid-naphthalene.

The antibody–antigen molecular ratio in the precipitate was found by analysis to be 0.7, which, with antigen known to be bivalent, leads to the average valence 2.8 for the antibody molecules in the precipitate. Further evidence that the antibody valence is greater than 1 is given by the observation that the precipitate is soluble in excess of antiserum.

A simple physicochemical theory of the precipitation of RX antigen with mixed antiserum and of its inhibition by haptens is developed and compared with experiment.

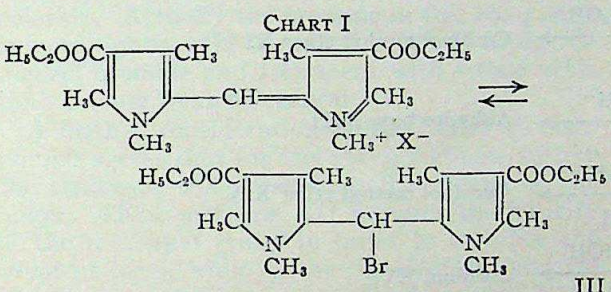
Effect of Substituents on the Structure of the Dipyrrylmethenes. Some Relationships between the Dipyrryl- and the Triphenylmethane Dyes[1,2]

BY KARL J. BRUNINGS AND ALSOPH H. CORWIN

Although a large number of dipyrrylmethene salts having a wide variety of substituents on the pyrrole rings have been prepared for the purpose of synthesizing naturally occurring pyrrole pigments,[3] the correlation of the effect of substitution and a study of the significance of these compounds to the general theory of organic dye salts has not been undertaken. General observations on the behavior of this large body of pigments has led to the conclusion that the dipyrrylmethene salts are best represented as coplanar resonating ionic structures (I), Chart I.

CHART I



I X = Br^-
II X = ClO_4

Thus, from the standpoint of structure, color and general dye characteristics these salts are closely related to the triphenylmethane dyes. However, there is a marked difference between these two classes of dyes in their behavior toward hydroxyl ions. Treatment of the dipyrrylmethene salts with alkali yields, in a great number of cases, stable highly colored free bases (VI, Chart II), whereas similar treatment of the triphenylmethane dyes yields colorless covalent carbinol bases instead of the corresponding Homolka bases. Such anhydro bases are not readily formed in the triphenylmethane series and go over into the colorless carbinols in the presence of hydroxyl ion. The dipyrryl carbinols, on the other hand, are practically unknown and have been suggested by several authors[3,4,5,6] as unstable intermediates in the preparation of methene salts by certain pyrrole condensations. In one instance,[7] a dipyrryl carbinol ether was isolated by treatment of a methene salt with alcoholic potassium hydroxide.

Recently, the authors prepared a stable carbinol from a di-N-methyl methene perchlorate II.[8] This system is similar to dimethylamino substituted triphenylmethane dyes in that it cannot exist in the form of a free base. Since the carbinol derivative was so unusual in the pyrrole series, a careful study of the properties of the parent methene salts was made. Evidence was found suggesting the existence of a covalent form of the di-N-methyl dipyrrylmethene bromide III. Thus, the unusual features of this methene system which gave rise to stability of the covalent carbinol also exerted their influence on the structure of the methene halide. Since the electronic interpretation of the effect of alkyl substitution on the nitrogens required that the stability of the ionic form of this system be enhanced, an explanation of the exactly opposite effect observed was sought elsewhere and found in a scale model of the coplanar resonating ion.

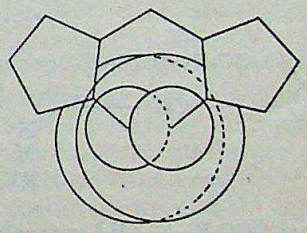


Fig. 1.

The strong interference of the methyl groups requires that the normal bond distances and angles, van der Waals radii and the normal coplanar configuration of the pyrrole rings be distorted in the resonating ion. These modifications must subtract from the usual stabilization due to resonance, thereby leading to a decrease in the margin of energy between the un-ionized covalent methyl bromide and the ionic form. Unfortunately, the covalent dipyrrylmethyl bromide could not actually be isolated in this case and therefore it seemed desirable to investigate the general effects of substitution on the structure of these pyrrole dyes and to attempt the preparation of a colorless covalent dipyrrylmethyl halide. The success of such an undertaking would be expected to lead to an explanation of the relationship of these compounds to the triphenylmethane dyes.

This paper reports the preparation of two covalent dipyrryl methyl bromides and presents a series of other derivatives which demonstrate the effect of pyrrole substituents on the structure of these methene dyes. All of the dipyrrylmethene salts and the dipyrrylmethyl halides were prepared by bromination of the corresponding di-

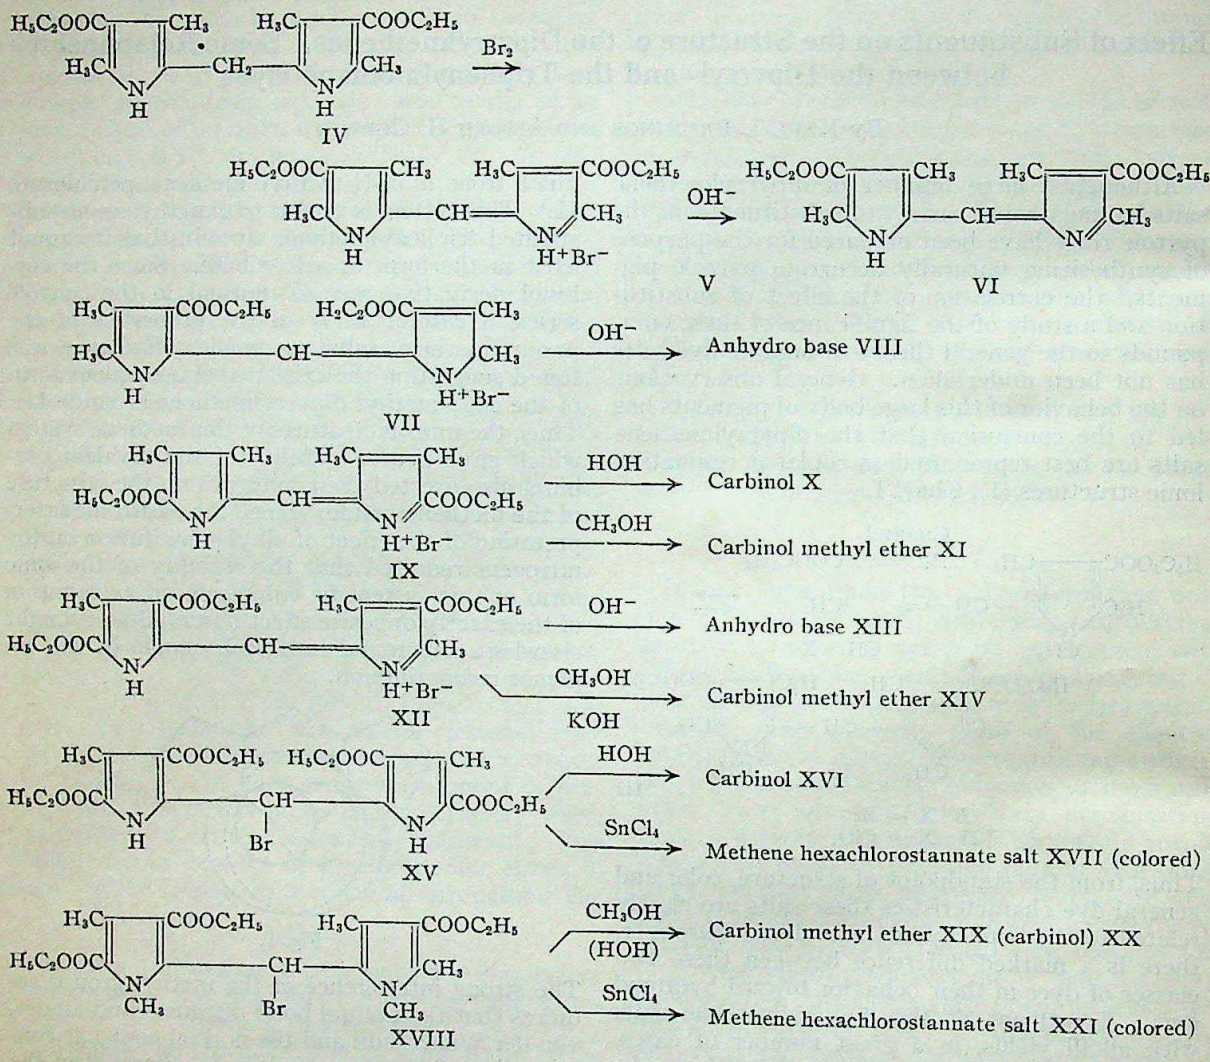
CHART II



pyrrylmethane leuco bases in carbon tetrachloride solution. Each methene was studied with respect to its behavior toward hydroxyl ion and alcoholic potassium hydroxide. The results are described by the structural formulas and equations in Chart II.

A comparison of the behavior of the methene bromides V, VII, and IX demonstrates the importance of the position of groups on the tendency toward stable dipyrryl carbinol formation. The methenes (V and VII) having a single carbethoxy group in either of the beta (3 or 4) positions of each pyrrole ring yield stable methene free bases VI and VIII in the manner of a great variety of these compounds. The α,α'-dicarbethoxy methene IX, on the other hand, gives a quite stable colorless dipyrryl carbinol X by merely suspending the highly colored methene crystals in neutral water, while the dipyrryl carbinol methyl ether XI is obtained by dissolving the methene in methanol. Thus it may be argued that carbethoxy groups in the alpha positions increase the tendency toward covalency in these systems. The special effect of the alpha carbethoxy groups was first noted by H. Fischer[9,10,11] who stated that α,α'-dicarbethoxy methanes do not yield methenes by oxidation (ferric chloride) but rather tetrapyrrylethanes. Since the α,α'-dicarbethoxy methene hydrobromide IX was prepared by oxidation of the corresponding methane with bromine, it represents an exception to this empirical rule. However, it should be pointed out that the conditions (solvent, oxidizing agent, temperature, etc.) of the reaction used in this work are quite different from those employed by Fischer in the oxidation of dipyrrylmethanes.

The effect of the alpha-carbethoxy group would suggest that substitution of carbethoxy groups for methyl groups on the pyrrole rings generally leads to stabilization of the covalent forms of the methenes. This reasoning is substantiated by the

previously reported isolation of a stable carbinol ether from the tricarbethoxy dipyrrylmethene XII in which the additional effect of a single carbethoxy group has been introduced. The prime importance of the alpha carbethoxy groups is stressed by the fact that this methene having only one carbethoxy group in the alpha position yields the usual methene free base XIII on treatment with alkali.

By utilizing the strong effect of the carbethoxy groups in both of the alpha positions and the additional effect of substituting carbethoxy groups in the 3 and 3′ positions it was possible to prepare the colorless covalent dipyrrylmethyl bromide XV. The behavior of this compound is analogous to that of the well-known triphenylmethyl bromide and, like the parent compound of the triphenylmethane dyes, it may be converted into the colored ionic form by treatment with anhydrous stannic chloride. Actually the bromine in this compound is more tightly held than in the case of triphenylmethyl bromide and treatment with strong acids leads to only weak coloration.

A further consideration of this series of compounds shows that for any given methene system the structure will depend on the nature of the anion. Thus, methene XII requires the basicity of the methoxyl group in order to stabilize the covalent form, while in the presence of hydroxyl ion the methene reverts to the free base XIII. In the case of methene IX both hydroxyl and methoxyl ion stabilize the covalent form. Finally, the tetracarbethoxy system XV remains in the covalent form even in the presence of the weakly basic bromide ion.

Now, since compound XII, containing three carbethoxy groups, shows its tendency toward covalent structures only in the form of its carbinol ether, it might be argued that the introduction of steric hindrance by methylation of the nitrogens would so decrease the stability of the coplanar ionic form that even the methene bromide would exist in the covalent dipyrryl halide structure. This prediction is fully borne out by the preparation of the colorless di-N-methyl dipyrrylmethyl bromide XVIII. Once again this compound is analogous to triphenylmethyl bromide and is converted to a highly colored form by solution in strong acids or by treatment with anhydrous stannic chloride. The bromine in this derivative is less tightly bound than in the case of the tetracarbethoxydipyrrylmethyl bromide XV and the carbon–bromine bond is hydrolyzed by water so rapidly that great care must be exercised in protecting the compound from the atmosphere in preparing it for analysis.

The present series coupled with the previously reported data on the di-N-methyl dipyrrylmethene system I permits the following conclusions: (1) the structure of the dipyrrylmethenes is profoundly influenced by the substituents on the pyrrole rings; (2) the position of the substituents is critical; (3) substitution of carbethoxy groups increases stability of the colorless covalent form of the methene; conversely alkyl substitution favors the ionic salt structure; (4) alkyl substitution on the pyrrole nitrogens results in steric interference causing a decrease in the stability of the ionic coplanar form and is, therefore, opposite to the effect predicted on the basis of the electrical effect of alkyl groups.

Now, these observations are almost precisely those which have been made in the triphenylmethane series and the effects in both classes of dyes are supported by the same electronic interpretations. Finally, a consideration of the structural differences of the two systems leads to a satisfactory explanation of the relationships discussed in the early part of this paper.

The tendency of the triphenylmethyl halides toward ionic dissociation is explained by the resonance stabilization of the carbonium ion. Essentially the resonance forms of the ion describe the ability of the system to distribute the positive charge on the ortho and para positions of the phenyl groups and the bridge carbon atom. By substituting amino or dimethylamino groups in the para position of the benzene rings we convert the triphenylmethyl halide system into dye salts (pararosaniline, crystal violet, etc.). The positive charge is now shared by the amino nitrogens and the coplanar resonating cation is highly stabilized since the energy of positively charged nitrogen is lower than that of positively charged carbon. On the other hand, if carboxy groups are substituted in the para positions, we should expect the resulting structures to be covalent and therefore colorless. Some para carboxy substituted triphenyl carbinols and triphenylmethyl halides have been prepared and are, in fact, colorless covalent compounds.[12,13,14] The tendency of the carbethoxy groups to enter into resonance with the benzene rings by the withdrawal of electrons opposes the withdrawal of electrons from the triphenylmethyl system required for ionization of the halogen. The substitution of alkyl groups which are electron repelling by inductance would be opposite in effect to the carboxyl substitution and should increase the stabilization of the ionic form although their influence would be small. On the basis of qualitative measurements the tritolylmethyl halides are found to be more dissociated than the parent triphenylmethyl halide.[15,16,17]

Now it is well known that only para substituted triphenylmethenes are chromophoric dye systems. This suggests that the position of substitution in the benzene rings is critical. It was Baeyer and Villiger who first recognized the importance of position of substitution in the triphenylmethyl

system.[18] These investigators prepared a series of ortho, meta and para methoxy derivatives and devised a rough quantitative method for comparing the tendency toward ionization of the carbinols. They observed that the degree of ionization of *p,p',p''*-trianisylcarbinol in a mixture of concentrated acetic and sulfuric acids was many times greater than that of the parent triphenyl carbinol; the ortho derivative was much less ionized than the para, while meta derivatives were hardly more ionized than triphenyl carbinol. The very weak effect of ortho substitution was not considered surprising by these authors and since that time it has been considered axiomatic that only para substitution gives triphenylmethane dyes.

On the basis of the electronic interpretation of the effect of these groups we should expect meta substitution to be relatively ineffective in influencing the structure of these dyes, but there is no apparent reason why ortho substitution should not be as potent as para in stabilizing the resonating cation. However, if we construct a model of the triphenyl carbonium ion (Fig. 2) similar to the type drawn for the di-N-methyl dipyrrylmethene[8] (Fig. 1), assuming coplanarity of the system and utilizing the accepted bond angles and distances in aromatic molecules, strong overlapping of the van der Waals radii of the ortho hydrogens is observed. This steric hindrance of

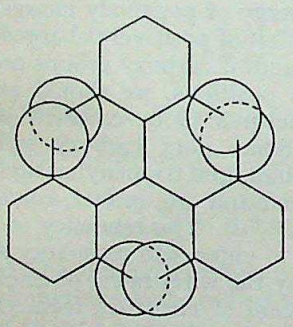

Fig. 2.

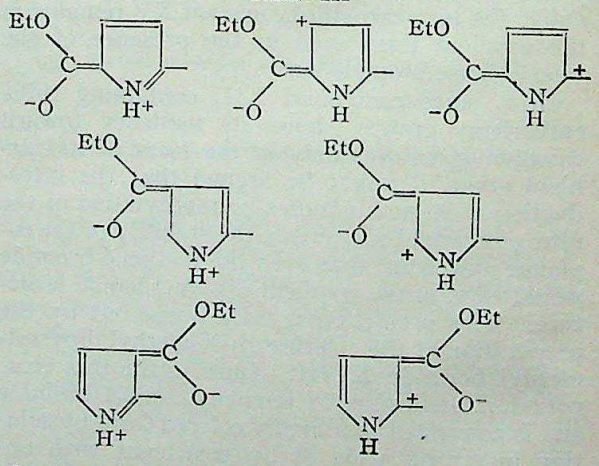
the ortho hydrogens has been pointed out recently by G. N. Lewis,[19] who suggests that deviation of the phenyl groups from complete coplanarity gives rise to isomerism in the triphenylmethane dyes. He finds evidence of two forms of crystal violet in the shoulder of its absorption maximum in the visible. It is not necessary to assume that this steric interference of the ortho hydrogens makes the concept of the resonance stabilized cation untenable since by bending of the carbon–hydrogen bonds, penetration of the van der Waals radii, and slight deviation from coplanarity the conditions of aromaticity can be approached. But these factors of accommodation can only occur with an expenditure of energy which must be subtracted from the energy of resonance stabilization. Replacement of the ortho hydrogens with still larger groups will decrease the resonance stabilization even more and it is not unreasonable to assume that this steric effect will eventually nullify whatever other influence the ortho substituent might have. The magnitude of the energy necessary to accommodate such sterically hindered structures and for that matter, the resonance energy of an unhindered system has not been determined and can only be inferred by comparison of the chemical and physical properties of a series of compounds.

The foregoing interpretation of the relationships in the triphenylmethane dyes provides an explanation of the observations on the dipyrrylmethenes reported in this paper. Thus, it is the pyrrole nitrogens with their ability to stabilize the positive charge of the cation by resonance which are responsible for the ionic character and finally the color of the dipyrrylmethene pigments. We may say that a pyrryl group is equivalent to a para aminophenyl group in stabilizing the carbonium ion. This tendency of the pyrrole rings to supply electrons for the ionization of the halogens in the dipyrrylmethyl halides will be opposed by the substitution of carbethoxy groups in the pyrrole rings. That the position of these groups is critical is apparent from an inspection of the resonance forms which can be written for the three types of carbethoxy substituted pyrrole rings in Chart III. It is observed that we can write

CHART III



three resonance forms in which electrons are removed from the ring in the case of alpha substitution while for the two beta (3 and 4) we can have only two. Thus, the alpha carbethoxy group will be most potent in attracting electrons from the dipyrrylmethyl system and, therefore, most effective in stabilizing the covalent colorless form of the methene halides. It may be equally well argued that the carbethoxy group increases the positive character of the methene bridge carbon, thereby strengthening the carbon–halogen bond with respect to ionic cleavage. Consideration of the interaction of the carbethoxy group with

pyrrolenyl forms in the methene system shows that the β-carbethoxy can interact to give a higher energy form (two positive charges on one pyrrole ring) while the α-carbethoxy cannot. Again the difference favors a greater effect of the α-carbethoxy group in stabilizing the covalent form. A more careful analysis of all the possible resonance forms of the whole methene structure including higher energy forms will give a more accurate value of the ratio of effectiveness of the three positions and will, indeed, indicate differences between the two beta (3 and 4) positions. However, such an analysis is unnecessary for the large effects observed in the present study, but may be helpful in explaining fine differences in properties such as absorption spectra.

If we compare models of the N-free dipyrrylmethene ion (Fig. 1) and the triphenyl carbonium ion (Fig. 2), we observe that the interference of the hydrogens ortho to the bridge carbon is somewhat less for the former. This difference, however, is small and would represent only a minor contribution to the comparative effectiveness of dipyrryl groups in stabilizing the carbonium ion. Now in the formation of the free base of the dipyrrylmethene one of the hydrogens on the nitrogens is lost and with it the steric hindrance. Moreover, the distances are now favorable for the formation of an intramolecular six membered chelate ring involving the pyrrole nitrogens (Chart IV). Thus an additional factor must be

CHART IV
